Cestodes and Trematodes

Larry R. McDougald

Introduction

Many species of worm parasites are seen during necropsy examination of the digestive tract or other internal organs of poultry. Some of these are large enough to cause intestinal blockage in severe cases. Others are so small that a hand lens may be required to distinguish them from intestinal contents. If flattened in shape, they are probably "flatworms" belonging to the phylum Platyhelminthes. Tapeworms are in the class Cestoda, and flukes are in the class Trematoda. Accurate identification is essential for effective control. Species identification may give direction to control measures aimed at eliminating the intermediate host, thus breaking the life cycle. Others may require treatment with anthelmintics.

Cestodes

Most birds are hosts to some species of cestodes or tapeworms (phylum Platyhelminthes/class Cestoda). A high percentage of

---

E. E. Wehr authored the chapter on cestodes in earlier editions of this text, and W. W. Price, E. E. Byrd, and Newton Kingston authored a chapter on trematodes. Their contributions to materials included in this edition are gratefully acknowledged.

Table 27.5.   Tapeworms and hosts from poultry in the United States.

Tapeworm	Definitive Hosts (occasional hosts)	Intermediate Hosts	Degree of Pathogenicity
Amoebotaenia cuneata	Chicken (turkey)	Earthworm	Mild
Choanotaenia infundibulum	Chicken (turkey)	Housefly, beetle	Moderate
Davainea proglottina	Chicken	Slug, snail	Severe
Hymenolepis carioca	Chicken (turkey, bobwhite quail)	Stable fly, dung beetle	Unknown
H. cantaniana	Chicken (turkey, peafowl, bobwhite quail)	Beetle	Mild or harmless
Raillietina cesticillus	Chicken (turkey, guinea fowl, bobwhite quail)	Beetle	Mild or harmless
R. tetragona	Chicken (guinea fowl, peafowl, bobwhite quail, turkey)	Ant	Moderate to severe
R. echinobothrida	Chicken (turkey)	Ant	Moderate to severe
R. magninumida	Guinea fowl (chicken, turkey)	Beetle	Unknown
Davainea meleagridis	Turkey	Unknown	Unknown
Drepanidotaenia watsoni	Wild turkey	Unknown	Unknown
Imparmargo baileyi	Wild turkey	Unknown	Unknown
Raillietina georgiensis	Wild turkey (domestic turkey)	Ant	Unknown
R. ransomi	Wild turkey	Unknown	Unknown
R. williamsi	Wild turkey	Unknown	Unknown
Metroliasthes lucida	Turkey (guinea fowl, chicken)	Grasshopper	Unknown
Diorchis nyrocae	Wild and domestic duck	Copepod crustacean	Unknown
Fimbriaria fasciolaris	Duck (chicken)	Copepod crustacean	Unknown
Hymenolepis anatina	Wild and domestic duck	Freshwater crustacean	Severe
H. compressa	Duck, goose	Unknown	Unknown
H. collaris	Wild and domestic duck (chicken)	Freshwater crustacean (snail = auxiliary)	Unknown
H. coronula	Duck	Crustacean, snail	Unknown
H. lanceolata	Goose, duck	Crustacean	Severe
H. megalops	Duck	Unknown	Unknown
H. parvula	Wild and domestic duck	Leech	Unknown

chickens or turkeys may be infected with tapeworms if they are reared on range or in backyard flocks. These parasites are found more frequently in warmer seasons, when intermediate hosts are abundant. Many species of tapeworms are now considered rare in intensive poultry-rearing regions because the birds do not come in contact with intermediate hosts. Beetles and houseflies inhabiting poultry houses still act as intermediate hosts for the 2 large chicken tapeworms known only by the scientific names *Raillietina cesticillus* and *Choanotaenia infundibulum.*

Some infections of the larger tapeworms may appear to block completely the intestine of an infected bird, but mortality from cestodiasis or long-term effects are rare. Different species vary considerably in pathogenicity, so species identification is worthwhile.

Diagnosticians are often satisfied with a diagnosis of "cestodiasis" or "taeniasis" without making further attempts at identification. However, prevention and control strategies may vary with each species of tapeworm. Only after the species has been determined can an assessment of flock damage and possible control measures be considered (Table 27.5). For identification of the less common species, specialized textbooks may be needed to supplement the keys and illustrations included in this text (8, 11, 15, 16).

Tapeworms or cestodes are flattened, ribbon shaped, usually segmented worms. The term *proglottid* is used to describe these individual segments, because the latter term is defined otherwise by classic zoologists (see Fig. 27.33). One to several gravid proglottids are shed daily from the posterior end of the worm. Each proglottid contains one or more sets of reproductive organs, which may become crowded with a mass of eggs as the maturing proglottid becomes a gravid proglottid.

Tapeworms are characterized by complete absence of a digestive tract and obtain their nourishment by absorption from the gut contents of the host. Although the duodenum, jejunum, or ileum is the usual site for attachment, 1 species (*Hymenolepis megalops*) from ducks is found in the cloaca or bursa of Fabricius. Birds become infected by eating an intermediate host, thus allowing the larval stage of the tapeworm access to the intestine. This larval tapeworm is known as a cysticercoid (see Fig. 27.34C). The intermediate host may be an insect, crustacean, earthworm, slug, snail, or leech depending upon the species of tapeworm.

Most cestodes are host specific for a single or a few closely related birds. Identification of the parasite to genus and species will help pinpoint the intermediate host. The diagnostician then may be able to suggest practical control measures. Completion of a two-host life cycle depends upon a unique set of ecologic conditions which juxtapose the host and the intermediate host. Thus, minor changes in flock management may cause a break in the life cycle and comprise an effective control measure.
27.33. Adult tapeworm (*Davainea proglottina*). Although readily seen with the naked eye, this species has been called a "microscopic tapeworm," because it is small and often overlooked.

27.34. Larval stages of the chicken tapeworm (*Raillietina cesticillus*). A. The egg is encapsulated by a membrane derived from the uterus wall. Eggs are occasionally found free in feces, but more often enclosed within a gravid proglottid. B. Hexacanth embryos escape from shell membranes; active hooks and enzymes from secretory glands assist in penetration of gut wall of the beetle intermediate host. C. Cysticercoid that has developed in the hemocoele of a beetle. D. Scolex in the cysticercoid has evaginated after exposure to bile and enzymes in gut of the fowl.

History, Incidence, and Distribution

More than 4000 species of tapeworms have been described from animals (14), with many of the earlier species bearing the genus name *Taenia.* Because no poultry tapeworms are currently listed in this genus, the term *taeniasis* is no longer appropriate, and the term *cestodiasis* would be a better substitute for infection with poultry tapeworms. Slender threadlike forms (*Hymenolepis carioca*) may require some magnification to distinguish individual proglottids, thus indicating that they are tapeworms. Some small forms (e.g., *Davainea proglottina*) are almost microscopic.

Classification

More than 1400 species of tapeworms have been described from wild and domestic birds. Because most of them have no common name, they are best recognized by their genus and species names.

Three families (Davainidae, Dilepididae, and Hymenolepidae) and 10 genera (*Amoebotaenia, Choanotaenia, Davainea, Diorchis, Drepanidotaenia, Imparmargo, Metroliasthes, Raillietina, Hymenolepis, Fimbriaria*) are recognized here, as they may appear in birds brought to diagnostic laboratories in the United States.

Morphology and Life Cycles
Adults
The anatomic features needed to identify poultry tapeworms are illustrated by describing *Davainea proglottina* (Fig. 27.33). This species differs from most other tapeworms in possessing only 1 or 2 each of immature, mature, and gravid proglottids compared with dozens or hundreds in other species. The entire connected chain of proglottids is called a strobila. Besides the strobila, 2 other regions, the scolex and the neck, are recognized. Anchorage is accomplished by the scolex with the assistance of 4 pairs of suckers or acetabula, which may possess 1 or 2 rows of acetabular hooks. If hooks are present, the species is described as armed; if absent, it is unarmed. A plunger-shaped organ known as the rostellum is frequently present at the anterior end. The rostellum may assist in anchorage by means of 1 or 2 rows of rostellar hooks and by the suction created by partial withdrawal of the rostellum into the scolex. The neck is an undifferentiated area between the scolex and the strobila from which new proglottids proliferate.

A set of both male and female reproductive organs are found in each proglottid. Morphologic differences in size and location of these organs are used in taxonomic descriptions of different

species. Older gravid proglottids containing numerous eggs are shed individually or in short chains late in the day after the worm has absorbed and stored nutrients from the gut contents of the host. *D. proglottina* generally sheds 1 gravid proglottid per day, and *Raillietina cesticillus* may produce as many as 10–12.

Onchosphere

Within the uterus, the fertilized egg develops into a multicellular embryo called an onchosphere or hexacanth embryo. The onchosphere is a multicellular larva containing penetration glands and numerous muscular attachments to activate the hooks. Each gravid proglottid may contain several hundred of these multicellular embryos or eggs. Distinctive membranes (Fig. 27.34A) surrounding the eggs may be useful in identifying the species.

Cysticercoid

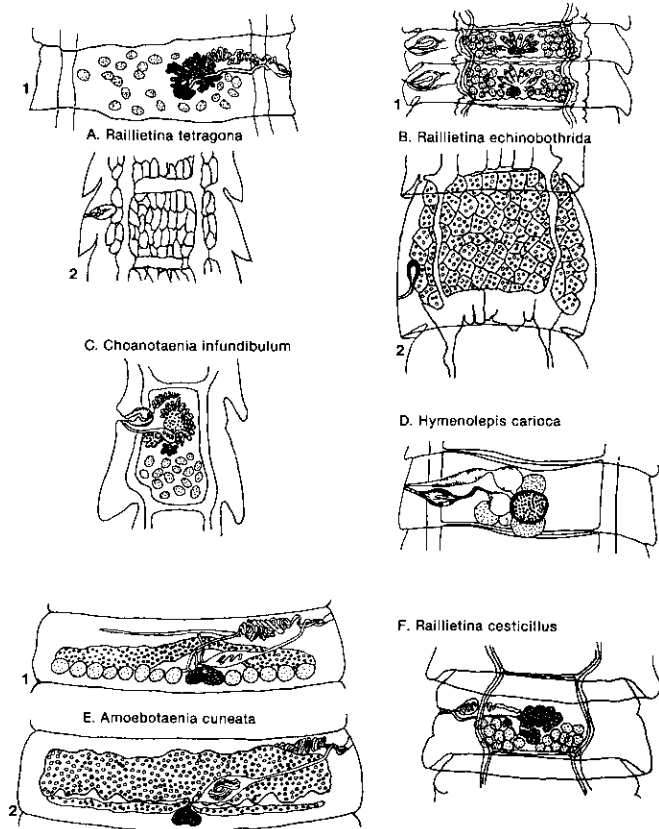
Intermediate hosts such as beetles, houseflies, slugs, or snails become infected by swallowing individual eggs from the feces, or they devour the entire proglottid after being attracted by odor or movement. The 6-hooked embryo hatches from the egg in the gut of the intermediate host and penetrates the gut wall. The larva reorganizes and changes in polarity to become a cysticercoid in about 2 weeks (Fig. 27.34C,D). The cysticercoid remains within the body cavity of the intermediate host until the latter is eaten by the bird host. In the digestive tract the cysticercoid is activated by bile and attaches to the intestine to begin the formation of a strobila. The first gravid proglottids appear in the feces 2–3 weeks after the cysticercoid is swallowed.

Diagnosis and Identification

Distinctive characteristics of tapeworms may best be demonstrated by examining 1) the scolex (Figs. 27.33, 27.35), 2) the eggs (Figs. 27.34, 27.37), or 3) individual proglottids of recently shed, and whole live specimens (Figs. 27.33, 27.36) (11). Although differential staining can be used to show the internal organs of mature proglottids, this procedure is too slow for most diagnostic laboratories. Preservation in alcohol or formalin, although required before staining, often obscures useful characteristics needed for rapid identification. The intestine is best opened with scissors under water, thus permitting the strobila to float free, revealing the area to which the scolex is attached. Recovery of the scolex is worth considerable effort, as its characteristics alone may indicate the species. Freeing the scolex may be accomplished by 1) teasing apart the mucosa with 2 dissecting needles, 2) cutting a deep gouge into the mucosa under the attachment point with a sharp scalpel, or 3) leaving the intestine submerged in saline for a few hours in the refrigerator. Wet-mount preparations of the scolex examined under a coverglass with 3100 or higher magnification may reveal sufficient characteristics to make a species identification. Hook characteristics may require measurement with an ocular micrometer under higher magnification. Semipermanent cleared preparations of scolices may be made by using a drop of Hoyer's solution (prepared by adding to 50 mL of distilled water the following ingredients in this order: 30 g gum arabic flakes; 200 g chloral hydrate; and 20 g glycerin).
27.35. Tapeworms of chickens. Scolex characteristics: A. *Hymenolepis cantaniana*. 1. Scolex and strobilia (Ransom); 2. Hook (Yamaguti); 3. Scolex (Neveu-Lemaire); 4. Scolex (Wehr). B. *H. carioca* scolex. C. *Amoebotaenia cuneata* (Monnig). 1. Rostellar hook; 2. Entire worm. D. *Raillietina cesticillus*. 1. Scolex (Ackert); 2. Scolex (Monnig); 3. Rostellar hook (Ransom). E. *R. tetragona*. 1. Scolex (Monnig); 2.B3. Rostellar and acetabular hooks (Ransom). F. *R. echinobothrida*. 1. Scolex (Monnig); 2.B3. Rostellar and acetabular hooks (Ransom). G. *Choanotaenia infundibulum*. 1. Hook (Ransom); 2. Scolex (Monnig).

Distinctive egg characteristics may be demonstrated by teasing apart a gravid proglottid under a coverglass (Fig. 27.37). Wet preparations of mature or gravid proglottids under low magnification may reveal diagnostic characteristics such as the location, size, and shape of the cirrus pouch and the location of the genital pore and the gonads. If further details of the internal structure of the proglottid are required for identification, it may be necessary to kill, fix, stain, destain, dehydrate, and permanently mount the specimen (1).

Tapeworms of Chickens

A dichotomous key is given to the eight species of tapeworms commonly found in chickens from the continental United States. In such keys, successive selections must be made between 1a and 1b, 2a and 2b, etc., until a species name is designated. After


27.36. Mature and gravid proglottids of chicken tapeworms. A. *Raillietina tetragona*. 1. Mature proglottid (Ransom); 2. Gravid proglottid showing egg capsules (Neveu-Lemaire). B. *R. echinobothrida*. 1. Mature proglottid (Fuhrmann); 2. Gravid proglottid (Lang). C. *Choanotaenia infundibulum* (Fuhrmann). D. *Hymenolepis carioca* (Sawada). E. *Amoebotaenia cuneata*. 1. viewing a portion of the worm under the microscope, make a comparison of the appropriate figures organized under scolices (Fig. 27.35), eggs (Fig. 27.37), or proglottids (Fig. 27.36). With rare species, additional descriptions from other texts may be required (16).

Key to Species

1a. Minute forms, less than 1 cm long.
   A very limited number of proglottids
   with the terminal proglottid being
   gravid with eggs 2
1b. Longer than 1 cm 3
2a. Wedge-shaped worm. Contains
   about 20 proglottids. Posterior
   proglottids wide, short   *Amoebotaenia*
   (Figs. 27.35C,27.36E, 27.37) . . . .*cuneata*
2b. Contains only 2–5 proglottids,
   rarely 9. Posterior proglottids as   *Davainea*
   long as wide (Fig. 27.33) . . . .*proglottina*
3a. Threadlike, never more than
   1.5 mm wide; fragile scolex
   is usually lost; often more than
   100 worms in a single bird;
   proglottids short and wide,
   genus *Hymenolepis* 4
3b. Robust worms, gravid proglottids
   wider than 2 mm 5
4a. Mature worms with gravid
   proglottids present, less than
   12 mm long (Fig. 27.35A) . . . .*H. cantaniana*
4b. Mature specimens with a total
   length including gravid proglottids
   of more than 12 mm
   (Figs. 27.35B, 27.36D) . . . .*H. carioca*
27.37. Eggs of chicken tapeworms (high power). A. *Amoebotaenia sphenoides* showing distinctive granular layer. B. *Choanotaenia infundibulum* with elongated filaments. C. *Davainea proglottina*. D. *Raillietina cesticillus*: Gravid proglottid showing distinctive funnel-shaped structures between membranes. E. *Hymenolepis carioca* or *H. cantaniana* showing football-shaped embryophore with granular accumulations at the poles. F. Capsules containing 6–12 eggs. Found in the chicken (*Raillietina tetragona*, *R. echinobothrida*) and 2 turkey tapeworms (*R. georgiensis*, *R. williamsi*).

5a. 5–12 embryos enclosed in
single capsule; verify by opening
terminal proglottid; view under
a coverglass (Fig. 27.37F) 6
5b. Embryos in single egg capsules
enclosed in distinct membranes
(Examine under high power) 7
6a. Cirrus sac small (75–100 mm long).
Suckers markedly oval in shape
(Figs. 27.35E, 27.36A) . . . .*R. tetragona*
6b. Cirrus sac large (130–180 mm).
Suckers round (Figs. 27.35F, 27.36B)   . . .*R. echinobothrida*
7a. Outer membrane prolonged in   *Choanotaenia*
2 elongated filaments (Fig. 27.37B)   . . . .*infundibulum*
7b. Outer membrane smooth and round,
2 elongated filaments Fig. 27.34A,
27.37D) . . . .*R. cesticillus*

Species descriptions are given for these 8 chicken tapeworms to assist in verifying tentative identifications.

Amoebotaenia cuneata *(Linstow 1872)*
Diagnostic Characteristics
This short (less than 4 mm, 25–30 proglottids) tapeworm may be recognized as whitish projections among the villi of the duodenum (Fig. 27.35C); a triangular anterior end with a pointed scolex gives the entire worm a wedge-shaped anterior. Suckers unarmed, rostellum armed with a single row of 12–14 distinctive hooks 25–32 mm long, 12–15 testes located transversely in a single row across the posterior end of the proglottid (27.36E), genital pores usually alternate regularly, located at extreme anterior point of proglottid margin; 6-hooked single embryos, surrounded by a distinctive granular layer (Fig. 27.37A); embryonal hooks, 6 mm.

Life History
Several species of earthworms belonging to the genera *Allotophora, Pheritima, Ocnerodrilus,* and *Lumbricus* act as intermediate hosts for this tapeworm. Literature descriptions of pathogenicity range from "comparatively slight" to "cause of death." No controlled experiments have been reported.

Choanotaenia infundibulum *(Bloch 1779)*
Diagnostic Characteristics
This large robust tapeworm is extremely white and is readily seen attached to the upper half of the intestine: Mature worms up to 23 cm long; large rostellum armed with a single row of 16–22 large (25–30 mm) hooks, suckers unarmed (Fig. 27.35G); genital pores irregularly alternate; 25–60 testes are grouped in posterior portion of proglottid (Fig. 27.36C); eggs are with distinctive elongated filaments (Fig. 27.37B); and embryonal hooks are 18 mm long.

Life History and Pathogenicity
Houseflies and several species of beetles are proven natural hosts. Other insects including 9 families of beetles, grasshoppers, and termites are proven experimental hosts. Gravid proglottids

are released 13 days after swallowing an infected fly. No controlled experiments testing pathogenicity have been reported.

Davainea proglottina *(Davaine 1860)*
Diagnostic Characteristics
This microscopic tapeworm may be recognized in the duodenal mucosa by protrusion of the gravid proglottids above the villi if the open intestine is floated in water. Eggs are without distinctive membranes, but embryonal hooks are distinctive, 10–11 mm long (Fig. 27.37C). Mature worms measure up to 4 mm long; never with more than 9 proglottids; suckers are armed with 3–6 rows of hooks (Fig. 27.33); the rostellum is armed; genital pores regularly alternate and are located near the anterior margin; and the cirrus is disproportionately large.

Life History
Several species of slugs and snails host larval stages of this tapeworm. More than 1500 cysticercoids have developed along the digestive tract of susceptible slugs, where they have remained infective for more than 11 months. Tapeworms may live as long as 3 years; more than 3000 worms have been recovered from a single bird.

Pathogenicity
This parasite is one of the more harmful species in young birds. In controlled experiments, a 12% reduction in growth rate has been reported (5). Uncontrolled reports include emaciation, dull plumage, slow movements, breathing difficulties, thickened mucosal membranes that produce hemorrhage and fetid mucus, leg weakness, paralysis, and death.

Hymenolepis cantaniana *(Polonio 1860)*
Diagnostic Characteristics
This short hymenolepid tapeworm (maximum length 2 cm) superficially resembles the longer *H. carioca.* It is usually listed as unarmed, but rostellar hooks have been described by European investigators (Fig. 27.35A); the fragile rostellum is frequently lost; genital pores are unilateral, anterior to middle of proglottid; eggs are similar to those of *H. carioca;* embryonal hooks measure 13–14 mm.

Life History
Dung beetles (Scarabeidae) are intermediate hosts; each beetle may carry 100 or more cysticercoids. A unique larval development involves budding, which produces many cysticercoids from a single onchosphere. This tapeworm is considered relatively nonpathogenic, although no controlled experiments have been reported.

Hymenolepis carioca *(Magalhaes 1898)*
Diagnostic Characteristics
Several thousand specimens of this extremely slender species have been found in the duodenum of a single chicken or turkey. The worm is so slender (about 1 mm in diameter) that the hundreds of inconspicuous proglottids look more like a thread than a worm. Suckers are unarmed; rostellar sacs are present; rostellum

is rudimentary (Fig. 27.35B); there are three testes, usually in a straight row; genital pores are unilateral, located anterior to middle of proglottid margin (Fig. 27.36D); an inner membrane enveloping the onchosphere is elongated into a football shape with granular deposits at poles (Fig. 27.37E); embryonal hooks measure 10–12 mm.

Life History

Twenty-six species belonging to nine families of beetles and one species of termite are experimental or natural intermediate hosts; dung and ground beetles are the most common source of infection. Reports incriminating the housefly are probably erroneous.

Pathogenicity

Experimental infections establishing several hundred worms per bird had no effect on weight gains. These results indicate that this species is relatively nonpathogenic.

Raillietina cesticillus *(Molin 1858)*

Diagnostic Characteristics

Scolex of this large robust tapeworm (up to 15 cm long) embeds deeply in the mucosa of the duodenum or jejunum. The distinctive, wide, flat, rostellum bears a double row of 300–500 hammer-shaped hooks. The flattened rostellum acts as a retractable piston drawing into an outer sleeve of the scolex, thus, providing a firm grip on the mucosa (Fig. 27.35D1,D2); there are 4 unarmed weak suckers; genital pores alternate irregularly (Fig. 27.36F); there are 20–30 testes posteriad in proglottid; single eggs are encapsulated in uterine membranes; and mature eggs have 2 distinctive funnel-shaped filaments between the middle and inner membranes (Fig. 27.37D).

Life History

More than 100 species of beetles belonging to 10 families are proven natural or experimental intermediate hosts. A minute histerid beetle (*Carcinops pumilio*) is the natural intermediate host in broiler houses. The darkling beetle (*Alphitobius diaperinus*), grasshoppers, ants, and lepidopterous larvae have proved negative as experimental hosts. As many as 930 cysticercoids have been found in a single ground beetle.

Pathogenicity

Early reports attribute this parasite with causing emaciation, degeneration, and inflammation of villi, reduction of blood sugar and hemoglobin, and reduced growth rate. None of these early reports could be confirmed in extensive controlled experiments with broilers and layers maintained on optimum nutritional diets (2). Experimental infections (135 worms/bird) produced by feeding 300 cysticercoids caused no reduction in weight gain in broilers or reduced egg production in layers when compared with uninfected controls.

Raillietina tetragona *(Molin 1858)*

Diagnostic Characteristics

These are moderately large tapeworms measuring up to 25 cm long × 3 mm wide. Scolex (Fig. 27.35E1) anchors in the poste-

rior half of the intestine; the rostellum is armed with 90–100 hooks, 6–8 mm long, arranged in a single or double row (Fig. 27.35E2); suckers are oval shaped, armed with 8–12 rows of minute hooks, 3–8 mm long (Fig. 27.35E); genital pores are usually unilateral (Fig. 27.36A); the uterus breaks up into capsules containing 6–12 eggs (Figs. 27.36A2, 27.37F), similar to *R. echinobothrida* from chickens and *R. williamsi* and *R. georgiensis* from turkeys; and the cirrus sac is small (75–100 mm long), more anterior in proglottid margin than with *R. echinobothrida*.

Life History

Several species of small ants that nest under rocks or boards act as intermediate hosts. The minimum prepatent period after feeding cysticercoids to chickens is 13 days.

Pathogenicity

Weight loss was demonstrated in controlled experiments (9) with white leghorns and hybrids infected with an average of 12–16 worms/bird. Decreases in egg production in 4 breeds of hens occurred after administering 50 cysticercoids/bird, causing reduced glycogen levels in livers and the intestinal mucosa of infected chickens.

Raillietina echinobothrida *(Megnin 1881)*

Diagnostic Characteristics

This species resembles *R. tetragona* but differs in the following characteristics: The strobila is larger (34 cm long × 4 mm wide); the scolex has rounded suckers containing 200–250 hooks, 10–13 mm long (Fig. 27.35F) with 8–15 rows of hooks 5–15 mm long (Fig. 27.35F2,3); genital pores are in the posterior half of the proglottid (Fig. 27.36B2); the cirrus sac is large (130–180 mm long); and gravid proglottids frequently loosen from each other in the center, making a windowlike arrangement not found in *R. tetragona.*

Life History

As with *R. tetragona,* numerous species of ants have been found naturally infected with cysticercoids. Concurrent infections with both *R. echinobothrida* and *R. tetragona* cysticercoids have been found in ants.

Pathogenicity

R. echinobothrida is usually listed as one of the most pathogenic tapeworms, because its presence has often been associated with nodular disease of chickens. Nadakal *et al.* (10) reported parasitic granulomas approximately 1–6 mm in diameter at the sites of worm attachment 6 months after experimental infection with 200 cysticercoids. The condition was associated with catarrhal hyperplastic enteritis as well as lymphocytic, polymorphonuclear, and eosinophilic infiltration.

Tapeworms of Turkeys

Six species of tapeworms from domestic and/or wild turkeys have been reported from the United States (12). Because these tapeworms are readily transferred between wild and domestic

turkeys, wild turkeys provide a reservoir for these parasites of domestic birds. No controlled experiments on pathogenicity have been reported for any species. Descriptions included here are limited to the 2 species with known life cycles. Scolex (Fig. 27.38) and proglottid characteristics (Fig. 27.39) of different species are organized in separate figures to facilitate comparisons if complete specimens are unavailable.

Raillietina georgiensis *(Reid and Nugara 1961)*
Description and Diagnostic Characteristics
This species is a large (15–38 cm long × 3.5 mm wide) robust tapeworm from domestic and wild turkeys. Scolex (Fig. 27.38A) is armed with a double row of 230 moderate length (12–23 mm) rostellar hooks and 8–10 circles of acetabular hooks, 8–13 mm long (Fig. 27.38A2,A3); genital pores are unilateral, located in middle of the proglottid (Fig. 27.39A); eggs are in uterine capsules, similar to *R. tetragona* and *R. echinobothrida.*

Life History
A small brownish ant (*Pheidole vinelandica*) that frequents turkey ranges has been found naturally infected; gravid proglottids appear in droppings within 3 weeks after turkeys have fed on infected ants. This tapeworm was introduced to a domestic farm by wild turkeys.

Pathogenicity
Enteritis is present if parasites are found in large numbers. Some host damage is assumed on the basis of a close relationship to *R. echinobothrida* from chickens.

Metroliasthes lucida *(Ransom 1900)*
Description and Diagnostic Characteristics
This species is a long tapeworm (20 cm) from turkeys and guinea fowl, rarely in chickens. There are unarmed scolex and suckers, 200–250 mm in diameter (Fig. 27.38C); genital pores irregularly alternate, near middle of margin in mature proglottids but posterior in gravid proglottids; uterus consists of 2 sacs side by side, visible to the naked eye in gravid proglottids, and is known as the parauterine organ (Fig. 27.39C2,C3); eggs have three membranes, 75 × 50 mm.

Life History
Several species of grasshoppers serve as intermediate hosts; cysticercoid development requires 15–42 days depending on temperature. Pathogenicity is unknown.

Tapeworms of Ducks and Geese

Domestic ducks and geese frequently become infected with numerous species of tapeworms introduced by wild ducks and

A. Fimbriaria fasciolaris

geese. Some of these species have occasionally been reported in chickens. Two of the more common species are described in this section. Life cycles usually involve crustaceans or other aquatic invertebrates. No controlled pathogenicity studies have been made on any of these species.

Fimbriaria fasciolaris (Pallas 1781)

Description and Diagnostic Characteristics
This large (5–43 cm long × 1–5 mm wide) twisted tapeworm of ducks also occurs in chickens and 31 species of wild birds. This distinctive flaring anterior neck region is known as the pseudoscolex; strobila is unsegmented, but cross-striations give the impression of segmentation (Fig. 27.40A1); there are minute scolex (Fig. 27.40A3,A4) attached to pseudoscolex, 100–130 mm wide; suckers are unarmed; the retractile rostellum has 10–12 hooks 17–22 mm long (Fig. 27.40A2); genital pores are unilateral and closely crowded together; onchospheres are 35–45 mm in diameter; hooks are 16 mm long.

Life History
Cysticercoids develop in copepod crustaceans (*Diaptomus* sp., *Cyclops* sp.); intermediate hosts are ingested with drinking water to infect the definitive host. Pathogenicity is unknown.

Hymenolepis megalops *(Nitzsch, in Creplin 1829)*

Description and Diagnostic Characteristics
This cosmopolitan tapeworm of waterfowl (Fig. 27.40B) is 3–6 mm long and readily recognized by the large scolex (1–2 mm wide) attached to the cloaca or the bursa of Fabricius. Suckers and rostellum are unarmed, the latter containing a rudimentary central pit; eggs are not in capsules.

Life History
Onchospheres develop into cysticercoids after 18 days in ostracod crustacea. The definitive host is infected by eating ostracods.

Pathogenicity
Reports range from "severe damage" to "mortality if other cestodes (*H. coronula, H. furcigera*) are also present."

Prevention and Control

The change in production methods in commercial poultry, from backyard or range management to confinement rearing in large houses, has brought on marked reductions in tapeworm infections in chickens and turkeys. These birds no longer have easy access to the required insect or other invertebrate hosts for most cestode and trematode parasites. *Davainea proglottina,* one of the most pathogenic species, was reported from 23% of the chickens submitted to the diagnostic laboratory in New York in 1932. No cases have been found in recent years, probably because poultry no longer has easy access to garden slugs. We can expect a more diverse fauna of cestodes in birds reared under free range conditions.

Prevention of contact with the intermediate host is the first step to consider in tapeworm control. Elimination of intermediate hosts may provide additional benefits besides tapeworm control. If *Choanotaenia infundibulum* appears in a cage layer facility, housefly control will benefit the producer by preventing nuisance and public health complaints (see Chapter 32). If *Raillietina cesticillus* tapeworms appear in broiler houses, beetle control measures for the darkling beetle (*Alphitobius diaperinus*) may also reduce populations of the true intermediate host *Carcinops pumilio,* a minute histerid beetle. Identification of worm species will help to suggest control measures, where the control of the intermediate host is to be redommended.

Treatment

In the United States, there are no products for use in feed for treatment of tapeworms in poultry. Historically, butynorate (dibutyltin dilaurate) was used for treatment of 6 species of chicken tapeworms (*Raillietina cesticillus, R. tetragona, Choanotaenia infundibulum, D. proglottina, Hymenolepis carioca,* and *Amoebotaenia sphenoides*) (3). Thus, all efforts toward control must be directed toward prevention by reducing populations of the intermediate hosts.

Trematodes

Trematodes (flukes) are flat, leaflike, parasitic organisms belonging to the phylum Platyhelminthes, class Trematoda. They differ from the cestodes (class Cestoda) in having a digestive system, and they do not form proglottids. The life cycle of all trematodes parasitizing birds requires a molluscan as an intermediate host; some species also use a second intermediate host. Because adult trematodes and larval metacercariae invade almost every cavity and tissue of birds, they may show up unexpectedly at necropsy.

More than 500 species belonging to some 125 genera and 27 families are known to occur in the 4 orders of birds most likely to be submitted to diagnostic laboratories as domestic or pet birds (4). Twenty of these flukes are considered potentially dangerous to poultry in the Western Hemisphere. These flukes belong to 4 orders: Anseriformes (ducks and geese), Galliformes (chickens and turkeys), Columbiformes (pigeons and allies), and Passeriformes (perching birds). Flukes are less host specific than tapeworms, so wild birds often introduce infection in areas where domestic poultry is reared. Because many snails live in ponds and streams, ducks and geese are the most frequently parasitized. The oviduct fluke (*Prosthogonimus* sp.), which is a frequent parasite of many species of wild birds, sometimes causes problems with ducks and chickens (6). This species will be used to illustrate fluke morphology and life history. *P. macrorchis* is the species name recognized in the United States, and this fluke is known as *P. ovatus* or by other specific names in other countries.

Morphology and Life History

The body of the adult fluke (Fig. 27.41) is a flattened oval, and it bears 2 suckers. The digestive system consists of the mouth (within the oral sucker), the pharynx, a short esophagus, and 2 intestinal ceca. An anus is lacking in the trematodes. Two testes and one ovary are present in the same individual. After fertilization, the zygote is enclosed along with yolk cells from the vitellaria by an eggshell. Large numbers of eggs are stored in a prominent convoluted uterus. The excretory system, which originates in a series of flame cells bearing a tuft of cilia, drains with a series of collecting tubules that empty through an excretory pore near the posterior end of the parasite. The arrangement pattern of these collecting tubules is used as a family characteristic in the classification of flukes.

Life Cycle

Adult flukes continually shed eggs, which pass out with the feces of the host. These eggs contain an embryo that develops into a larval stage known as a miracidium. In this group of trematodes, the miracidium hatches after the egg is swallowed by a susceptible snail. Larval development continues within the snail through a succession of stages known as sporocysts and cercariae. The cercariae emerge from the snail and swim about in a lake or pond. Some are drawn into the brachial basket of a dragonfly naiad. The cercaria encysts (metacercaria) and remains in the insect until either the naiad or an infected adult dragonfly is eaten by a bird (Fig. 27.42).
27.41.   Morphology of an adult trematode (*Prosthogonimus macrorchis*) (Macy).

Identification

Twenty-four trematodes that are occasionally seen in birds at diagnostic laboratories have been described with keys by Kingston (4). More extensive listings of species are provided by Yamaguti (17), McDonald (7), and Schell (13). The latter text also describes methods of identifying, collecting, preserving, and staining trematodes with emphasis on North American families and genera.

Pathogenicity

Prosthogonimus sp., popularly known as the oviduct fluke, has caused economic losses to poultry producers by 1) drastically reducing egg production after a recent infection and 2) occasionally being enveloped within a hen's egg and later discovered by a complaining customer. Other organs of the bird invaded by flukes include 1) metacercarial cysts in the skin of chickens and turkeys (*Collyriclum faba*); 2) small adult flukes in the conjunctival sac of the eye (*Philophthalmus gralli*); 3) adults in the liver, pancreas, and bile duct of ducks and turkeys (*Amphimerus elongatus*); 4) adults in the collecting tubules of the excretory system of chickens, turkeys, and pigeons (*Tanaisia bragai*); 5) adults and eggs in the circulatory system of ducks by three species of blood fluke; and 6) 14 species of flukes that invade various areas of the digestive tract.

Control

If the life cycle is known and evidence of pathogenicity or economic loss is clear, changes in management are indicated. Efforts should be directed toward fencing poultry off from access to

Chapter 28
Protozoal Infections

Introduction
Larry R. McDougald

Protozoal diseases are common in poultry and other birds, and some cause moderate or severe losses. Parasitic diseases differ from viral and bacterial diseases by their eukaryotic nature and often-complicated life cycles. Many parasites utilize intermediate hosts.

Confinement rearing and high-density flocks in the rearing of commercial poultry have increased the exposure to diseases such as coccidiosis and cryptosporidosis, which have short, direct life cycles. In contrast, parasitic diseases that depend on an intermediate host for transmission, such as flukes, many cestodes, and some nematodes, have been practically eliminated from commercial flocks because the specific invertebrates used as hosts are not present in poultry houses. Blackhead disease, caused by the protozoan *Histomonas meleagridis,* can be transmitted directly from bird to bird within a turkey flock, and may utilize intermediate hosts to reach the next susceptible flock.

Control of parasites is largely by treatment or prevention through the use of chemotherapeutic agents. Only with coccidiosis has a good measure of success been achieved by vaccination. The program most widely practiced in control of coccidiosis is continuous administration of anticoccidial drugs in the feed. Such programs allowed better uniformity of treatment and centralized decisions on the choice of programs. This system has proved more reliable than on-farm practices and is used in most commercial poultry flocks today. Success of antiparasitic products may be affected by drug resistance, toxicity from misuse, and a limited spectrum of activity. Despite universal acceptance of this practice, the poultry industry has been under intense pressure to reduce the reliance on chemotherapy. Faced with rising costs, the pharmaceutical industry has shown little interest in developing new products for antiparasitic use, making it unlikely that we will have replacements for the products already available. Immunization against coccidiosis with live vaccines has become more reliable and effective with recent improvements in administration techniques and vaccine strain development. Actions by the Food and Drug Administration (removing the nitroimidazoles from use in animals) have left us with no chemotherapy for treatment of blackhead disease (histomoniasis) in chickens and turkeys. It is ironic that this action has occurred at a time when widespread outbreaks of histomoniasis are causing severe clinical disease in broiler breeder pullets and in turkeys. We are left with no tools other than management or indirect treatment for prevention and control of this disease. As long as highly effective products were available for treatment of outbreaks, research on blackhead disease languished. In the absence of effective treatments, considerable new research has begun, so that we may eventually have vaccines or other treatments for histomoniasis.

Effective control of parasitic diseases depends on accurate diagnosis of the species involved and the extent to which a flock is affected. Serologic methods are rarely used in diagnosis, because the organisms and/or the gross lesions produced by many species are distinctive. Disinfection and quarantine have been of little use in control of coccidiosis and some other parsitic diseases.

Diagnosis is done by gross and microscopic examination of birds taken from a flock for necropsy, or by microscopic examination of feces or tracheal swabs of live birds. Although feasible, serological tests have not been developed for general use. ELISA, Western blot, and other tests are commonly applied in research. PCR testing is now feasible for coccidiosis and histomoniasis, but has been applied only on a research basis.

Protozoa were historically placed in a single phylum, containing all one-celled animals. The complex organization and vastly different structure of protozoa led to the separation of various classes into 7 different phyla (1). Two of these phyla contain species that are important parasites of poultry: The phylum Apicomplexa is characterized by the presence of an apical complex in sporozoites, and all are intracellular parasites. Genera of poultry parasites in this phylum include *Eimeria, Isospora, Haemoproteus, Leucocytozoon, Plasmodium, Toxoplasma, Sarcocystis, Wenyonella, Tyzzeria,* and *Cryptosporidium.*

The second phylum, Sarcomastigophora, includes the flagellates and amebas. Generally, they possess pseudopodia, flagella, or both as locomotor organelles. Genera in this phylum, which are important to poultry, include *Histomonas, Trypanosoma, Chilomastix, Entamoeba, Endolimax,* and *Spironucleus.* The discovery of *Cochlosoma* associated with losses in turkeys and ducks suggests yet another emerging parasitic disease (2, 3).

Encephalitozoon cuniculi, a protozoan in a third phylum, Microspora, recently has been discovered infecting chickens and other birds. This protozoan is egg-transmitted. Infection can be associated with embryo mortality but is usually unapparent. Affected birds may show inactivity, lameness, mild diarrhea, and weight loss. Parasites have been identified in the digestive tract,

urogenital organs, and muscle. In embryos, brain and heart also were found to be infected (4, 5). It is not known how widespread or important microsporidians may be in poultry.

Coccidiosis

Larry R. McDougald and Steve H. Fitz-Coy

Introduction

Coccidiosis is a disease of universal importance in poultry production. The protozoan parasites of the genus *Eimeria* multiply in the intestinal tract and cause tissue damage, with resulting interruption of feeding and digestive processes or nutrient absorption, dehydration, blood loss, loss of skin pigmentation and increased susceptibility to other disease agents. Historically, the spectacular onset of coccidiosis with bloody diarrhea and high mortality inspired awe and dread on the part of poultry growers and bird fanciers. Like many parasitic diseases, coccidiosis is largely a disease of young animals because immunity quickly develops after exposure and gives protection against later disease outbreaks. Unfortunately, no cross-immunity exists between species of *Eimeria* in birds, and later outbreaks may be the result of different species. The short, direct life cycle and high reproductive potential of coccidia in poultry often lead to severe outbreaks of disease in small backyard flocks or in the modern poultry house, where 15–30,000 chickens may be reared on litter.

Coccidiosis may strike any type of poultry in any type of facility. The disease may be mild, resulting from the ingestion of a few oocysts, and may escape notice, or it may be severe as a result of ingestion of millions of oocysts. Most infections are relatively mild, but because of the potential for the disastrous outbreak and the resulting financial loss, almost all young poultry are given continuous medication with low levels of anticoccidial drugs, which prevent the infection or reduce infections to a low, immunizing level. Vaccines against coccidiosis have in the past been used mostly in breeder pullets and in turkeys. Vaccination of broilers has rarely been practiced because even light infections with some species of coccidia can affect weight gain, feed conversion, and pigmentation of the skin. However, new vaccines with improved administration techniques are targeting this larger market with encouraging results.

Classification and Taxonomic Relationships

The biology and taxonomy of coccidia were reviewed by Long (24) and Pellerdy (37). Coccidia are members of the phylum Apicomplexa, which is characterized by the presence of an apical complex in sporozoites. All apicomplexans are intracellular parasites. The genera *Eimeria, Isospora, Haemoproteus, Leuco-*
28.1. Diagram of sporulated oocyst of genus *Eimeria*. The oocysts of all *Eimeria* contain 4 sporocysts, each with 2 sporozoites, after sporulation.

cytozoon, Plasmodium, Toxoplasma, Sarcocystis, Wenyonella, Tyzzeria, and *Cryptosporidium* are found in poultry.

The most common apicomplexans in poultry belong to the genus *Eimeria* described in this section or the genus *Cryptosporidium* discussed in a later section of this chapter. The oocyst, a thick-walled zygote shed in fecal matter by the infected host, is fairly distinctive and is often used in diagnosis and identification of species. Oocysts are enclosed in a thick outer shell and consist of a single cell that begins the process of sporulation to yield the infective stage in 48–72 hours. Infective oocysts contain 4 sporocysts, which in turn contain 2 sporozoites (Fig. 28.1).

The closely related parasites, *Sarcocystis, Toxoplasma, Cryptosporidia,* and avian malaria, are discussed in the sections "Miscellaneous and Sporadic protozoal infections" and "Cryptosporidiosis."

When oocysts are ingested, the oocyst wall is crushed in the gizzard, and the sporozoites are released from sporocysts by the action of chymotrypsin and bile salts in the small intestine. Sporozoites enter epithelial cells or are taken into intraepithelial lymphocytes, where development begins. Species of coccidia are identified on the basis of 1) oocyst morphology, 2) host specificity, 3) immune specificity, 4) appearance and location of gross lesions within the natural host, and 5) length of the prepatent pe-

riod. The host specificity of *Eimeria* in birds and mammals is very strict, so that parasites from different species of birds or animals can be considered different species, even though they may have similar-appearing oocysts.

Biological characteristics useful in the identification of species are 1) location of lesions in the intestine; 2) appearance of gross lesions; 3) oocyst size, shape and color; 4) size of endogenous tissue stages (schizonts, merozoites, meronts, gametocytes); 5) location of the parasites within tissues; 6) minimum prepatent period in experimental infections; and 7) immunogenicity in comparison with reference strains. In recent years biochemical and molecular tools have also been used for identification of coccidia. Techniques of value include the electrophoretic pattern of metabolic enzymes (40) and PCR (42). Monoclonal antibodies are useful in experimental work but have not been developed to be specific for species identification. Digital image analysis (6) is useful for analysis of photographic imagery. For diagnostic purposes, the traditional biological characteristics are usually adequate. However, taxonomic difficulties are encountered in in identification of species with morphologically similar oocysts which are found with overlapping tissue specificity. Species can be identified by comparison of isolates with several criteria listed in Table 28.2 or 28.3.

Life Cycle

Coccidiosis differs from bacterial and viral diseases in the self-limiting nature of its development. The life cycle of *E. tenella* (Fig. 28.2) is typical of all *Eimeria,* although some species vary in the number of asexual generations and the time required for each developmental stage. After the oocyst wall is crushed in the giz-

zard and the sporozoites are released, the sporozoites enter cells in the mucosa of the intestine and begin the cell cycle leading to reproduction. At least 2 generations of asexual development (sometimes as many as 4) called schizogony or merogony give rise to a sexual phase, where small, motile microgametes seek out and unite with macrogametes. The resulting zygote matures into an oocyst, which is released from the intestinal mucosa and is shed in the feces. With each species, the reproductive potential from a single ingested oocyst is fairly constant. The entire process takes 4–6 days, depending on species, although oocysts may be shed for several days after patency is reached. In some species (*E. tenella, E. necatrix*), the maximum tissue damage may occur when second-generation schizonts rupture to release merozoites. Other species may have small scattered schizonts, which cause little damage, but the gametocytes may elicit a strong reaction with cellular infiltration and thickened, inflamed tissues.

Relationship between Coccidiosis and Other Poultry Diseases

The tissue damage and changes in intestinal tract function may allow colonization by various harmful bacteria, such as *Clostridium perfringens*, leading to necrotic enteritis (17, 26), or *Salmonella typhimurium* (2, 3). Cecal coccidiosis (*E. tenella*) may contribute to increased severity of the blackhead organism (*Histomonas meleagridis*) in chickens. Experimental infections with the 2 organisms were characterized by a higher incidence of hepatic disease, as compared with monoinfection with *Histomonas* (28).

Immunosuppressive diseases may act in concert with coccidiosis to produce a more severe disease. Marek's disease may interfere with development of immunity to coccidiosis (4), and infec-
28.2. The 7-day life cycle of *E. tenella* includes 2 or more asexual and 1 sexual cycle during the 6 days after an oocyst has been swallowed by the host. The new generation of oocysts becomes infective to the next host after sporulation.

tious bursal disease (IBD) may exacerbate coccidiosis, placing a heavier burden on anticoccidial drugs (29).

Coccidiosis in Chickens

Coccidiosis remains one of the most expensive and common diseases of poultry production in spite of advances in chemotherapy, management, nutrition, and genetics. The disease is often diagnosed in birds brought to diagnostic laboratories (1), but the vast majority of cases are diagnosed in the field and handled by poultry service personnel. The current expense for preventive medication exceeds $90 million in the United States and more than $300 million worldwide.

Incidence and Distribution

Coccidia are found wherever chickens are raised. Their strict host specificity eliminates wild birds as sources of infection. The most common means of spread of coccidia is mechanical, by personnel who move between pens, houses, or farms. Coccidial infections are self-limiting and depend largely on the number of oocysts ingested and on the immune status of the bird. Surveys in North and South America revealed coccidia present in almost all broiler farms (25, 30, 32). Very high percentages of positive flocks were also reported from Europe (5, 23, 43). Oocysts in the litter or droppings of broiler chickens are usually most numerous between 3 and 5 weeks of age and often decline thereafter. Few oocysts are found after birds are removed from a farm, because the parasites are killed by ammonia or composting heat in poultry litter or droppings. The ubiquitous nature of poultry coccidia precludes the possibility of elimination or prevention of coccidia by quarantine, disinfection, or sanitation.

Etiology and Diagnosis

Nine species of *Eimeria* have been described from chickens (Table 28.1). New evidence suggests that all should be considered valid. Concurrent infection with 2 or more species of coccidia is common (31). Each species causes separate and distinct, recognizable diseases, independent of the other species.

Characteristics useful in the identification of species are as follows: 1) location of the lesions in the intestine; 2) appearance of the gross lesion; 3) oocyst size, shape, and color; 4) size of schizonts and merozoites; 5) location of parasites in tissues (type of cell parasitized); 6) minimum prepatent period in experimental infections; and 7) immunogenicity against reference strains. In recent years, more emphasis has been placed on biochemical and physiologic identification of coccidia. Promising new tools for species identification include electrophoresis of metabolic enzymes (41) and PCR (42). Monoclonal antibodies are useful in experimental work but have not been suitably specific to distinguish species, probably because of common antigens. For diagnostic purposes, the traditional characteristics are adequate, and a satisfactory diagnosis can be made from Table 28.2. Cross-immunity and biochemical studies require pure species isolates propagated from single oocysts. The severity of infection based on gross lesions is often graded on a scale of 0–4 as described by Johnson and Reid (22), where 0 is normal and 4 is the maximum lesion. Microscopic examination of lesions or droppings is also used to grade infections, by counting the number of parasite forms in a field. In this techinque, at least 5 fields should be examined. A typical scoring system used by some diagnosticians is based on the species, number, and type of parasites. For *E. maxima* a typical score system is: 0 = no parasites, 1 = 1–10 parasites/field, 2 = 11–20, 3 = 21–49 and 4 = 50 or more/field. With other species, 1 = 1–25/field, 2 = 26–50, 3 = 51–75 and 4 = greater than 75.

Eimeria acervulina *Tyzzer 1929*

This species is the most frequently encountered in commercial poultry in North and South America (30, 31, 32) and is commonly reported in other continents. Oocysts are ovoid and often show thinning of the shell at the small end. The average size of oocysts is 18.3 $\times$ 14.6 µm, but the range is 17.7–20.2 $\times$ 13.7–16.3 µm.

Pathogenicity

Severity of infection may vary with the isolate, the number of oocysts ingested, and the immune state of the bird. Ingestion of 10^3, 10^4, 10^5, or 10^6 oocysts by young white rock chicks resulted in mild to severe coccidiosis, with lesion scores ranging from 1.1 (10^3 oocysts) to 4.0 (10^6 oocysts) (38). Reduction in rate of weight gain was also proportional to the infective dose. Watery and mucoid droppings may be seen as early as 4 days postexposure. Heavy infections often cause lesions to coalesce, and sometimes mortality may result. Light to moderate infections may produce little effect on weight gain and feed conversion but may cause loss of carotenoid and xanthophyll pigments from the blood and skin because of reduced absorption in the small intestine. The intestinal mucosa may be thickened, resulting in poor feed conversion. Egg production may be depressed in laying birds.

Gross White Plaques, Arranged Transversely

The intestine may be pale and contain watery and mucoid fluid. The gross lesion in light infections is limited to the duodenal loop, with only a few plaques/cm. In heavy infections, lesions may extend some distance through the small intestine, and plaques may overlap or coalesce. The plaques are generally smaller in heavy infections due to crowding. The lesions may be composed of schizonts, gametocytes, and developing oocysts. Microscopy of smears from intestinal lesions usually reveals numerous oocysts and gametocytes of varying stage of development.

Histopathology of the small intestine reveals the ovoid gametocytes in the mucosal cells lining the villi. In moderate to heavy infections, the tips of villi are broken off, leading to truncation and fusion of villi and thickening of the mucosa. Some epithelial cells may contain more than one parasite. Capillaries may be engorged with red blood cells and there is infiltration of granulocytes in the area parasitized. Schiff's reagent will stain the macrogametes and developing oocysts a brilliant red, because of the polysaccharide used in oocyst wall formation.

Eimeria brunetti *Levine 1942*

About 10–20% of field isolates in surveys in the United States and South America contained *E. brunetti* (25, 30, 31). The oocysts of *E. brunetti* average 24.6 $\times$ 18.8 µm and are easily confused with *E. tenella*. This species is found primarily in the lower

small intestine, usually from the yolk sac diverticulum to near the cecal juncture. In severe cases, the lesion may extend from the gizzard to the cloaca and extend into the ceca (Fig. 28.3 E–H). Most field infections are difficult to recognize based on gross lesions but can be confirmed by observation of typically sized oocysts by microscopy. The average oocyst size is 24.6 × 18.8 μm, with a range of 20.7–30.3 by 18.1–24.2 μm. Oocysts are ovoid, with a length/width index of 1.31.

Pathogenicity

Although less serious than *E. tenella* or *E. necatrix, E. brunetti* can produce moderate mortality, loss of weight gain, poor feed conversion, and other complications. Inoculation with $1–2 \times 10^5$ oocysts frequently will cause 10–30% mortality and reduced gain in survivors. Light infections of *E. brunetti* are overlooked easily unless careful attention is paid to the lower small intestine. Such light infections can cause reduced weight gain and poor feed conversion, even though gross lesions are not clearly apparent.

Gross Lesions and Histopathology

At early stages of infection, the mucosa of the lower small intestine may be covered with tiny petechiae and have some thicken-

ing, loss of color and watery contents. In heavy infections, the mucosa is badly damaged, with coagulation necrosis appearing on days 5–7 postinfection (PI) and with a caseous eroded surface over the entire mucosa. Coagulated blood and mucosal casts will be apparent in the droppings. Thickening of the mucosa and edematous swelling occurs in severe infections, especially on the sixth day PI.

The asexual stages of first- and second-generation schizogony generally occur in the upper small intestine. Histopathology on the fourth day of infection reveals schizonts, cellular infiltration, and some damage to the mucosa. By the fifth day, many of the tips of villi are broken off. Merozoites invade the epithelium and develop into sexual stages in the lower small intestine and ceca. In severe cases, the villi may be completely denuded, leaving only the basement membranes intact.

Eimeria hagani *Levine 1938*

The taxonomic status of *E. hagani* was considered by some to be in doubt because the original description was incomplete. However, a strain of *E. hagani* was studied in depth by Oluleye (36). The oocysts average 18.0 × 14.7 μm (sporulated 19.6 × 14.7 μm). Sporocysts are 11.3 4× 6.9 mm, and sporozoites are

12.9 × 2.1 μm. The prepatent period is 98 hrs. Sporulation requires 17–44 hrs at 23.5°C. The gross lesions consist of petechiae and white opacities in the upper small intestine. There is not blood, although the mucosa can appear reddish. The intestinal contents may be creamy or watery. In histopathology, the parasites are seen in the tips of villi, some as far as 2/3 down the length. Maturation of first generation schizonts is 36–48 hrs, second generation at 60 hrs, and third generation by 96 hrs. The schizonts average 14.4 × 13.2, 6.2 × 5.8, or 8.9 × 3.1 μm for first, second- or third-generation schizonts, respectively. Merozoites were 8.8 × 1.1 mm. Immunity is species specific, separating it from *E. acervulina, E. mitis, E. mivati,* and other species. This species is described as producing hemorrhagic spots, catarrhal inflamation, engorged capillary beds and watery intestinal contents between 96 and 120 hr PI, and is moderately pathogenic.

Eimeria maxima *Tyzzer 1929*

The mid-small intestine is often parasitized with *E. maxima,* from below the duodenal loop past the yolk sac diverticulum, but in heavy infections, the lesions may extend throughout the small intestine. *E. maxima* is an easy species to recognize because of the characteristic large oocysts, 30.5 × 20.7 mm (21.5–42.5 × 16.5–29.8), which usually have a distinctive yellowish color (Fig. 28.3A,F,G,H,I,J). Oocysts have a shape index of 1.473. An abundance of yellow-orange mucus and fluid often is in the midgut. This species can be differentiated from *E. necatrix* by the lack of large schizonts associated with the lesions and from *E. brunetti* by the larger oocysts and the appearance and location of the lesions.

Pathogenicity

E maxima is moderately-highly pathogenic. Infection with 50–200 × 10³ oocysts causes poor weight gain, morbidity, diarrhea, and sometimes mortality. Some isolates are capable of 30% mortality in 5-week-old chickens with 100,000 oocysts. There is often extreme emaciation, pallor, roughening of feathers, and anorexia. Producers interested in maintaining good skin color in chickens must be concerned with subclinical infections because of the effect of this species on absorption of xanthophyll and carotenoid pigments in the small intestine.

Gross Lesions and Histopathology

Minimal tissue damage occurs with the first 2 asexual cycles, which develop superficially in the epithelial cells of the mucosa. When the sexual stages develop in deeper tissues on days 5–8 PI, lesions develop because of congestion and edema, cellular infiltration, and thickening of the mucosa. Infected host cells become enlarged, pushing into the subepithelial zone. Microscopic hemorrhages occur near the tips of the villi, and foci of infection can be seen from the serosal surface. The intestine may be flaccid and filled with fluid, and the lumen often contains yellow or orange mucus and blood. This condition has been described as "ballooning." Microscopic pathology is characterized by edema and cellular infiltration, developing schizonts through day 4, and sexual stages (macrogametes and microgametes) in deeper tissues on

days 5–8. In severe infections, considerable disruption of the mucosa occurs.

Eimeria mitis *Tyzzer 1929*

The lower small intestine is the normal site of this parasite, from the yolk sac diverticulum to the cecal necks. The lesions are normally indistinct with this species, but the potential for pathogenic effects on weight gain and morbidity is well documented (13). Oocysts average 16.2 × 16.0 (shape index 1.01), giving them a subspherical appearance.

Pathogenicity

Infection with 5 × 10⁵ − 5 × 10⁶ oocysts will reduce weight gain and cause morbidity and loss of pigmentation in broiler chickens. In layers, this species may affect egg production and induce a molt. The lack of distinct gross lesions causes this species to be overlooked or misdiagnosed in subclinical infections.

Gross Lesions and Histopathology

Clinically, the gross lesion is very slight and can be easily overlooked. The lower small intestine appears pale and flaccid, and microscopic examination of smears from the mucosal surface may reveal numerous tiny oocysts (15.6 × 14.2 mm). The infection is distinguished easily from *E. brunetti* by the smaller, round oocysts. In light infections, the appearance of the gross lesion may be similar to *E. brunetti.* The gross lesions of this species are unremarkable because the developing parasites do not tend to localize in colonies as do other species, and the schizonts and gametocytes are superficial in the mucosa.

Eimeria mivati *Edgar and Siebold 1964*

This species was first identified in 1959 as a small strain of *E. acervulina* and later named as a separate species (11). The zone of infection extends from the duodenal loop to the ceca and cloaca in heavy infections. Oocysts are broadly ovoid, averaging 15.6 × 13.4, and the shape index is 1.16.

Considerable controversy exists on the validity of *E. mivati* as a species, dating from the work of Shirley with isoenzymes and later work with species-specific primers for PCR. However, recent evaluation of field samples have produced isolates that fit the morphologic description of Edgar and Seibold, and do not react with primers for other known species. Results using the ITS1 and ITS2 region primers indice that these organisms are different from the other 7 known species for which specific primers have been developed. Further work is needed to settle the taxonomic status of this species.

Pathogenicity

Infection with 5 × 10⁵ – 1 × 10⁶ oocysts of *E. mivati* causes reduced weight gain and morbidity. Mortality as high as 40% has been seen in experimental infections (personal observations).

Gross Lesions and Histopathology

Early lesions appear in the duodenum and later in the midgut and lower small intestine. In light infections, isolated lesions resemble those of *E. acervulina* but are more circular in shape. These

lesions, representing colonies of gametocytes and developing oocysts, may be seen from the serosal surface of the gut. Gross lesions sometimes include red petechiae and round white spots for 72–240 hr PI. Histopathology reveals parasitism of the mucosal cells of the villi of the small intestine. In contrast to *E. acervulina,* this species may be found from the tip to the base of villi, sometimes causing severe denuding of the mucosa.

Eimeria necatrix *Johnson 1930*

Because of the spectacular lesions in the small intestine, this species was one of the best known by early poultry producers. The lesion is found in the small intestine in approximately the same location as *E. maxima* (Fig. 28.3A–D). Probably because of the low reproductive capability of *E. necatrix,* it is not able to compete with other coccidia and is diagnosed mostly in older birds such as brooder pullets or layer pullets 9–14 weeks old. The intestine often is dilated to twice its normal size (ballooning), and the lumen may be filled with blood and fluid laden with merozoites and clusters of large mature schizonts. The oocysts are ovoid and average 20.4 × 17.2 mm, which is near in size to those of *E. tenella.* Curiously, the oocysts are found only in the ceca, rather than in the intestine where lesions are found. The sexual stages (gametocytes) develop ceca, and are scattered rather than clustered. *E. necatrix* is a poor producer of oocysts.

Pathogenicity, Gross Lesions, and Histopathology

E. necatrix along with *E. tenella* are the most pathogenic of the chicken coccidia. Infection with 10^4–10^5 oocysts is sufficient to cause severe weight loss, morbidity, and mortality. Survivors may be emaciated, suffer secondary infections, and lose pigmentation. Droppings of infected birds often contain blood, fluid, and mucus. Naturally occurring infections have caused mortality in excess of 25% in commercial flocks. In experimental infections, 100% mortality is possible. Layer pullets suffering outbreaks at 7–20 weeks of age may suffer mortality, morbidity, loss of uniformity, and decreased egg-laying potential. Gross lesions may be seen as early as 2–3 days PI, associated with first-generation schizogony, but the severe lesions at 4–6 days PI are caused by second-generation schizogony. The intestine may be ballooned; the mucosa thickened; and the lumen filled with fluid, blood, and tissue debris. From the serosal surface, the foci of infection can be seen as small white plaques or red petechiae. In dead birds, these lesions appear white and black, giving rise to the expression "salt and pepper" appearance. Smears examined microscopically on days 4–5 PI may contain numerous clusters of large (66 mm) schizonts, each containing hundreds of merozoites. The clusters of schizonts deep in the mucosa often penetrate the submucosa and damage the layers of smooth muscle and destroy blood vessels. In these instances, the foci are large enough to be seen from the serosal surface. Later, scar tissue may be seen where epithelial regeneration is incomplete. Few pathogenic effects are seen with the invasion of the cecal mucosa by the third-generation schizonts and gametocytes because of the nonclustering nature of these stages. The third-generation schizonts produce only 6–16 merozoites.

Lesions may extend from the ventriculus-gizzard junction to the ileo-cecal junction in severe infections, causing dilation (ballooning) and thickening of the mucosa. The lumen may be filled with blood and pieces of mucosal tissue. Microscopic examination of smears from the mucosal surface reveals numerous clusters of large schizonts, which are characteristic for this species and distinguish it from others that overlap in habitat. Also, oocysts are never associated with lesions of this species.

Histopathology of midgut from affected birds reveals a submucosa and lamina propria crowded with large clusters of schizonts. Often, large areas of the mucosa are sloughed off, and the lesion may extend through the muscle layers to near the serosal membranes.

Eimeria praecox *Johnson 1930*

This species is named from the short prepatent period (about 83 hours); hence a "precocious" parasite. Even though *E. praecox* is often overlooked because no prominent lesions exist, it is easily detected by timed infections of experimental birds. The oocysts are recognized easily because they are generally larger than those of other species found in the duodenum. At 21.3 × 17.1 mm, they are larger than *E. acervulina, E. mivati,* and *E. mitis* and smaller than *E. maxima.* The shape index is 1.25.

Pathogenicity, Gross Lesions, and Histopathology

Heavy infections cause reduced weight gain, loss of pigmentation, dehydration, and poor feed conversion. The gross lesions consist of watery intestinal contents and sometimes mucus and mucoid casts. Most of the infection is confined to the duodenal loop. Small pinpoint hemorrhages may be seen on the mucosal surface on days 4–5 of infection. Recent studies suggest that this species may cause morbidity and reduced weight gain (15). Severe infections may cause dehydration. The epithelial cells of the sides of the villi (but not the tips) are most often infected. There may be several parasites in each cell. Three to four asexual generations are normal, followed by gametogony. Infections with this species cause little tissue reaction.

Eimeria tenella *(Railliet and Lucet 1891)* *Fantham 1909*

E. tenella is the best known of poultry coccidia, because of the easily recognizable lesions and often spectacular losses it causes in commercial broilers or layer pullets. This species inhabits the ceca (rarely adjacent intestinal tissues), causing a severe disease characterized by bleeding, high morbidity and mortality, lost weight gain, emaciation, loss of skin pigmentation, and other signs. Oocysts are ovoid, averaging 22.0 × 19.0 mm (shape index 1.16). Diagnosis is dependent upon finding cecal lesions with prominent blood and often firm bloody cores and accompanying clusters of large schizonts and oocysts (Fig. 28.3I–L).

Pathogenicity, Pathogenesis, and Epidemiology

Experimental inoculation with 10^4 or more sporulated oocysts can cause morbidity, mortality, and greatly reduced weight gain, making this one of the most pathogenic species in chickens. Inoculation with 10^3 oocysts is sufficient to cause bloody droppings and other signs of infection. The most pathogenic stage is

the second-generation schizont, which matures at 4 days PI. Like *E. necatrix,* this species produces clusters of large schizonts, which may contain hundreds of merozoites. The schizonts develop deep in the lamina propria, so that the mucosa and associated blood vessels are disrupted when the schizonts mature and merozoites are released. Onset of mortality in a flock is rapid. Most of the mortality occurs between days 5 and 6 PI, and in acute infections, it may follow the first signs of infection by only a few hours. Blood loss may reduce the erythrocyte count and hematocrit value as much as 50%. The maximum effect on weight gain is seen at 7 days PI. Some of the weight lost from dehydration may be regained quickly, but growth will always lag behind that of uninfected birds. The exact cause of death is not known, but toxic factors are suspected. Blood loss alone does not account for mortality. In a few cases, death may result from gangrenous or ruptured cecal pouches. Extracts of infected cecal pouches produce acute blood coagulation and death when injected intravenously into other chicks. The possible role of bacterial products in mortality from coccidiosis is suggested by the lack of mortality from *E. tenella* in germ-free chicks.

Gross Lesions and Histopathology

Even during maturation of the first generation of schizonts, small foci of denuded epithelium may be seen. By day 4 PI, the second-generation schizonts are maturing, and hemorrhages are apparent. The cecal pouch may become greatly enlarged and distended with clotted blood and pieces of cecal mucosa in the lumen. On days 6 and 7, the cecal core becomes hardened and drier; eventually it is passed in the feces. Regeneration of the epithelium is rapid and may be complete by day 10. The infection usually can be seen from the serosal surface of the ceca as dark petechiae and foci, which become coalesced in severe infections. The cecal wall is often greatly thickened because of edema and infiltration and later scar tissue.

Microscopically, the first-generation schizonts are widely scattered and mature at 2–3 days PI. Small focal areas of hemorrhage and necrosis may appear near blood vessels of the inner circular muscles of the muscularis layer. Heterophil infiltration of the submucosa proceeds rapidly as the large second-generation schizonts develop in the lamina propria. These are found in clusters or colonies that generally are progeny of a single first-generation schizont. Maturation of the second-generation schizonts is accompanied by excessive tissue damage, bleeding, disruption of the cecal glands, and destruction of the mucosa and muscularis layer. Microgametes and macrogametes are seen in the tissues on days 6 and 7, and mature oocysts are released into the lumen in large numbers. Regeneration of the epithelium and glands may be complete by day 10 in light infections, but the epithelium may never completely recover in severe infections. Lost muscularis mucosa is not replaced, and the submucosa becomes densely fibrosed.

Epidemiology of Coccidiosis

Natural and Experimental Hosts

The chicken is the only natural host of these 7 species of *Eimeria*. Reports of these species of *Eimeria* infecting other birds can be considered spurious. Cross-transmission of *Eimeria* spp. from chickens to other host species has been unsuccessful except for a few instances in which severely immunocompromised birds were used.

Naive chickens of all ages and breeds are susceptible to infection. However, immunity develops after mild infections, limiting further infection. Newly hatched chicks often have high levels of maternal antibodies but it does not appear that this limits susceptibility. Outbreaks are common at 3–6 weeks of age and are seldom seen in poultry flocks at less than 3 weeks. In special situations, infections may be seen as early as 1 week of age. Data from routine necropsy of chickens over several years in the USA (Personal observations of S. Fitz-Coy, based on gross and microscopic evidence) showed that the prominent species were *E. acervulina* (97%), *E. maxima* (64%), and *E. tenella* (64%). Less common species were *E. mivati, E. brunetti, E. mitis* and *E. praecox*. Surveys of coccidia in broiler houses in Georgia demonstrated that oocysts of coccidia build up during the growth of a flock and then decline as the birds become immune to further infection (39). This self-limiting nature of coccidial infections is widely known in chickens and other poultry. There is no stimulation of cross-protective immunity between species of coccidia. Thus, several outbreaks of coccidiosis are possible in the same flock, with different species involved in each. Breeder pullets and layer pullets are at greatest risk because they are kept on litter for 20 weeks or more. Normally, the infections with *E. acervulina, E. tenella*, *E. mitis, E. mivati, E. praecox*, and *E. maxima* are seen at 3–6 weeks of age and then *E. necatrix* at 8–18 weeks of age. *E. brunetti* is seen both early and late.

Coccidiosis rarely occurs in layers and breeders during the laying cycle, because of prior exposure to coccidia and resulting immunity. If a flock is not exposed to a particular species early in life or if immunity is depressed because of other diseases, outbreaks may occur after layers are moved to production houses. Outbreaks of any species in layers can reduce or eliminate egg production for several weeks.

Transmission and Vectors

Ingestion of viable sporulated oocysts is the only natural method of transmission. Infected chickens may shed oocysts in the feces for several days or weeks. The oocysts in feces become infective through the process of sporulation in about 2 days. Susceptible birds in the same flock may ingest the oocysts through litter-pecking or the contamination of food or water.

Although no natural intermediate hosts exist for the *Eimeria* spp., oocysts can be spread mechanically by many different animals, insects, contaminated equipment, wild birds, and dust. Oocysts generally are considered resistant to environmental extremes and to disinfectants, although survival time varies with conditions. Oocysts may survive for many week in soil, but survival in poultry litter is limited to a few days because of the heat and ammonia released by composting and the action of molds and bacteria. Viable oocysts have been reported from the dust inside and outside broiler houses, as well as from insects in poultry litter (39). The darkling beetle, common in broiler litter, is a mechanical carrier of oocysts. Transmission from one farm to an-

other is facilitated by movement of personnel and equipment between farms and by the migration of wild birds, which may mechanically spread the oocysts. New farms may remain free of coccidia for most of the first growout of chickens until the introduction of coccidia to a completely susceptible flock. Such outbreaks, often more severe than those experienced on older farms, are often called "the new-house syndrome."

Oocysts may survive for many weeks under optimal conditions but will be quickly killed by exposure to extreme temperatures or drying. Exposure to 55°C or freezing kills oocysts very quickly. Even 37°C kills oocysts when continued for 2–3 days. Sporozoites and sporocysts can be frozen in liquid nitrogen with appropriate cryopreservation technique, but oocysts cannot be adequately infiltrated with cryoprotectants to effect survival. Threat of coccidiosis is less during hot dry weather and greater in cooler damp weather.

Diagnosis of Coccidiosis

Coccidiosis can best be diagnosed from birds killed for immediate necropsy. Attempts to identify characteristic lesions in birds that have been dead for 1 hour or longer are frustrated by the postmortem changes in the intestinal mucosa. The entire intestinal tract should be examined. A microscope should be available for viewing endogenous forms on questionable lesions. The finding of a few oocysts by microscopic examination of smears from the intestine indicates the presence of infection, but not a diagnosis of clinical coccidiosis. Coccidia and mild lesions are present in the intestines of birds 3–6 weeks old in most flocks. Coccidiosis should be diagnosed if the gross lesions are serious or if other economic parameters are threatened. Diagnosis should be based on finding lesions and confirming microscopic stages on necropsy of typical birds from the flock, rather than from culls. Cryptosporidia may be found in chickens or turkeys but are distinguished easily from *Eimeria* by their small size and location in the brush border of the mucosal cells (14, 19).

Microscopic Examination

Developing schizonts, gametocytes, and oocysts of coccidia may be seen in smears taken from the suspected lesion. A small amount of mucosal scraping should be diluted with saline on a slide and then covered with a coverslip. Oocysts or macrogametes are most easily seen, but in many cases, the lesion is caused by maturing schizonts. Diagnostic characteristics which are of value include the clusters of the large schizonts of *E. necatrix* and *E. tenella,* the small round oocysts of *E. mitis,* or the large gametocytes of *E. maxima.* Presence of clusters of large schizonts in the midgut area is pathognomonic for *E. necatrix,* and a similar finding in the ceca indicates *E. tenella.* Oocysts associated with lesions in the duodenum are *E. acervulina, E. mivati,* or *E. praecox*, and oocysts associated with lesions in the lower gut are *E. mitis, E. mivati* or *E. brunetti.*

Oocyst size and shape are less useful as diagnostic characteristics in chickens than once thought, because of the extensive overlapping in size of the species. However, the combination of oocyst size, location in the gut, and appearance of the lesions gives considerable confidence in diagnosis. Measurement of 20–30 oocysts of the predominant type of oocyst usually gives a good indication of the size of the unknown species. This information is useful in conjunction with other observations in the identification of species in field cases.

Lesion Scoring

The severity of lesions is roughly proportional to the number of oocysts ingested by the bird and correlates with other parameters such as reduced weight gain, loss of skin pigmentation and diarrhea. The most commonly used practice is based on the system devised by Johnson and Reid (22). In this technique, a score of 0–4 is assigned to a bird where 0 = normal and 4 = most severe case. This technique is most useful in experimental infections, where the dose of oocysts and medicaments are controlled, and the species are known. In the field, lesion scoring is generally useful in gauging the severity of infections but may not correlate with microscopic scoring. Even though several species of coccidia may be present at some time, only 4 separate sections of the intestine are usually scored. These are 1) the duodenum (upper), with lesions of *E. acervulina, E. mivati*; 2) the midgut from the duodenum past the yolk sac diverticulum, with lesions of *E. maxima, E. praecox, E. necatrix,* and *E. mitis*; 3) the lower small intestine from the yolk sac diverticulum to the cecal junctures, with lesions of *E. mitis, E. necatrix, E. maxima and E. brunetti*; and 4) the ceca, where only *E. tenella* is found.

Microscopic scoring

As with lesion scores, the severity of coccidiosis can be judged by the number and appearance of parasite forms seen upon microscopic examination of smears from the mucosa, lumen or feces. Microscopic scoring is particularly useful for detecting and rating species that do not produce easily seen gross lesions, such as *E. mitis, E. hagani* and *E. praecox.*

Droppings Score

In laboratory infections, the droppings score may be used in the same manner as lesion score for a rapid and fairly reliable rating of the infection (31). The extent of abnormal droppings is rated on a scale of 0–4, where 4 = maximum diarrhea, with mucus, fluid, and/or blood. This technique has obvious complications where birds are infected with more than one species of *Eimeria.*

Histopathology Methods

Ordinary methods in histopathology are satisfactory for routine examination of tissues infected with coccidia. Staining of sections with H & E or other common histologic stains will demonstrate developing stages. Specialized techniques will identify specific stages: Staining with Schiff's reagent gives a brilliant red color with the polysaccharide associated with the refractile body and with wall-forming bodies in the macrogamete. Monoclonal antibodies conjugated with fluorescent markers such as fluorescein are very useful in research because specific stages of parts of cells can be readily identified.

Procedures Used in Species Identification

Most of the species of coccidia are easily identified by attention to well-established biological characteristics (Table 28.1,

28.3)(25, 30, 32, 43). The largest oocysts belong to *E. maxima,* making it easily distinguished from other species. Some species are identified easily by the location and appearance of gross lesions in concert with the size of oocysts or schizonts (*E. acervulina, E. maxima, E. necatrix, E. tenella*). The lesions produced by other species are not reliably distinct, and oocyst sizes overlap with those of other species. For *E. praecox,* the best method is determination of prepatent period by timed inoculation of birds in laboratory cages. Oocysts produced in less than 90 hours can only be *E. praecox. E. brunetti* oocysts are indistinguishable from those of *E. praecox*, *E. tenella,* and *E. necatrix* on size alone, but the location in the lower gut and appearance of the lesions are reliable indicators. *E. mitis* is located in the mid-lower gut, has small subspherical oocysts, and has a prepatent period of 99 hours, separating it from *E. brunetti.*

Because of the overlapping size, area parasitized, and lack of distinct lesions, it has been difficult to separate *E. hagani* from other species of the duodenum with small oocysts. In this case, immunization tests were very useful (36). Poultry develop immunity to reinfection after inoculation with *Eimeria*, but there is no cross-protection between species. This strict specificity of immunity has been exploited as a technique for distinguishing species of coccidia for taxonomic purposes. This test requires pure cultures of the test species and test animals reared in isolation for mono-immunization and challenge. When *E. hagani* oocysts were used to immunize chickens, the resulting immunity protected against reinfection by the same culture but not against other species. Conversely, birds immunized with other species were not protected against infection with the culture of *E. hagani*. Overall, the technique is time consuming, requires extensive laboratory isolation facilities, and access to pure cultures of known species of coccidia but may be useful as a research tool when used in concert with other tests or observations.

Preservation of Coccidia for Experimental Work

Droppings or litter collected in the field, or intestinal contents in the diagnostic lab, can be saved for isolation of coccidia in a solution of 2–4% potassium dichromate. Aeration of oocyst suspensions is necessary to allow sporulation. A good-quality aquarium pump is highly effective and can be regulated with valves and tubes to service several bottles at one time. For short-term storage, suspensions of oocysts may be refrigerated at temperatures above 4°C. Freezing temperatures quickly kill coccidial oocysts, as do elevated temperatures. Oocysts are quickly killed by storage at 37°C or higher.

Prevention and Control

Control of Coccidiosis by Chemotherapy

Early emphasis in chemotherapy was centered on the treatment of outbreaks with sulfonamides or other compounds as soon as signs of infection were apparent. The concept of preventive medication emerged with the realization that most of the damage is done by the time signs of coccidiosis are widespread in a flock. Today, almost all broiler flocks receive preventive medication (Table 28.2). Treatment is used as a last resort or when other programs have failed. The historical aspects of chemotherapy have been reviewed extensively by McDougald (27). Consult a current Feed Additives Compendium for up-to-date information on approved products (12).

Characteristics of Anticoccidial Drugs

All types of drugs used for coccidiosis control are unique in the mode of action, the way in which parasites are killed or arrested, and the effects of the drug on the growth and performance of the bird. Following are the most important characteristics.

Spectrum of Activity. There are several important species of coccidia in chickens, several more in turkeys, and many others in other hosts. A drug may be efficacious against one or several of these parasites; very few drugs are equally efficacious against all.

Mode of Action. Each class of chemical compound is unique in the type of action exerted on the parasite, and even in the developmental stage of the parasite most affected. The chemical mode of action of some drugs is known to be a highly detailed event, and the action of other drugs remains a mystery. The sulfonamides and related drugs compete for the incorporation of PABA and metabolism of folic acid. Amprolium competes for absorption of thiamine by the parasite. The quinoline coccidiostats and clopidol inhibit energy metabolism in the cytochrome system of the coccidia. The polyether ionophores upset the osmotic balance of the protozoan cell by altering the permeability of cell membranes for alkaline metal cations.

Endogenous Stage Affected. The coccidia are prone to attack by drugs at various stages in the development in the host. Totally unrelated drugs may attack the same stage of parasite. The quinolones and ionophores arrest or kill the sporozoite or early trophozoite. Nicarbazin, robenidine, and zoalene destroy the first- or second-generation schizonts, and the sulfonamides act on the developing schizonts and on the sexual stages. Diclazuril acts in early schizogony with *E. tenella* but is delayed to later schizogony with *E. acervulina* and to the maturing macrogamete with *E. maxima.* The time of action in the life cycle has been construed as having significance in the use of drugs in certain types of programs in which immunity is desired, but there is no good evidence that this is true under practical conditions.

Coccidiocidal versus Coccidiostatic. Some drugs kill the parasite, but others only arrest development. When coccidiostatic medication is withdrawn, arrested parasites may continue to develop and contaminate the environment with oocysts. In such cases, a relapse of coccidiosis is possible. In general, the coccidiocidal drugs have been more effective than those that are coccidiostatic.

Effects of Drugs on the Target Animal. Most compounds used in animal feeds have good "selective toxicity," providing toxicity for the parasite but being nontoxic to vertebrates. Unfortunately, toxicity and side effects of drugs on the host are possible where formulation errors lead to overdose. Sometimes, a drug may exhibit side effects at the recommended use level. Some of the toxicity may be the result of management, genetics, nutrition, or other in-

Table 28.3. Diagnostic characteristics of *Eimeria* in turkeys.

teraction, and in other cases, the margin of safety is just too narrow. Environmental interaction is possible with nicarbazin, which interacts with high temperatures and high humidity to produce excess mortality. Also nicarbazin is highly toxic to layers, first causing a bleaching of brown-shelled eggs, mottling of yolks, reduced hatchability, and reduced production. The ionophores are highly toxic at elevated doses, causing a transient paralysis in mild overdoses or a permanent paralysis and mortality in more severe cases. Monensin was once thought to interact with methionine to reduce feather growth, but this relationship is not clear. Under some conditions, lasalocid will stimulate water consumption and excretion, resulting in a wet litter. With slight overdoses, most of the ionophores depress weight gain under laboratory conditions. A withdrawal period of 5–7 days is often practiced to allow "compensatory growth" to make up for the lost gain. The ionophores are known for their toxicity to other animals. Thus, monensin and salinomycin are highly toxic to horses. The lethal dose—50% (LD_{50}) for monensin in horses—is about 2 mg/kg body weight. Salinomycin is highly toxic to turkeys at levels greater than 15 g/ton and causes excessive mortality at the level recommended for use in chickens (60 g/ton), while monensin and lasalocid are well tolerated in turkeys at the level used for chickens.

Programs for Use of Anticoccidial Drugs in Broilers
In broilers, the objective is usually to produce the maximum growth and feed efficiency with minimum of disease, and in layers or breeders, the objective may be immunization. The choice of a product or program may depend on the season of the year or other factors which affect exposure. Several types of programs are practiced:

Continuous Use of a Single Drug. Often, a single product will be used from day 1 to slaughter, or with a withdrawal period of 3–7 days. Most products are approved for use until slaughter, but producers withdraw medication for economic or other reasons.

Shuttle or Dual Programs. The use of one product in the starter and another in the grower feed is called a "shuttle" program in the United States and a "dual" program in other countries. Some programs might contain as many as 3 drugs, with one drug in the starter, another in grower and yet another in the finisher. The shuttle program usually is intended to improve coccidiosis control. Intensive use of the polyether ionophore drugs for many years produced strains of coccidia in the field that have "reduced sensitivity" to the ionophores. It is a common practice to use another drug such as nicarbazin, diclazuril, or clopidol in either the starter or grower feed to bolster the anticoccidial control and take some pressure off of the ionophore. In other cases, the order of these drugs is reversed. The use of shuttle programs is thought to reduce buildup of drug resistance. At times, a high percentage of producers use some type of shuttle program.

Rotation of Products. It is considered sound management to make periodic changes in anticoccidial drug use. Most producers in the USA consider changes in the spring and in the fall. Rotation of drugs may improve productivity because of the buildup of isolates or species of coccidia that have reduced sensitivity after products have been used for a long time. Producers often notice a boost in productivity for a few months after a change of anticoccidial drugs. The seasonal rotation of products is intended to correspond with the intrinsic properties of the drugs. In the USA, nicarbazin must be used principally in the cooler months of the year, which also corresponds with maximum coccidiosis challenge. In the summer months, coccidiosis challenge tends to be milder, so weaker anticoccidials are used.

Drug Resistance
The development of tolerance to drugs by coccidia after exposure to medication is the most serious limitation to the effectiveness of these products. Surveys reveal widespread drug resistance in coccidia in the United States, South America, and Europe (16, 20, 23, 25, 31, 32). Even though coccidia develop less resistance to some drugs than to others, long-term exposure to any drug will produce a loss in sensitivity and, eventually, resistance. Drug resistance is a genetic phenomenon, and when established in a line of coccidia, will remain for many years or until selection pressure and genetic drift forces return to sensitivity in the population. Drugs such as the quinolones and clopidol have a well-defined mode of action, and resistance develops quickly as coccidia are selected with cytochromes, which do not bind as readily to the drug. The polyether ionophores, in contrast, have a more complicated mode of action involving the mechanisms of active transport of alkaline metal cations across cell membranes, and it has taken many years for coccidia to become tolerant, and in some cases, completely resistant. Many other drugs appear to be intermediate in selecting resistance in coccidia. The primary defense against drug resistance is the use of less intensive programs, shuttle programs, and frequent rotation of drugs. Rotation of programs, used alone, will not prevent the development of resistance. In some instances coccidia are able to become resistant to drugs after only a few months of use, and once developed, drug resistance is slow to dissipate. In recent years it has become a common practice to incorporate live coccidiosis vaccines in the rotation program, reasoning that the drug-sensitive vaccine strains tend to replace the drug resistant wild types. This approach has had demonstrable effects on the drug sensitivity profile on farms where it has been practiced.

Anticoccidial Drugs Used for Broilers in the United States
The products currently approved for use in chickens in the United States are listed in Table 28.2. Not all are still available commercially, but the approvals remain. Those used at present include monensin, narasin, salinomycin, semduramicin, and lasalocid (polyether ionophores), diclazuril, nicarbazin, amprolium 1 ethopabate, decoquinate, clopidol, sulfadimethoxine 1 ormetoprim, and sulfaquinoxaline. A product combining narasin with nicarbazin is also used, to take advantage of synergism between these molecules. Other products listed with approvals but lacking in significant activity include chlortetracycline and oxytetracycline. These products may prevent mortality from coccidiosis when given at high levels because of antibacterial activity but are

not of much value in general use. The polyether ionophores became the drugs of choice for prevention of coccidiosis in 1972 and remain the most extensively used today. Other drugs, such as clopidol, diclazuril, halofuginone, nicarbazin and robenidine, are used mostly in shuttle programs as an adjunct to the ionophores.

Immunization during Medication Programs in Broilers

Chickens develop immunity to coccidiosis after natural exposure and may even develop substantial immunity while receiving anticoccidial drugs (7, 18). The poultry industry has learned to take advantage of this phenomenon, practicing longer withdrawal programs of 2–3 weeks in some instances.

Coccidiosis Vaccines

Considerable research on coccidiosis vaccines in recent years has produced new live products. Increasingly, these products are finding use in the broiler industry. When live oocysts of coccidia are given to chickens at an early age, protection against the species contained in the inoculum is stimulated. The virulence of coccidia in these vaccines is attenuated largely by the size of the dose and by the means of administration. Some vaccines sold internationally or under development in the USA contain modified live coccidia with attenuation by genetic selection for short life cycle development. The use of coccidiosis vaccines in broilers has been limited by the possibility of adverse reactions, particularly a negative effect on feed efficiency. More recent advances in administration methods have overcome much of this limitation. The Coccivac products pioneered in this growing family, which now includes several other live vaccines in various countries (Coccivac®, Immucox®, Paracox®, Livacox®, BioVet®, Advent®, Nobilis®, In-OvoCox®, and others). Some new live vaccines have been prepared from attenuated lines of oocysts (e.g., Paracox7 and Livacox7). These vaccines normally contain 3 or more species of *Eimeria,* which are thought to be the most important. The *Eimeria* infecting poultry immunize only against themselves, so that the vaccine will only protect against the included species. As is well known, several species not normally included in the vaccines are capable of causing depressed gain, poor feed conversion, and loss of skin color, and are sometimes the cause of apparent vaccine failure. The success of some vaccines may depend more on a novel administration technique rather than attenuation. One experimental product was encapsulated in alginate beads and then mixed into the starter feed for "trickle administration." Other methods presently used are spray cabinet administration, direct eye-spray, *in -ovo* inoculation, or spraying the oocysts directly into feed or water in the poultry house. One product is mixed into gels, which are placed into the chick boxes for the chicks to eat (8). Other experimental approaches include inoculation of parasites or antigens *in ovo* and inoculation via the yolk sac diverticulum.

Monoclonal antibody technology has led to the identification of coccidial proteins, which offer some protection from infection when inoculated into young chicks. These proteins can be made in quantity if the gene that encodes the protein is cloned into a bacterial cell. Research is in progress identifying broad-spectrum antigens and appropriate routes of administration. One product based on this approach is CoxAbic®, which is composed of an antigen developed from a monoclonal protein produced in the gametocyte of *E. maxima*. The latter vaccine is given to hens in 2 doses, to confer maternal protection during the first 3 weeks of brooding.

Control Programs Used in Breeders and Layers

Pullets started on the floor and later reared as caged layers are not as dependent on immunity to coccidiosis as are floor layers. They are often protected against coccidiosis with preventive medication, as with broilers until they are moved to cages. Breeder pullets that will be kept on the floor during lay should have immunity to coccidiosis. Controlled exposure vaccination can be given by means of commercially produced live products (described above). Natural or "accidental" exposure assumes the presence of oocysts of important species. A broad-spectrum anticoccidial drug is sometimes given at the lowest approved level to provide protection for 6–12 weeks. Some producers reduce the level of the drug during the final 4 weeks in a step-down program, although as mentioned previously, chickens tend to develop immunizing infections despite the presence of the drug. This approach allows moderate numbers of coccidia to develop in the birds, stimulating the host immune system to protect against serious outbreaks. Such exposure rarely is insufficient to protect against all species, because not all species are present throughout the growing period. Outbreaks of *E. necatrix* have sometimes occurred at 8–16 weeks, after all medication has been stopped. Climatic and seasonal conditions may add to the inherent uncertainties of this method.

Disinfection and Sanitation

Older recommendations for coccidiosis control often suggest directions for sanitation and disinfection to prevent outbreaks. Most of these are no longer considered valid because 1) there have been too many failures in such programs; 2) oocysts are extremely resistant to common disinfectants; 3) complete house sterilization is never complete; and 4) an oocyst-sterile environment for floor-maintained birds could prevent early establishment of immunity and allow late outbreaks. In addition to disinfectants normally used in poultry houses, specific products have been used to target the oocyst for destruction. A product available in some countries contains an ammonium salt and sodium hydroxide (OO-cide®).

Chickens reared in cages rarely suffer outbreaks of coccidiosis. The exceptions are usually in single rows of cages in which there has been accidental fecal contamination of feed or water.

Coccidiosis in Turkeys

Coccidiosis in turkeys is common but is often unrecognized because the lesions in turkeys are less spectacular than those in chickens. Several species infect turkeys, but only about 4 are economically important. Typical signs of coccidiosis in turkeys are watery or mucoid diarrhea, blood-streaked feces, ruffled feathers, anorexia, and general signs of illness. Recovery is quick, so lesions could go undetected at necropsy. Several species have been found in commercial turkey farms throughout the United

States (8). Coccidia infecting domestic turkeys also infect wild turkeys. The common species of *Eimeria* found in commercial turkey operations are *E. meleagrimitis, E. adenoeides, E. meleagridis,* and *E. dispersa. E. gallopavonis* is seen in a low percentage of flocks. Range-rearing of turkeys can add significantly to the exposure of wildlife to coccidiosis and other diseases.

Turkeys of all ages are susceptible to primary infection, but birds older than 6–8 weeks are considered more resistant to the disease; they can suffer weight loss and morbidity but are not killed as easily as are younger birds. Reductions in the rate of weight gain are often unrecognized until adequate coccidiosis control measurers have been instituted.

Etiology

Seven species of *Eimeria* have been described in turkeys in the United States. Identifying characteristics of each species are listed in Table 28.3. *E. innocua and E. subrotunda* have been so rarely recovered that further work will be required to re-establish the validity of these species.

Besides the *Eimeria,* species reported from the turkey include *Isospora* and *Cryptosporidium* (see the next section). The *Eimeria* spp. are strictly intestinal, contrasting with *Cryptosporidium*, which may cause both respiratory and intestinal infection (17). The most pathogenic species of *Eimeria* are *E. adenoeides, E. meleagrimitis, E. gallopavonis*, and *E. dispersa*. Differentiation of oocysts of the pathogenic species from those of milder species is difficult because some of the species are poorly described. For instance, differentiation of *E. adenoeides* and *E. meleagridis* is difficult, as they inhabit the ceca and have oocysts that are fairly simlilar.

Eimeria adenoeides *Moore and Brown 1951*

Gross lesions appear primarily in the ceca but extend to the lower small intestine and cloaca. Cecal contents are often hardened into a core consisting of mucosal debris. The cecal and/or intestinal wall is often swollen and edematous. Oocysts are ellipsoidal and have a high shape index length/width (5/1.54). The oocysts average 25.6 × 16.6 mm. Typical oocysts of *E. adenoeides* are more pointed at one end than other species, aiding in recognition.

Pathogenesis

E. adenoeides is one of the most pathogenic of the turkey coccidia. Experimental infections of 25,000–100,000 oocysts in young poults may produce mortality up to 100% on day 5 or 6 PI. Turkeys several months old may lose considerable weight after infection. Outward signs of infection are apparent after 4 days PI. Feces are frequently fluid, may be blood-tinged, and may contain mucous casts. White or gray caseous cores may be produced in the ceca. In mild to moederate infections the cecal contents may be viscous and filled with oocysts. The lesions heal quickly, so no evidence of infection may be seen soon after the acute phase unless the cecal core remains.

Gross Lesions and Histopathology

By day 4 PI, the intestine may suffer congestion, edema, petechial hemorrhage, and mucous secretion. Five days PI, the ceca contain white caseous material, which condenses into a core. The serosal surface of the intestine appears pale and may be edematous and dilated.

Invasion of the submucosa by heterophils occurs throughout the intestine, especially in the lower small intestine, ceca and rectum. Epithelial cells at the tips of villi are most often invaded, but deep glands may also be parasitized. Edema is common deep in the muscular layers as the infection progresses. After day 5, regeneration of lost mucosa is rapid.

Eimeria dispersa *Tyzzer 1929*

The small intestine, principally the midgut region, is commonly parasitized, but some infection may occur in the cecal necks. Oocysts are large (average, 26.1 × 21.0 mm) and broadly ovoid (index = 1.24). Sporozoites lack a refractile body, and the oocyst wall is distinctively contoured and lacks the double wall common to other species. The prepatent period is 120 hours, longer than for other species.

Pathogenesis

Compared with some of the other species, the pathogenicity is low, but infection with $10^6 - 2 \times 10^6$ oocysts can cause reduction in rate of weight gain and diarrhea in young poults.

Natural and Experimental Hosts

The natural host of this species is apparently the bobwhite quail, in which the parasite is more pathogenic than in turkeys. This is the only *Eimeria* in chickens or turkeys known to infect more than one species. Experimental inoculation has produced patent infections in domestic and wild turkeys, Hungarian partridge (*Perdix perdix*), ruffed grouse (*Bonasa umbellus*), sharp-tailed grouse (*Pediocetes phasianellus campestris*), Japanese and bobwhite quail, and other pheasants. Infection in chickens often requires immunosuppression.

Gross Lesions and Histopathology

Three days PI, the duodenum appears cream-colored on the serosal surface. Later, the entire intestine may become dilated with thickening of the wall. Dilation continues on the fifth and sixth days, along with secretion of a cream-colored mucoid material containing denuded epithelium from the duodenum. Individual villi may become so dilated as to be visible to the naked eye.

The duodenum shows edema and progressively increasing congestion of capillaries. Separation of the epithelium and basement membranes may result in the lamina propria being exposed to a fibrin network or an open fluid-filled space. Necrosis is common on distal tips of villi. Parasites do not invade the glands.

Eimeria gallopavonis *Hawkins 1952*

Lesions are restricted to the area posterior to the yolk sac diverticulum and tend to be most severe in the lower small intestine and large intestine. Some foci of infection may be seen in the ceca. Oocysts are elongate, averaging 27.1 × 17.2 mm (index = 1.52). Differentiation of this species from *E. adenoeides* is often difficult. One difference is that *E. gallopavonis* has more rounded oocysts.

Pathogenesis

Experimental infection with $5 \times 10^4 - 2 \times 10^5$ oocysts causes mortality of 10–100% in 2–6-week-old poults. Mortality occurs 5–6 days PI.

Gross Lesions and Histopathology

On day 4 and 5 post-exposure, second- and third-generation schizonts are numerous in the ileum, necks of the ceca, and rectum. By day 6 the rectum is parasitized mostly with gamonts. Marked inflammatory and edematous changes on days 5–6 are followed by the sloughing of soft white caseous necrotic material containing numerous oocysts and flecks of blood on days 7 and 8.

Eimeria meleagridis *Tyzzer 1929*

Oocysts are ellipsoidal, averaging 24.4 × 18.12 mm (index 1.34). Visible lesions may be seen in the ceca with yellow-white caseous cores, but this species is considered virtually nonpathogenic. Oocysts resemble those of other pathogenic species in the ceca, and differentiation is difficult.

Pathogenesis

Most studies have characterized this species as almost nonpathogenic. Up to 5×10^6 oocysts produce little effect on the growth of 4–8-week-old poults. Earlier reports indicating greater pathogenicity may have come from mixed infections with *E. adenoeides.*

Gross Lesions and Histopathology

Nonadherent cream-colored caseous cecal cores are characteristics of infection in young poults. The core may be passed intact. The mucosa is somewhat thickened and may contain petechial hemorrhages in dilated portions of the ceca. The plugs disappear 5.5–6 days PI, and many oocysts may be found in cecal contents.

Edema and lymphocytic infiltration may be seen histologically, but less extensively than with *E. adenoeides* and *E. gallopavonis.* First-generation schizonts develop in the surface epithelium of the small intestine, but later stages occur in the cecal epithelium.

Eimeria meleagrimitis *Tyzzer 1929*

Infection with *E. meleagrimitis* is primarily upper intestinal but may spread throughout the small intestine in heavy infections. This is the most pathogenic of the upper-intestinal coccidia in turkeys. The oocysts are small (average, 19.2 × 16.3 mm) and ovoid (index = 1.17).

Pathogenesis

Experimental infection of young poults produces morbidity and mortality, lost weight gain, dehydration, and general unthriftiness. Inoculation of 2×10^5 oocysts produces some mortality and morbidity, but this species is not as pathogenic as *E. adenoeides.*

Gross Lesions and Histopathology

Infected birds show signs of dehydration. In the duodenum, enlargement and congestion are marked on days 5 and 6 of infection. Large amounts of mucus and fluid may be found in the lumen. Feces may contain occasional flecks of blood and mucous casts 5–7 days PI.

The tips of villi are most commonly parasitized, and the epithelium may be completely denuded, although hemorrhage is rare. Capillaries of the villi are markedly dilated and the tips edematous. Eosinophilic infiltration may begin as early as 2 hours PI and is extensive at the height of the infection.

Eimeria subrotunda *Moore, Brown, and Carter, 1954*

Poults inoculated with this species produced no gross lesions and it was considered nonpathogenic (34). Parasites develop primarily in the upper small intestine anterior to the yolk stalk diverticulum and are located in the epithelial cells in the tips of the villi. Oocysts are subspherical (index = 1.099) and average 21.77 × 19.81 mm. Oocysts have no refractile granule.

Eimeria innocua *Moore and Brown 1952*

This species is said to produce no gross lesions and is considered nonpathogenic. The area parasitized is the small intestine, in the epithelial cells at the tips of villi. Oocysts are subspherical (index = 1.072), and average 22.4 × 20.9 mm. Oocysts have no polar granule. Prepatent period for oocyst production is 114 hrs.

Undescribed Species

Several species of coccidia that do not fit descriptions of established species have been isolated from wild or domestic turkeys but have not been adequately described or named. Thus, some difficulty may be expected in identifying coccidia found in field cases unless the pathology and appearance are distinctive.

Prevention and Control of Turkey Coccidiosis

Drugs effective in chickens are generally effective in turkeys, but the optimal level of application may vary, and the toxicity of some drugs is significantly higher in turkeys than in chickens.

Treatment

As in chickens, treatment of outbreaks in turkeys is less desirable than the prevention by chemotherapy or immunization. When treatment is necessary, application of amprolium (0.012–0.025% in water) or a sulfonamide (dosage depending on drug, often given 2 days on drug, 3 days off, and 2 days on, sometimes repeated a second week) is recommended. The toxicity of sulfonamides limits their usefulness for turkeys.

Control by Chemotherapy

Most producers use anticoccidial drugs continuously in the feed at least 8 weeks. Generally, poults are confined to a brooding facility at that time. Later, the birds may be moved to range or to other facilities. Drugs approved historically for use in feed include amprolium (0.0125–0.25%), butynorate (0.0275%), sulfaquinoxaline (0.0175%), sulfadimethoxine (0.006–0.25%) + ormetoprim (0.00375%), monensin (54–90 g/ton), halofuginone (1.5–3.0 ppm); diclazuril (1.0 ppm), and lasalocid (75–125 ppm). Not all are available.

Prevention with Planned Immunization

The principle of immunization by exposure to a small number of pathogenic oocysts of the important species of *Eimeria* was developed with chickens and is represented by a single product for turkeys in the United States (Coccivac-T7, Schering-Plough, Millsboro, Delaware) and in Canada (Immucox7, Vetech, Guelph, Ontario). The inoculum is sprayed on the feed during the first 1–7 days, or sprayed on the poults at one day of age at the hatchery, and causes a mild infection. There are risks inherent in use of virulent strains of coccidia, and occasional treatment at 3–4 weeks of age is necessary if one of the species multiplies too rapidly, but the program has been used with moderate success.

Coccidiosis in Geese

Numerous species of coccidia have been described from domestic and wild geese. The most prevalent and damaging in commercial flocks are *E. truncata,* which causes renal coccidiosis, and *E. anseris*, which causes intestinal coccidiosis. Renal coccidiosis may produce high mortality from the blockage of kidney function in young goslings. Coccidia may be introduced into domestic flocks by migrating and resident wild geese.

Eimeria truncata *Raillet and Lucet 1891*

Flock losses due to renal coccidiosis have been reported as high as 87% in Iowa. Geese aged 3–12 weeks are affected, although the disease is most acute in goslings. Signs of infection include depression, weakness, diarrhea with whitish feces, and anorexia. Eyes become dull and sunken, and wings are drooped. Survivors may show vertigo and torticollis. Birds quickly develop immunity to reinfection.

Oocysts and endogenous stages of *E. truncata* are found only in the kidneys or cloaca near the junction of the ureters. Diagnosis of *E. truncata* is ensured by finding the distinctive oocysts in the kidneys and ureters. Oocysts average 21.3 × 16.7 mm and have truncated ends.

Natural and Experimental Hosts

Although thorough cross-infection experiments have not been done in most cases, *E. truncata* has been reported from domestic and wild geese, ducks, and swans.

Gross Lesions and Histopathology

The kidneys may be enlarged and protrude from the sacral bed. The normal reddish brown is altered to light grayish yellow or grayish red. Pinhead-sized grayish white foci or hemorrhagic petechiae may be seen; they contain numerous oocysts and accumulations of urates. Invading and growing parasites may distort the kidney tubules to many times the normal size. Eosinophils and signs of necrosis are present in focal areas.

Eimeria anseris *Kotlan 1933*

The oocysts average 19.2 × 16.6 mm. Differentiation from the 14 species listed by Pellerdy (37) may be difficult.

Pathogenesis

E. anseris may produce anorexia, tottering gait, debility, diarrhea and morbidity, and sometimes mortality. The small intestine becomes enlarged and filled with thin reddish brown fluid. Catarrhal inflammatory lesions are most intense in middle and lower portions of the small intestine. There may be large whitish nodules or a fibrinous diphtheroid necrotic enteritis. Under dry pseudomembranous flakes, the oocysts and endogenous stages of the parasite are found in large numbers. Parasite stages invade epithelial cells of the posterior half of the intestine in closely packed rows. Developing gametocytes penetrate deeply into subepithelial tissues of the villi.

Treatment

Various sulfonamide drugs have been used in treatment of renal and intestinal coccidiosis of geese. Some studies indicated a favorable response, but, unfortunately, there have been no controlled experiments.

Coccidiosis in Ducks

Coccidiosis in ducks is sporadic but is of sufficient frequency to warrant more attention from researchers. Cases involving moderate to heavy mortality have been reported on domestic duck farms in New York, New Jersey, Hungary, and Japan. Coccidia were recovered from every farm sampled on Long Island, New York. Clinical and subclinical coccidiosis appears to be common and can produce morbidity and mortality as well as poor performance.

Species of Coccidia and Descriptions

Although 13 species of coccidia have been reported from domestic and wild ducks, the descriptions are often insufficient to use in diagnosis (32). Many species will remain in doubt until further work is completed. Coccidia in ducks may be of *Eimeria, Wenyonella,* or *Tyzzeria.* The genus can be determined readily from the sporulated oocyst. The oocysts of *Eimeria* have 4 sporocysts, each containing 2 sporozoites; *Wenyonella* have 4 sporocysts, each with 4 sporozoites; and *Tyzzeria* have 8 naked sporozoites not contained within sporocysts.

Tyzzeria perniciosa Allen 1936, from domestic ducks in the United States, have thin-walled oocysts measuring 10–12.3 × 9–10.8 mm and sporulate to produce 8 free sporozoites.

Wenyonella philiplevinei Leibovitz 1968 is the best described of the coccidia from ducks. It is found in the lower intestine from the posterior jejunal annular band to the cloaca. The prepatent period is 93 hours. The oocysts have three-layered walls, measure 15.5–21 × 12.5–16 mm (average, 18.7 × 14.4), have a micropyle at one end, 1–2 polar granules, and no oocyst residuum. Sporulation results in 4 sporocysts/oocyst, each containing 4 sporozoites.

Pathogenesis of Duck Coccidiosis

Signs of infection with *T. perniciosa* usually include anorexia, weight loss, weakness, distress, morbidity, and up to 70% mortality. Hemorrhagic areas are common in the anterior portion of the

intestine but may be found throughout. Bloody or cheesy exudate is common. The epithelial lining may be sloughed in long sheets. Parasite invasion may extend through the mucosal and submucosal layers as deep as the muscular layers. Acute hemorrhage as early as day 4 may be followed by death on days 5–6.

With *W. philiplevinei*, the effects are limited to 72–96 hours PI. Occasional petechial hemorrhages appear in the posterior ileal mucosa. Diffuse congestion is found in lower intestinal mucosa. In severe infections, mortality may occur on day 4.

Coccidiosis in Pigeons

Coccidiosis in pigeons is similar to, but less severe than, that caused in chickens by *E. necatrix*. Young pigeons suffer the greatest losses, but mortality may occur in birds as old as 3–4 mo.

The most frequently occurring species of coccidia in pigeons is *E. labbeana* (Labbe 1896) Pinto 1928. Oocysts are spherical or subspherical, averaging 19.1 × 17.4 mm.

Pathogenesis
Mortality of 15–70% has been reported in young pigeons in various parts of the world. Subclinical infections may persist in older birds for long periods. Immunity does not appear to be as self-limiting as reported for other species. Common signs of infection are anorexia, greenish diarrhea, marked dehydration, and emaciation. Droppings may be blood tinged, and the entire digestive tract may be inflamed. The common condition of going light is frequently attributed to coccidiosis.

Treatment
Favorable response has been reported after the use of sulfonamides in drinking water at the same or half the level recommended for chickens. A product was introduced in 1987 in France and Belgium for specific use in pigeons. The active ingredient is clazuril, a close relative of the diclazuril under development for use in chickens. This product is highly effective in treating coccidiosis in pigeons.

Cryptosporidiosis
Larry R. McDougald

Introduction

Cryptosporidiosis is caused by small coccidian parasites of the genus *Cryptosporidium*, which live within the microvillous region of epithelial cells of the respiratory and gastrointestinal tracts of vertebrates. Naturally occurring infections have been reported from at least 9 different avian hosts. In chickens, turkeys, and quail, these parasites are primary pathogens that can produce respiratory and/or intestinal disease, resulting in morbidity and mortality. Species of *Cryptosporidium* infecting mammals have received considerable attention in recent years because of the widespread increase in immunocompromised hosts (5). Several reviews of the biology of *Cryptosporidium* are available (11, 12, 30, 42).

Human Health Importance

While cryptosporidiosis is important in humans and other animals, there is no evidence that *C. baileyi*, the avian species, causes any infection in other animals. Similarly, *C. parvum*,

which is the predominant human pathogen, is not commonly seen in poultry. There is good evidence that *C. meleagridis,* an occasional but highly pathogenic species in turkeys, may actually be synonymous with *C. parvum.* Species reported from poultry are summarized in Table 28.4.

History and Taxonomy

The type species *C. muris* was described from laboratory mice by Tyzzer (39), who later also described many of the life cycle stages and named a second species, *C. parvum* (40, 41). Many other species were named from a variety of vertebrate hosts because researchers assumed an unwarranted degree of host specificity. Only a few are now considered valid. Two species (*C. baileyi* and *C. meleagridis*) infect chickens, turkeys, and quail (29). In chickens and turkeys, *C. baileyi* causes both intestinal (cloaca and bursa of Fabricius) and respiratory infections, and small intestinal infections of *C. meleagridis* infections are associated with diarrheal disease in turkeys and quail. An isolate that causes

Table 28.4.   Distinguishing features of *Cryptosporidium* spp. infecting poultry.

Species	Host(s)	Site of Infection	Measurements of Oocysts (mm)
C. baileyi	Chicken, turkey, duck	Bursa of Fabricius, cloaca, respiratory epithelium	6.2 × 4.6 (mean), 6.3 – 5.6 × 4.8 – 4.5 (range)
C. meleagridis	Turkey, chicken	Small intestine	5.2 × 4.6 (mean), 6.0 – 5.6 × 4.8 – 4.5 (range)
Cryptosporidium spp.	Quail	Small intestine	Approximately 5

high mortality in quail, once thought distinct from *C. baileyi* and *C. meleagridis,* is now considered similar to *C. meleagridis* (29). However, as mentioned above, *C. meleagridis* may be a synonym of *C. parvum.*

Life Cycle and Morphology

Taxonomy of the coccidia is based on the differences in oocyst structure, sequence similarities in the 18s RNA gene, the heat shock gene (HSP-70), host specificity, and site of infection (4, 29, 41). In contrast to other coccidia found in poultry, *Cryptosporidium* spp. oocysts do not have sporocysts surrounding the sporozoites, 4 of which lie naked within the oocyst wall (Fig. 28.5). *C. baileyi* shows little host specificity among birds.

The life cycle of *Cryptosporidium,* like other true coccidia belonging to the suborder Eimeriorina, can be divided into 6 major developmental events (Fig. 28.6): excystation (release of infective sporozoites), merogony (asexual multiplication within epithelial cells), gametogony (formation of male and female gametes), fertilization (union of gametes), oocyst wall formation (to produce an environmentally resistant form), and sporogony (the formation of infective sporozoites within the oocyst wall).

The life cycle differs in several respects from that of *Eimeria* spp. infecting poultry (8). The intracellular stages of *Cryptosporidium* spp. are confined to the microvillous region of the host cell. Oocysts sporulate within the host cell and are infective when released in the feces. Oocysts are of 2 types: 1) thin-walled or 2) thick-walled. Thin-walled oocysts are not environmentally resistant and contain sporozoites surrounded by a single unit membrane. Upon release from the host cell, the sporozoites invade adjacent host cells. Thick-walled oocysts have a multilayered wall and are passed through the feces to infect other hosts. The majority of oocysts are the thick-walled form. In mammals, the thin-
28.6. Life cycle of *Cryptosporidium baileyi* as it occurs in the mucosal epithelium of the intestine (bursa of Fabricius and cloaca) and the respiratory tract of broiler chickens.

walled, autoinfective oocysts and type I meronts (asexual stages) cause reinfection within the same host, allowing severe infections to build up after ingestion of a small number of ingested oocysts. This is particularly important in immune-deficient hosts and may lead to a chronic life-threatening disease. Another feature of *Cryptosporidium* spp., which differs from *Eimeria* spp. in mammalian and avian hosts, is the frequent establishment of infections in the mucosal epithelium of a wide variety of organs. *C. baileyi* can infect the cloaca, the bursa of Fabricius, the upper and lower respiratory tracts, and the eyelids.

Diagnosis of cryptosporidiosis is difficult because of its diminutive size and its location at the brush border of the epithelial cell. The tiny oocysts are difficult to see with light microscopy, as they are only a fraction of the size of other coccidian oocysts and have no features to make them stand out against a light background. For the same reason, they can be missed even in histopathology. Phase contrast and interference contrast microscopy are useful in wet preparations. Oocyst morphology may be useful for species identification (Table 28.4). Only *C. baileyi* can be identified on the basis of morphology alone because it is larger and more ovoid than *C. meleagridis* from turkeys or quail. *Cryptosporidium* isolated from quail will not infect chickens or turkeys. Thus, the species infecting quail can only be distinguished from *C. meleagridis* on the basis of host specificity. Oocyst walls of all forms are about 0.5 mm thick, colorless, and have no micropyle (Fig. 28.5).

Incidence and Distribution

Cryptosporidium spp. are prevalent in domesticated, caged, and wild birds, reported from 30 bird species. The reported worldwide distribution of *Cryptosporidium* spp. in avian hosts corresponds to the regions in which poultry health specialists and biologists have used appropriate diagnostic tools and will continue to expand as awareness of their importance as primary pathogens increases.

Cryptosporidiosis in Chickens

Cryptosporidium (probably *C. baileyi*) was diagnosed in 6.8% of 1000 consecutive histology cases of chickens in Georgia (16). In North Carolina, *Cryptosporidium* spp. oocysts were found in the feces of 9 (27.3%) of 33 broilers, 3 (10%) of 30 broiler breeders, and 1 (5.9%) of 17 layers (25). Using an ELISA, 22% of 454 broiler flocks in the Delmarva region were found to have birds that were seropositive for *Cryptosporidium* spp. when they were processed (6, 35). The number of positives among different companies sampled ranged from 2.8–40%. These investigations did not distinguish between intestinal and respiratory infections. Goodwin found respiratory cryptosporidiosis widespread in farms under contract to a broiler complex in North Georgia (16). The factors responsible for clinical expression of respiratory cryptosporidiosis are not understood but may cause high mortality and morbidity, with subsequent lower weight gains and higher feed/gain ratios (10). Experimentally induced respiratory and intestinal infections in broiler chickens have established the

pathogenic potential of *C. baileyi* (2, 28). These and other data indicate that *Cryptosporidium* spp. are common in broiler chickens, and could have a significant impact on productivity and performance.

Pathogenesis and Epidemiology

Oocysts are picked up from heavy fecal contamination of the litter or cages. *C. baileyi* generally invades the epithelium of the cloaca and bursa of Fabricius. Respiratory infections apparently result from the inhalation or aspiration of oocysts that are present in the environment. As few as 100 oocysts can result in intestinal infections when given orally, or in respiratory infections when inoculated intratracheally. Oocysts of *C. baileyi* are infective at the time they are passed in the feces, and no vectors have been identified. Because *C. baileyi* can infect a variety of avian hosts, it is possible that wild birds may serve as carriers. Although *C. baileyi* is not infective for mammals, it is possible that rodents (mice and rats) and insects can serve as mechanical carriers (18).

Mild to heavy intestinal and respiratory signs can be seen as early as 3 days after inoculation of oocysts. Intestinal disease is usually mild. No overt signs of gastrointestinal disease occur in chickens receiving oocysts by gavage into the crop.

Signs of respiratory disease may appear within the first week after intratracheal (IT) inoculation of *C. baileyi* oocysts into 7- or 9-day-old broiler chickens, sometimes with severe morbidity and mortality (2, 9, 26). Oral inoculation of broilers with 4×10^5 oocysts produced only asymptomatic intestinal infections.

Respiratory signs of sneezing and coughing occur in most IT-inoculated chickens by 6 days postinoculation (PI). By 12 days PI, respiratory signs are more severe, and many of the birds extend their heads to facilitate breathing. Severe respiratory signs are present for about 3–4 weeks PI, after which there may be gradual improvement. Weight gains were depressed with respiratory infection but not with intestinal infections (9). Chickens were more resistant to intratracheal inoculation at 28 than at 7 or 14 days of age (28).

Airsacculitis and pneumonia can occur as early as 6 days but are more common 12–28 days following IT inoculation of *C. baileyi* oocysts. Early in the disease process, posterior thoracic air sacs are slightly thickened and contain foamy, clear to white or gray fluid. By day 12, air sacs may become very thick and contain white caseous exudate. The lungs of birds with severe airsacculitis are almost always affected and exhibit focal consolidation (10–80%), particularly in the ventral region. Abdominal air sacs may also be affected.

Histopathology of IT-inoculated chicks shows large numbers of parasites throughout the microvillous region of the epithelium lining the trachea and bronchi (15). Cilia are lost by replacement with developing parasites by 4 days PI (Fig. 28.7). By 12 days, almost all cilia may be replaced by developing parasites, and the mucociliary elevator function ceases in affected trachea and bronchi. Histologic lesions include epithelial cell hyperplasia, thickening of the mucosa by mononuclear cell infiltrates with some heterophils, loss of cilia, and discharge of mucocellular exudate into the airways. There is accumulation of mucus, sloughed epithelial cells, lymphocytes, macrophages, and parasites in the

28.7. The mucosal surface of the primary bronchi obtained from a broiler chicken 4 days after intratracheal inoculation of *Cryptosporidium baileyi*, as shown by scanning electron microscopy. Some developmental stages of the parasite can be seen among the cilia of the respiratory surface. At this stage of infection, the mucociliary elevator is probably still functional, and the bird would not have overt signs of respiratory distress. On days 10–18 after intratracheal inoculation, developmental stages of the parasite form a virtual monolayer on the respiratory surface. Few or no cilia can be found. (White)

28.8. *Cryptosporidium baileyi* in the lungs of a broiler chicken: Accumulation of lymphoid cells around bronchi 6 days after intratracheal inoculation of *C. baileyi* oocysts. (H & E stained histologic section) Inset: A higher magnification of the villus (arrow) showing the numerous developmental stages of the parasite on the epithelial surface.

tertiary bronchi and atria of the lungs. Affected lobules are expanded by accumulation of exudate and infiltration of mononuclear cells (Fig. 28.8). Affected air sacs lined with respiratory epithelium also contain large numbers of parasites and suffer similar changes.

Intestinal (cloaca and bursa of Fabricius) cryptosporidiosis in chickens (produced by *C. baileyi*) may result in histologic lesions but does not usually result in gross lesions or in overt signs of disease. Several reports suggest, however, that performance of broilers can be adversely affected. An unusually high mortality was associated with *C. baileyi* infection in the bursa of Fabricius, and there were lower pigmentation scores when inoculated birds were compared with noninfected controls (2, 19).

Interaction of *C. baileyi* and other respiratory pathogens predisposes birds to secondary invasion by *Escherichia coli* because of the disruption of the mucociliary elevator (9). Infectious bronchitis virus and *E. coli* also enhance the severity of *C. baileyi*-induced respiratory disease in chickens.

Cryptosporidiosis in Turkeys

Two species of *Cryptosporidium* found in turkeys are *C. meleagridis* (35) and *C. baileyi*. However, the description of *C. meleagridis* is indistinguishable from *C. parvum*. The intestinal (bursa of Fabricius and cloaca) and respiratory infections produced by *C. baileyi* are similar to those described previously for chickens (8, 9, 27).

Slavin reported small intestinal cryptosporidiosis (34) due to *C. meleagridis* in a flock of 10–14-day-old turkey poults. Illness was associated with diarrhea, unthriftiness, and moderate mortality. More than 30 years later, several outbreaks of this disease were reported (17, 43), although the number of reported cases is low.

Turkey poults infected with *C. meleagridis* may develop severe diarrhea. Numerous parasites are seen lining the brush border of the mucosa of the middle and lower small intestine. The gut becomes pale and distended with cloudy mucoid fluid and gas bubbles. Villi in the affected regions become atrophic; crypts become hypertrophic; and large numbers of lymphocytes, heterophils, and some macrophages and plasma cells accumulate within the lamina propria (17).

There are several case reports of severe respiratory cryptosporidiosis in commercial turkeys caused by *Cryptosporidium* spp. (probably *C. baileyi*) (14, 22, 32, 37). The disease may have upper or lower respiratory involvement. Upper respiratory infections may cause acute bilateral swelling of infraorbital sinuses, similar to that reported for birds infected with *Mycoplasma* spp., and serous conjunctivitis (14, 22). Case reports of lower respiratory tract infections reported signs including rattling, coughing, sneezing, and gasping (32, 37). The trachea and bronchi were colonized, with concomitant airsacculitis and pneumonia.

Microscopic lesions of the infected tissues included deciliation of the epithelium and inflammation.

Intratrachael (IT) inoculation with *C. baileyi* from the intestinal tract of broiler chickens into the trachea of turkeys produced respiratory signs similar to those observed in natural outbreaks (27).

Although there are reports of clinical outbreaks, the importance of *Cryptosporidium* spp. in commercially reared turkeys is not clear.

Cryptosporidiosis in Quail

Both respiratory and intestinal cryptosporidiosis have been reported in commercially grown quail, but the species involved has not been adequately described. Field reports suggest similiar respiratory disease and low mortality similar to that seen with cryptosporidiosis in chickens (38). Histologic examination revealed parasites in the microvillous region of epithelial cells lining the nasal cavity, trachea, bronchi, salivary glands of the roof of the mouth, esophageal glands, and bursa of Fabricius. Pathologic changes in the respiratory mucosa were similar to those described previously for chickens infected experimentally with *C. baileyi*. In another spectacular case of cryptosporidiosis, 5 successive hatches of 25,000 young quail (*Colinus virginianus*) developed severe, fatal intestinal cryptosporidiosis (23). Diarrhea developed 4–6 days after hatching, and mortality soon exceeded 90%. At necropsy, numerous developmental stages of the parasite were observed in the microvillous border of the small intestine. No parasites were observed in the cecum, colon, bursa of Fabricius, respiratory tract, or other tissues. Oocysts, obtained from the intestines of these infected quail, were not infective to day-old broilers. Based on recent work, this isolate was probably *E. meleagridis* (29).

A similar outbreak was reported from young quail due to a combination of *Cryptosporidium* sp. and a reovirus isolated from intestinal contents (33). Subsequent laboratory studies (20) suggested that the *Cryptosporidium* and not the reovirus was responsible for the intestinal disease.

Prevention and Control

There are no effective anti-cryptosporidial drugs or vaccines, and other approaches to the control are still experimental. Sanitation or disinfection may provide some help, but there are no proven programs that can be recommended.

Sanitation

The oocysts of *Cryptosporidium* spp. infecting poultry are remarkably resistant to chemical agents that readily kill most viral, bacterial, and fungal pathogens. Destruction of oocysts in commercial production facilities is not considered practical. In the laboratory, oocysts remain viable for months when stored at 4°C in a solution of 2.5% potassium dichromate. Oocyst viability is also maintained after a 10–15 minute incubation in 25% commercial bleach (sodium hypochlorite). Incubation of *C. baileyi* oocysts for 30 minutes at room temperature in each of 9 commonly used disinfectants mixed with water at the highest concen-

tration recommended by the manufacturers had little or no effect on viability (36). Incubation in 50% ammonia resulted in the greatest reduction in excystation, and 50% commercial bleach destroyed many of the oocysts. Steam cleaning is a safe and effective means of disinfecting contaminated laboratory cages because oocysts are destroyed by temperatures greater than 65°C.

Immunity

A single intestinal and/or respiratory infection with *C. baileyi* can stimulate an immune response in broiler chickens of sufficient magnitude to clear the parasite from the infected mucosae and to protect the host against reinfection of the same species (6, 9). Experience with cryptosporidiosis in other animals suggests that immune protection may be short-lived. Oral or IT inoculation of oocysts into 8–14-day-old broilers results in heavy infections of the exposed mucosae for 14–16 days and then a rapid clearance of the parasite. High titers of circulating antibodies specific to *C. baileyi* can be detected after primary infections, and the birds exhibit a delayed hypersensitivity reaction to *C. baileyi* oocyst antigens. Data from laboratory studies and from a serologic survey suggest that acquired immunity may be important in the protection of broilers from cryptosporidiosis during the last several weeks of growout. Studies are needed to identify antigens of *Cryptosporidium* spp. that may be candidates for use as vaccines.

Diagnosis and Culture

Active infections in poultry, both respiratory and intestinal, can be diagnosed by identifying oocysts from fluids obtained from the respiratory tract or from the feces. Identification of *Cryptosporidium* spp. oocysts differs somewhat from techniques used for the oocysts of *Eimeria* spp. For viewing, oocysts are concentrated and observed by standard brightfield or phase contrast microscopy (7), acid-fast staining (13, 31), negative staining (4, 21), and staining with auramine-O for examination by fluorescence microscopy (25). These techniques allow one to readily distinguish *Cryptosporidium* spp. oocysts from yeast cells or *Blastocystis* that are often present in specimens.

Fecal or respiratory specimens can be collected and submitted fresh, in 10% formalin or in an aqueous solution of 2.5% potassium dichromate. A highly effective method of obtaining specimens in the field and in the laboratory is with moist cotton tipped swabs. Vigorous swabbing of the tracheal or cloacal epithelium will remove oocysts from the microvillous border. The swabs are placed in a tube containing 1 mL of water or fixative for transportation to the laboratory. *Cryptosporidium* infection can also be detected by demonstrating other stages of the life cycle from fresh or stained mucosal scrapings from the mucosa (24). Abbassi (1) described a semiquantitative microscopic slide flotation method that was reliable for *C. baileyi* in feces and organs of chickens. These parasites also appear in histologic sections stained with hematoxylin and eosin as 2–6-mm basophilic bodies within the brush border of the epithelial cells. Because of the small size of these parasites, transmission electron microscopy (TEM) is useful to reveal developmental stages and oocysts

within the host cells. Inoculation of chicken embryos (10 day) with oocysts of *C. baileyi* is a good method for propagation of this species in the laboratory, providing about 50% of the number of oocysts obtained from chickens (44).

Previous exposure to the parasite can be demonstrated by testing for serum antibodies specific to *Cryptosporidium* sp. by ELISA or other immunologic tests (6, 35).

Amplification of DNA sequences with PCR is a useful tool for identifying some species of *Cryptosporidium* (29), but studies with 8 DNA loci revealed homologies between *C. meleagridis* and the human pathogen *C. parvum*, which could not be resolved by PCR (3).

Cochlosoma anatis Infection

Alex J. Bermudez

Introduction

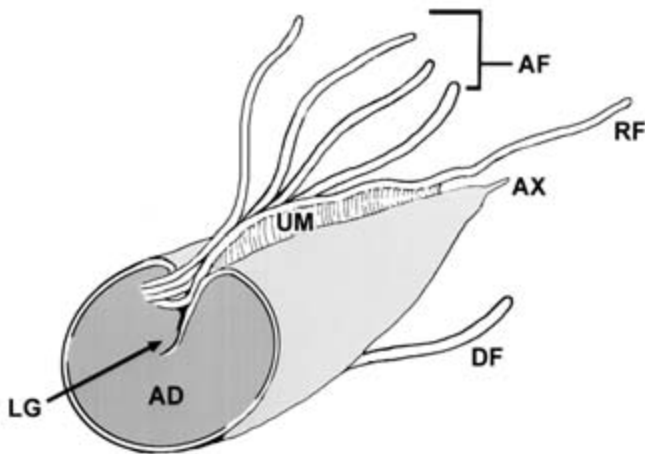
The generic name *Cochlosoma* was created by Kotlan in 1923 to include a peculiar flagellate, *Cochlosoma anatis*, found in the intestines of the European domestic duck (25). The most striking feature of these flagellated protozoa is a distinct ventral adhesive disk. The significance of these enteric protozoa has been uncertain for many years. Previous editions of *Diseases of Poultry* suggest that *C. anatis* is either a parasite of unknown significance (15) or apparently nonpathogenic (17). These conclusions were based on the limited and conflicting published reports that were available. Recent case reports and research suggest *C. anatis* is a significant pathogen in both turkeys and ducks (1, 4, 7, 24). The parasite appears to cause limited pathology to the intestinal tract but causes a diarrhea and stunting of both turkey poults and ducklings. Research on this protozoon continues to be hampered by the fact that it cannot be cultured in artificial media (14) and must be collected from the feces or intestines of infected birds. These experiments cannot completely exclude bacteria, viruses, or other protozoa that may interact synergistically with *C. anatis*.

Etiology and Classification

Kotlan created the generic name *Cochlosoma* in 1923 to describe a protozoon identified in the duck (25). Tyzzer, in 1930, described 2 similar genera from the intestines of the ruffed grouse. He erected a new family, Cochlosomidae, to include the type genus *Cochlosoma* Kotlan (25), and *C. anatis* is the type species for this family (22). Numerous authors have noted similarities between *Cochlosoma* and both *Giardia* and *Trichomonas* (7, 11, 19, 21). The resulting question is whether *Cochlosoma* should be assigned to the order Retortamonadida or Trichomonadida. The adhesive disc is the primary similarity between *Cochlosoma* and *Giardia* (12). *Cochlosoma* has a parabasal apparatus, tubular axostyle, and crescent shaped pelta, all of which are similar to trichomonads (12). Pecka *et al.* conducted an extensive ultrastructural study of *Cochlosoma* in an attempt to more accurately classify these protozoa (22). In this report, a close relationship between *Cochlosoma* and Retortamonadida was excluded and the ultrastructural homology of C*ochlosoma anatis* with *Trichomonas* was demonstrated, justifying the classification of this genus within the order Trichomonadida Kirby, 1947 and family Cochlosomatidae Tyzzer, 1930, emend. (13, 22). These taxanomic relationships have been confirmed by the phylogenetic analysis of the small-subunit rRNA gene (10).

Morphology

By light microscopy, *C. anatis* is general pyriform to ovoid in shape, 6–12 microns long and 4–7 microns wide. The anterior end is wide and tapering to a narrowly rounded posterior end. A characteristic adhesive disc is on the anteroventral surface, which opens on the left side and is the predominate morphologic feature on light microscopy (Fig. 28.9). The parasite has a single nucleus, which can be distinguished readily on Giemsa or trichrome-stained impression smears (7). The trophozoites are distinguished easily from other protozoan flagellates in wet mount preparations by their characteristic motion. Flagella produce a whipping motion, which causes a stiff jumping or jerking motion and results in the parasite rotating around its long axis, as it moves forward. This motion is in contrast to the jerking motion of *Trichomonas* with its distinct undulating membrane and the rapid darting motion of *Hexamita* (19). Although *C. anatis* does possess a distinct undulating membrane based on scanning electron microscopy studies, this feature is not distinct on wet mount preparations of the parasite examined under standard light microscopy.

Numerous authors have described the morphology of *C. anatis* with scanning electron microscopy as is illustrated by Figure 28.10 (7, 14, 22, 27). On scanning electron microscopy, the trophozoite has a conical shape. The prominent ventral adhesive disc forms the base of the cone, and the body tapers toward the proximal end (7). The parasite has a prominent lateral grove, an undulating membrane, 6 flagella, and an axostyle (14). On the
28.9. *Cochlosoma anatis* as viewed by light microscopy in a wet mount preparation of mucosa of the jejunum of a turkey. Numerous protozoan cells are evident between the intestinal villi. Bar = 80 mm. Inset: Higher magnification; distinct ventral disc indicated by arrows. Bar = 10 mm.


28.10. *Cochlosoma anatis*: Prominent external features, ventral view. Ventral adhesive disc (AD), recurrent flagellum (RF), undulating membrane (UM), anterior flagella (AF), axostyle (AX), and anterior opening to the lateral groove (LG). The lateral groove runs the full length of the trophozoite adjacent to the undulating membrane. Not visible is the origin of the single dorsal flagellum (DF).

left side, the disc is interrupted by a lateral groove, which extends along the length of the body (22). Four anterior flagella emerge as 2 pairs, just above the lateral groove, on the left wall of the ventral disc (22, 27). These flagella tend to turn backward along the lateral groove being confined to the groove by their apical portions (22). The recurrent flagellum arises with the 4 anterior

flagella and is associated with the undulating membrane and continues beyond it by a free trailing portion (22). The sixth flagellum arises to the left of the body midline on the dorsal surface (27). The distance of this flagellum from the anterior margin is about half the diameter of the ventral disk (27). The axostyle extends from the posterior end of the trophozoite as a thin projection (22). The organelle structure of *C. anatis* has been extensively characterized by Pecka *et al.* using transmission electron microscopy (22).

Transmission, Incubation Period, and Life Cycle

Bollinger and Barker reported that oral or cloacal inoculation of fecal material containing *C. anatis* reproduced the disease in ducklings (1). Ducks shed trophozoites by 7 days post inoculation (1). Oral transmission was also demonstrated experimentally in turkeys (14). Some turkeys were positive for *C. anatis,* based on intestinal mucosal scrapings, by 4 days postinoculation, and all poults were infected by 6 days post inoculation (14). Transmission was also readily successful when naïve turkeys were placed with infected turkeys. House flies have been implicated as a potential means of transmission from the environment to a susceptible host (18).

Reproduction in this species was recorded briefly by Kotlan. He observed longitudinal division and cysts with 4 or more nuclei but published no drawings of divisional stages or of the cysts and gave no dimensions for the cysts (22). Division of *C. anatis* by longitudinal fission has also been described in subsequent studies, but no cysts have been reported (11, 25). Studies by Evans *et al.* (8) document both the longitudinal binary fission of

C. anatis as well as pseudocyst formation. Pseudocysts also produced active *C. anatis* infection in turkeys (8).

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Naturally occurring *C. anatis* infections have been described in the turkey, duck, goose, and coot (1, 7, 21, 25). Experimental *C. anatis* infections have been produced in bobwhite quail and chickens (14). *Cochlosoma* spp. infections have been reported in a wide variety of wild birds including the Eastern robin, American magpie, woodcock, waxbill, and a variety of finches (21, 23, 25). Only 2 *Cochlosoma* species have been recorded in mammals: *Cochlosoma pipistrelli* in bats of the family Phyllostomatidae (21) and *Cochlosoma soricis* in shrews (27). These reports suggest wild birds, particularly waterfowl, may serve as a reservoir for *C. anatis* and that mammals are probably not a reservoir for this protozoan.

Site of Infection

Cochlosoma is found in the cecum of the European domestic duck, and mainly in the colon or lower ileum of ducks (11). Travis found these protozoa to be common in the cloaca of ducks, frequently present in the colon and occasionally present in the cecum (25). Similarly, Watkins *et al.* found *C. anatis* to be present only in the last 10 cm of the colon and in the cloaca of ducks (27). One-day-old ducklings experimentally inoculated with *C. anatis* were infected in both the jejunum and colon 25 days post inoculation (1). In a goose, *C. anatis* was found primarily in the colon and also in the cecum (21).

In a study of infectious catarrhal enteritis (hexamitiasis) in turkeys, numerous poults were concurrently infected with *Cochlosoma* throughout the intestinal tract, and in adults, infection was noted in the region of the cecal tonsil (19). Cooper *et al.* describe a natural outbreak of enteritis in turkeys in which large numbers of *C. anatis* were found in the small intestines with isolated protozoa found in the ileum and none in the cecum or colon (7). In an experimental infection of turkeys, trophozoites were present in the duodenum, jejunum, and ileum of all birds and also the cecum and colon of some birds (14). *C. anatis* was present in the ileum of bobwhite quail and the cecum of one experimentally inoculated chicken (14).

Clinical Signs and Pathogenicity

Kotlan noted in his first description of *C. anatis* infection in ducks that the intestinal wall was swollen and catarrhal at the point where a mass of the flagellates were attached and the intestinal contents were mixed with blood. Kimura was unable to attach any pathogenic significance to this organism in ducks but noted inflamed intestinal tracts that were ascribed to a bacterial infection rather than to *C. anatis* (11). Travis did not observe pathogenic changes in the birds he studied (25). Severe runting and mortality were reported in ducklings that were infected with *C. anatis* (1). Numerous *C. anatis* with low numbers of *Trichomonas* and *Hexamita* were observed, and no other microscopic lesions were noted. *C. anatis* was highly suspected as the

cause of the runting and the pathogenicity of *C. anatis* was then studied experimentally in ducks. Although the inoculum contained low numbers of *Hexamita* spp. and trichomonads and *Campylobacter jejuni* was isolated, it was concluded that *C. anatis* was at least implicated in the severe runting (reduced body weight and delayed feather growth) of ducklings. Many infected ducklings also died of secondary gram-negative bacterial septicemia (1). The same authors in a separate experiment found *C. anatis* infection increased intestinal villus length and altered mucosal enzyme concentrations in ducklings (2).

McNeil and Hinshaw found that *C. anatis* was often present in the intestines of turkeys in cases of hexamitiasis (19). They questioned the significance of this parasite in turkey poults, because in their experience, *C. anatis* was always found in association with Spironucleus (*Hexamita*) or in combinations with *Spironucleus* and *Salmonella*. Campbell reported a case of *C. anatis* infection in turkeys in which affected turkeys, 2–10 weeks of age, had severe catarrhal enteritis (6). Although the clinical signs in these cases were attributed to *C. anatis* because it was the predominate organism, *Trichomonas* and *Spironucleus* were also usually present. Cooper *et al.* identified *C. anatis* as the likely etiologic agent in a series of cases of diarrhea and enteritis in turkeys (7). Affected turkeys were depressed and ruffled, and many had a yellowish diarrhea. In this series of 6 cases, *C. anatis* was consistently present, although other potential viral or bacterial pathogens were also identified in individual cases. Affected turkeys were 7–12 weeks of age, and body weight gains were depressed an average of 16% at processing. During necropsy, small intestines were distended with fluid and ingesta. Dilated congested regions, focal intestinal distension, or bullae, were found in the duodenum and jejunum. Significant microscopic lesions were also noted in infected turkeys including blunting and fusion of the villi, a mixed cellular infiltrate of the lamina propria, and crypt hyperplasia. Because other enteric pathogens, including enteric viruses, were identified in some of these cases, it is possible that these microscopic changes were not entirely the result of a *C. anatis* infection. Recent experimental *C. anatis* infections in turkeys would suggest that this protozoan causes little or no microscopic change in the intestinal tract (3).

Experimental studies in turkeys were conducted that compared uninoculated controls, *C. anatis* infected poults, and poults inoculated with *C. anatis* and treated with metronidazole. *C. anatis* infection caused a significant decrease in weight gain and an increase in feed conversion in comparison to uninoculated controls or inoculated poults concurrently treated with metronidazole (5). An experimental study using turkey poults showed that a combination of *C. anatis* and turkey coronavirus was more pathogenic than either agent alone (24). However, both the *C. anatis* and coronavirus infected poults gained less than the negative controls. These findings are interesting in that *C. anatis* infections in turkeys often occur in combination with a variety of enteric viruses or other enteric pathogens. All these experimental findings with *C. anatis* are in general agreement with the case report by Cooper *et al.* in which a 16% decrease in body weight was noted in *C. anatis* infected flocks (7).

Finch aviaries have reported significant mortality in young

finches, 6–12 weeks of age, as the result of *Cochlosoma* infections (16, 23). Clinical signs included debility, dehydration, and the passing of whole seeds in the droppings.

The exact role of the ventral adhesive disc in the pathogenicity of *Cochlosoma* is still unknown. In multiple scanning and transmission electron microscopy images, a clear indentation in the mucosal brush border of the hosts with the same size and shape as the ventral adhesive disk suggests that the ventral disc serves for the attachment to the intestinal mucosa (7, 22, 27). It appears likely that this attachment to the microvillous border plays some role in the decreased production parameters seen in *C. anatis* infected turkeys and ducklings. Whether this attachment causes a direct pathologic effect, a mechanical blockage of nutrient absorption, or in some other way interferes with nutrient utilization has not been fully characterized.

Prevention and Control

Treatment

Multiple reports have shown that natural or experimental *Cochlosoma* infections can be treated successfully with members of the nitroimidazole family. However, these products are no longer available for use in poultry. Experimental infection of ducklings treated orally at 12 days post inoculation with 7.5 mg of metronidazole per 100g of body weight for 5 days resulted in complete compensatory weight gain (1). In an outbreak of *Cochlosoma* infection in waxbills, 250 mg/L of metronidazole in the drinking water for 3 days successfully treated the infection (23). During a survey for *Cochlosoma* infection in finches, the evaluation of the efficacy of metronidazole and ronidazole showed that at all dosages and duration of treatments investigated resulted in the clearance of the infection (9). Metronidazole and dimetridazole at 15 mg/L in the drinking water of turkeys did not reduce the number of organisms, but when given at either 30 or 60 mg/L, metronidazole, dimetridazole, and ronidazole successfully eliminated the organism (20). Metronidazole administered at 100 mg/L in the drinking water completely eliminated the negative production effects of *C. anatis* infection in turkeys (5).

Roxarsone at 0.002% in the drinking water did not reduce the number of *C. anatis* trophozoites in infected birds (20). The use of roxarsone in the drinking water at the recommended concentration (0.002%) improved the production performance compared with a *C. anatis* infected group but did not cure the *C. anatis* infection (3). Finally, roxarsone in the drinking water given at 2 times the label recommended dose (0.004%) for 2 days followed by 3 days at 0.002% prevented the negative production effects of a *C. anatis* infection and significantly decreased the parasitic burden (3). These results suggest roxarsone can be used as an effective treatment for *C. anatis* infection in turkeys, and this drug is the only effective treatment that can be used legally in food animals in the United States.

Prevention

As with most poultry diseases, the prevention of *C. anatis* infection can best be accomplished by not introducing the organism onto the poultry farm. Introduction by both human traffic and wild birds, particularly waterfowl, would appear to be the greatest risk factors for the introduction of this parasite onto the farm. *C. anatis* is killed in infected droppings that are allowed to dry at room temperature for 24 hours (3). Phenolic or quaternary ammonium disinfectants and 10% formalin all kill the protozoa with a 10-minute contact time (5). Given these parameters, eradication of this parasite can be accomplished readily from a depopulated farm.

Nitarsone, a feed additive, has been used to prevent *C. anatis* infection in turkeys in the United States. The efficacy of this prevention program is uncertain. Feeding nitarsone prior to the inoculation of turkeys with *C. anatis* did not prevent infection, and no differences were observed in trophozoite numbers in treated and control poults (26). Other experimental studies suggest that nitarsone can significantly decrease the parasitic burden of infected poults during a 2-week experimental period (3). In this study, production losses were only slightly ameliorated using this feed additive.

Histomoniasis (Blackhead) and Other Protozoan Diseases of the Intestinal Tract

Larry R. McDougald

Introduction

Histomoniasis affects mainly the ceca and liver of many gallinaceous birds, although it may be found in the bursa of Fabricius, kidney, spleen and other tissues (36). Morbidity and death occur as a result of liver damage. Caused by the protozoan *Histomonas meleagridis*, the disease is characterized by ulceration and inflamation of the cecal walls, engorgement of the ceca with large caseous casts, inflamation of the mesenteries, and severe necrosis of the liver. It has been called infectious enterohepatitis or blackhead. The signs leading to the use of the term *blackhead* are neither pathognomonic nor distinctive because many other diseases may produce a similar appearance (Fig. 28.11A). The roles of the cecal worm (*Heterakis gallinarum)* as an intermediate host, earthworms as accessory hosts*,* and the ability of the organism to colonize new hosts by cloacal contact comprise one of the most intriguing relationships in parasitology. Research on histomoniasis became neglected after the discovery of highly effective control measures in the late 1960s, leaving considerable basic biological and biochemical work undone.

Economic Significance

Annual losses from mortality in turkeys has been estimated to exceed 2 million dollars. Other types of poultry also suffer losses. Decreased production from morbidity, loss of flock uniformity and chemotherapy expense increase the cost of production of broiler breeder hens. Although histomoniasis is usually less severe in chickens, losses from morbidity and mortality are estimated to be greater in chickens than in turkeys because of the frequency of occurrence and the numbers of birds involved (1). Clinical blackhead disease in broiler breeder pullet flocks reached epidemic proportions in the mid-late 1990s and continues as a severe threat to production of breeder hens. Outbreaks of histomoniasis in leghorn pullets in Georgia and Florida caused up to 20% mortality and high morbidity. Chicken houses may become badly contaminated by *Heterakis* worm eggs, causing outbreaks in flock after flock. In many instances, poultry companies have discontinued the use of individual farms because of intractable contamination with *Heterakis* and *Histomonas.* The nitroimidazole antihistomonals were disallowed by the Food and Drug Administration in the 1990s, leaving no products available for treatment of blackhead disease. Histomoniasis remains an important limit to productivity in chickens, turkeys, and other fowl. This disease has no public health significance, as it affects only birds.

History

Histomoniasis in turkeys was first described in 1895. The literature has been reviewed in depth (23, 28, 34). Discovery that

chickens suffered a milder form of the blackhead, and often re-mained carriers resulted in the first useful recommendation for control: Turkeys should not be reared with chickens or on a range where chickens have been produced during the previous several years. The role of cecal worms (*Heterakis*) and earthworms as in-termediate hosts for *Histomonas* explains this long period of in-fectivity on uninhabited range.

Tyzzer described the parasite as a simple cell with flagella as well as pseudopodia and published extensive observations on its biology (38, 39). The complicated nature of the pathogenesis of histomoniasis was described in detail between 1964 and 1974 by studies showing that certain bacteria are necessary in addition to the histomonads to produce disease. This interesting *Histomonas*-bacteria connection was discovered using germ-free techniques at the Universities of Georgia and Notre Dame. More recently, it was found that *Eimeria tenella*, the cecal coccidium, contributes significantly to the development of liver lesions in the chicken (27), and that histomoniasis is able to spread from bird to bird by means of cloacal contact with fresh droppings.

Etiology and Classification

The causative agent is *H. meleagridis,* a flagellated ameboid pro-tozoan of about 10 μm. A larger (17 μm), nonpathogenic, four-flagellated histomonad found in the cecum was named as a sep-arate species, *H. wenrichi.*

The disease is commonly called blackhead, after the mistaken impression that birds commonly developed a blackened head sooner after death than with other diseases. Other common names include histomoniasis and enterohepatitis.

Other agents, such as trichomonads and fungi (*Candida albi-cans*), have been advanced as etiologic agents of blackhead (34).

However, these organisms are causing separate, unrelated dis-eases. The term *pseudo-blackhead* has been sometimes used to describe cases that did not respond to antihistomonals, but this term has little diagnostic value. Differential diagnosis used to re-solve questionable infections include microscopic observation, histopathology and culture of responsible organisms.

Morphology

H. meleagridis in its nonamoeboid state is nearly spherical, about 10 μm (3–16 μm) in diameter. The amoeboid phase is highly pleomorphic. Pseudopodia may be observed if the slide is warmed during microscopy (see Fig. 28.12). Cecal lumen forms have a single flagellum 6–11 μm in length. A pelta and an ax-ostyle are wholly contained within the cell. The parabasal body is V shaped and anterior to the nucleus. The nucleus is spheroid to ellipsoid or ovoid and averages 2.2×1.7 μm. These organisms lack mitochondria, instead relying on other organelles (hy-drogenosomes) for energy metabolism. Hydrogenosomes are only observed by means of electron microcrospy.

The tissue forms usually lack flagella and reportedly exist in several different forms: 1) Parasites in the invasive stage at the peripheral areas of the lesions are 8–17 μm in size, amoeboid, and appear to form pseudopods. 2) A vegetative stage is larger (12–21 μm) and more numerous and is clustered in vacuoles in degenerating tissue. 3) A third stage present in older lesions is eosinophilic and smaller and may represent a degenerating form.

Life Cycle

The Role of Heterakis gallinarum

The survival and transmission of this organism is intimately as-sociated with the cecal nematode *H. gallinarum* (38). It is doubt-ful that any other organism or mechanism is responsible for sur-
28.12.   Examples of *H. meleagridis* (A, B, C) compared with *H. wenrichi* (D, E) showing variations for each species. A. Tissue type *H. meleagridis* in fresh preparation from liver lesion; viewed with phase-contrast microscopy. B. *H. meleagridis*; transitional stage with pseudopodia but no flagellum, in lumen of the cecum. Distribution of chromatin suggests the beginnings of binary fis-sion. C. An organism from culture, with free flagellum typical of lumen-dwelling forms. (Honigberg and Bennett) D. Small *H. wenrichi*, structurally distin-guishable from *H. meleagridis* by its larger size and by presence of 4 fla-gella. E. *H. wenrichi* as viewed in stained smear from cecum in which packets of *Sarcina* were abundant. Drawn from living specimens (A, B, D, and E) or tissue sections.

vival of histomoniasis from one flock to the next. Early attempts to find the histomonad in cecal worm eggs were inconclusive until Gibbs (10) demonstrated small bodies seen with the light microscope. Lee (19) observed a small form (3 μm) by electron microscopy, and histomonads have been cultured *in vitro* from heterakid eggs (35).

Histomonads are found in intestinal epithelial cells of very young worms or newly hatched larvae. The mechanism of egg infection by histomonads has not been determined. Springer *et al.* (36) found that triturated male worms recently removed from chickens carry viable histomonads. Female worms are less likely to transmit viable histomonads until the eggs within them mature. Unembryonated eggs are unlikely to transmit the infection. The female worms probably become infected with the histomonads during copulation and incorporate the protozoan into eggs before shell formation.

In the ceca of its host, the histomonad leaves the worm larva and multiples in the lumen and mucosa. Within 2–3 days the tissue forms enter the bloodstream and are carried to the liver by the hepatic-portal system. In the cecal tissues and in the liver the cells divide and grow, forming necrotic areas that are visible on gross inspection. Infection of other organs sometimes occurs, including the bursa of Fabricius, the kidney, the pancreas, and the spleen. The DNA of histomonads is also found in other tissues where lesions are not seen.

The Role of Earthworms

Earthworms can serve as transport hosts in which heterakid eggs hatch and survive. The larvae persist indefinitely in tissues in an infective state (21). The earthworm, thus, serves as a means for collection and concentration of heterakid eggs from the poultry yard environment.

Earthworm transmission of *Histomonas* to the ringnecked pheasant (*Phasianus colchicus torquatus*) has been of documented importance in a partridge-pheasant histomoniasis outbreak at a game-rearing station in central Iowa (18). On range or pastures, where climate and soil types favor survival of heterakids and earthworms, the latter must be considered in attempts to control a recurrent histomoniasis problem.

Transmission by Direct Contact

Transmission of blackhead within a turkey flock occurs readily by direct contact between susceptible birds and infected birds or fresh droppings and does not require an intermediate host (12, 13, 15). These findings illustrate how an outbreak can spread through a flock of turkeys in a week or two, killing most of the birds. In chickens, there is little evidence that infections spread in this way, placing more emphasis on contamination of the soil with cecal worm eggs (11).

Although direct infection of turkeys by oral ingestion of viable histomonads in fresh droppings or diseased tissues is possible, their extremely delicate nature makes this route rather unlikely. Histomonads cannot survive long outside the host unless protected by the heterakid egg or earthworm. Several studies showed that oral ingestion of organisms in feces or from cultures did not produce infections in turkeys unless the acidity of the crop was neutralized.

Pathogenicity

Characteristics of the definitive host influence clinical manifestations of infection by *Histomonas meleagridis* more than variations of pathogenicity of the parasite. These characteristics include species, breed, and intestinal flora.

Although naturally occurring infections occur in several species, the turkey is considered the most susceptible host because most infected turkeys suffer morbidity and death. Chickens are easily infected but often have a milder form of the disease. Outbreaks lead to an increase in mortality, culling, and loss of flock uniformity. Some other birds (peacocks, pheasants, etc.) are also severely affected. Variation in susceptibility has been found among different breeds and strains of chickens. Chickens 4–6 weeks old are most susceptible to infection, although turkeys of any age are highly susceptible. The 1990s rash of clinical outbreaks in broiler breeder pullets were unexplained, but it was suspected that concurrent outbreaks of immunosuppressive viral infections contributed by depressing T-cell responses.

Bacterial flora are also important in the development of blackhead disease. Lesions of histomoniasis were not produced in germfree turkeys or chickens unless bacteria were introduced (37). Disease was produced when *Clostridium perfringens*, *Escherichia coli, B. subtilis,* or mixed cultures were present. Isolates of *Histomonas* grown *in vitro* frequently lose pathogenicity in successive passages (6, 7). This fact discouraged early workers from attempting vaccine development using attenuated clutures because there was no way to stabilize the degree of attenuation (39). Although field strains with variable pathogenicity have been found, none has been characterized, with the exception of *H. wenrichi,* now listed as a separate species.

Susceptibility to Physical and Chemical Agents

The naked protozoan is not resistant to environmental conditions outside the bird. Thus, it is not important to practice extensive decontamination, even after an outbreak. Much attention is given to control of the intermediate host, the cecal worm. This is more important in chickens than in turkeys, because chicken farms are often contaminated with cecal worms. Turkey farms are rarely contaminated with histomonad-bearing worms, otherwise every flock would suffer blackhead outbreaks. Instead, outbreaks occur from the fresh introduction of worm eggs into a facility, usually on the shoes of the workers.

Control of worms depends on frequent application of benzamidazole-type wormers. Longer treatment is necessary (2–3 days) for a high degree of worms control. Some veterinarians recommend litter or soil treatment to reduce contamination by worm eggs, but there is no experimental evidence that this is effective.

Incidence and Distribution

There have been no surveys to describe the prevalence of histomoniasis. However, the disease probably occurs wherever suit-

able avian hosts exist. In general, it is more prevalent in areas favoring the coexistence of the cecal worm *Heterakis gallinarum*, but it is regularly reported by diagnostic laboratories in the United States, Canada, and Mexico (1). Recent outbreaks in Europe emphasize the international prevalence of this disease. The scientific literature includes many reports from Asia. Outbreaks in turkeys tend to be sporadic, while exposure in chickens may be chronic. Most of the commercial breeder pullet facilities in North America are thought to be contaminated with *Heterakis,* which are potent reservoirs for histomoniasis. Game birds reared in captivity and some wild birds also serve as reservoirs.

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Numerous gallinaceous birds are reported as hosts for *H. meleagridis.* The turkey, chicken, chukar partridge, peacock, pheasant and ruffed grouse may be severely affected, while guinea fowl, bobwhite quail, and ostrich have a milder form of the disease. Ducks may become asymptomatic carriers. The coturnix quail can be infected experimentally, but it is a poor host.

Vectors

The common cecal worm, *Heterakis gallinarum*, is the only worm known to serve as an intermediate host for blackhead (38). Even closely related nematodes are unable to serve as hosts. Worm ova are resistant to environmental conditions and may remain infective for 2–3 years. Most gallinaceous birds are host to the cecal worm, and wild populations may serve as reservoirs. The common earthworm has been shown to consume and harbor infective larvae of the cecal worm, thus serving as a vector. While poorly documented, arthropods such as flies, grasshoppers, sowbugs and crickets may serve as mechanical vectors. Diagnosticians are sometimes confused by the inability to find cecal worms in birds with histomoniasis. Some of the reasons for this are that the cecal worm remains in larval form for 2–3 weeks and is very small (2–3 mm). Also, the development of histomoniasis destroys the environment for the worm, so that many are killed or expelled.

Incubation Period

Disease is caused when histomonads penetrate the cecal wall, multiply, enter the bloodstream, and eventually parasitize the liver. Overt signs of histomoniasis are apparent from 7–12 days and occur most commonly 11 days postinfection (PI). The infection begins with reddening and thickening of the cecal mucosa within 3 days. The incubation period varies with the size of the infective dose. Infections from worm eggs require longer than those beginning from cloacal exposure within an outbreak. Experimentally, cecal and liver lesions in turkeys develop about 3 days earlier with cloacal inoculation compared with infection via heterakid eggs. Once an infection is established in a turkey facility from introduction of cecal worm ova, the outbreak may spread rapidly by direct contact. Turkeys become infective to others within 2–3 days after becoming infected.

Clinical Signs

Signs of histomoniasis in turkeys (Fig. 28.11B) include yellow feces, drowsiness, dropping of the wings, walking with a stilted gait, closed eyes, head down close to the body or tucked under a wing, and anorexia. Sick birds tend to huddle together. The head may or may not be cyanotic, a sign observed by those who gave the disease the name blackhead. About 6–12 days PI, turkeys become emaciated. Infections in chickens may be mild and go unnoticed or may be severe and cause high mortality. Sulfur-colored droppings are seen in the later stages of disease when liver function is severely damaged and bile pigments are excreted through the kidneys. In chickens, the main signs are drooping feathers, morbidity, and closed eyes. Cecal discharges may contain blood, and caseous cecal cores are common. Sometimes gross pathology of blackhead in chickens may resemble cecal coccidiosis.

Clinical Pathology

In chickens, total leukocytes are increased, composed mainly of heterophils, lymphocyte, and basophils. Hemoconcentration occurs with severe dehydration.

In turkeys there is a decline in serum nitrogen, uric acid, and hemoglobin levels during the incubation period, but these return to normal prior to death. Blood sugar levels rise during the cecal phase, decrease during liver lesion development, and drop below normal prior to death. Serum albumin falls very low, but the globulins increase significantly during the acute infection in turkeys (25).

Plasma levels of glutamic oxaloacetic transaminase (GOT) and lactic dehydrogenase (LDH) increase as liver lesions develop in turkeys (26), but glutamic pyruvic transaminase (GPT) remains essentially unchanged. There is very little GPT activity in avian liver or other tissues, suggesting that it is not an important enzyme in birds. Appearance of a brilliant yellow urine pigment coincides with depressed liver function and elevated enzymes resulting from tissue damage. In acutely ill turkeys, the proportion of hemoglobins in the methemoglobin state in the blood is greatly elevated, possibly contributing to cyanosis and the purported blackhead appearance.

Morbidity and Mortality

The degree of illness is variable especially in chickens and other birds. Turkeys are more uniformly affected, with flock mortality commonly 80–100%. The time of onset in chickens varies. Blackhead may be diagnosed at 6–7 weeks of age in a flock, then at earlier ages in successive flocks as the disease reservoir becomes established in a facility. Outbreaks are seen as early as 3 weeks. Farmer and Stephenson (8) reported that turkeys confined to areas contaminated by chickens suffered 89% morbidity and 70% mortality. Although losses from histomoniasis in chickens are generally low, mortality has exceeded 30% in some naturally occurring infections. Mortality may occur as early as 6 days PI in experimental infections, but is most common at 9–12 days PI. Occasionally, a strain of *Histomonas* with apparent high virulence for chickens is found. There are no reference strains of *Histomonas*, precluding easy study of this phenomenon.

Gross Lesions

The primary lesions of histomoniasis develop in the ceca and liver (see Fig. 28.11). In recent years, lesions are also reported from other organs, such as the spleen, the bursa of Fabricius, pancreas and kidneys (36). Lesions are observed initially in the ceca. After tissue invasion by histomonads, cecal walls become thickened and hyperemic. Serous and hemorrhagic exudate from the mucosa fills the lumen of ceca and distends the walls with a caseous or cheesy core, and ulceration of the cecal wall may lead to perforation of the organ and cause generalized peritonitis.

Liver lesions in turkeys are often apparent a few days after infection and are highly variable in appearance. Often, the lesion is described as a circular depressed area of necrosis up to 1 cm in diameter and is circumscribed by a raised ring. Although these lesions are often seen (Fig. 28.11C,F), they may take on other appearances. In heavy infections, lesions may be small, numerous, and mostly subsurface, and they may involve a large part of the liver. In rare cases of recovery, lesions leave purulent scars on the surface of the liver. The liver may be enlarged and discolored green or tan. Lesions in lung, kidney, spleen, and mesenteries are sometimes recognized as white rounded areas of necrosis.

Histopathology

Initial invasion of the cecal wall results in hyperemia and heterophil leukocyte infiltration, probably a combined response to bacteria, histomonads, and heterakid juveniles (2). Within 5–6 days, numerous histomonads are visible as pale, lightly stained, ovoid bodies within lacunae in the lamina propria and muscularis mucosa. Large numbers of lymphocytes and macrophages have infiltrated tissues by this time, and the heterophil population has also increased. Cecal cores are composed of sloughed epithelium, fibrin, erythrocytes, and leukocytes along with trapped cecal ingesta. The core initially may be amorphous and red tinged, but by about 12 days, it appears laminated, dry, and yellowish from buildup of successive layers of exudate. By 12–16 days, giant cells appear in the tissues of the cecum. Coagulation necrosis and histomonad invasion extend well into the muscular tunic, extending nearly to the serosa. In survivors, histomonads are scarce within the tissues by 17–21 days and are mostly concentrated near the serosal layers. Large numbers of giant cells form and may appear grossly as granulomata bulging upon the serosal aspect of the cecum. Old lesions, after recovery, are characterized by lymphoid centers scattered throughout the cecal tissue. Expulsion of cores and the regeneration of epithelium may occur, particularly in chickens, but the cecum may suffer permanent damage.

The liver has microscopic lesions visible by 6–7 days PI and consisting of small clusters of heterophils, lymphocytes, and monocytes near portal vessels. Histomonads are difficult to visualize in these areas. After 10–14 days, the lesions are enlarged, becoming confluent in some areas. There is extensive lymphocytic and macrophage infiltration, and heterophils are present in moderate numbers. Hepatocytes in centers of the lesions necrose and disintegrate. Many individual or clustered histomonads are visible in lacunae near the periphery of lesions. From 14–21 days PI, necrosis becomes increasingly severe, resulting in large areas consisting of little more than reticulum and cellular debris.

Histomonads at this stage are present mostly as small bodies in macrophages. If recovery occurs, foci of lymphoid cells remain, along with areas of fibrosis and regenerating hepatocytes.

Immunity

Immunity to blackhead has not received much study, and most of the reports on this topic are more than 50 years old. Early work suggested that a partial immunity developed after infections, which might or might not be adequate to protect against reinfection (3, 39). Most work with immunity in turkeys has relied on drug treatment to terminate infections, because turkeys usually die from the disease.

Attempts to immunize chickens and turkeys with histomonads attenuated *in vitro* have been only partially successful. Some protection was demonstrated against cloacal inoculation of pathogenic or attenuated strains of histomonads, but very little against histomonad-containing heterakid eggs (22). Although reports are not in agreement, some protective immunity is obtained while drug therapy is being administered. Research on the use of attenuated strains for immunization was abandoned because it was considered impossible to stabilize the degree of attenuation *in vitro* and impractical to inoculate birds with the live cultures.

Chickens and turkey produce antibodies against *H. meleagridis* antigens prepared from infected livers and ceca, and after natural or experimental infections. In some reports, antibodies in turkeys and chickens did not confer resistance to reinfection. Such antibodies persisted for a considerable time (3). Birds recovering from histomoniasis may harbor parasites in the ceca without signs or lesions of the disease (5).

Recent experimental work suggests that infected birds develop precipitins and lysins in the serum, and that birds given injections of *H. meleagridis* antigen may develop good protection against reinfection.

Passive Immunity

Attempts to transfer immunity from resistant to susceptible chickens and turkeys by repeated intraperitoneal injections of serum from immune birds have been unsuccessful. When birds receiving immune serum were challenged by cloacal inoculation of infected liver homogenates, turkeys died from histomoniasis, and all chickens developed typical cecal lesions (4, 5).

Diagnosis

Most experienced poultry workers make a field diagnosis in turkeys on the basis of gross appearance of lesions. Laboratory confirmation is sometimes necessary to rule out concurrent infections with other agents that affect the cecum or liver (coccidiosis, salmonellosis, aspergillosis, and upper digestive tract trichomoniasis). Chickens are more likely to have lesions in the ceca that can be confused with other diseases, particularly cecal coccidiosis.

The presence of characteristic lesions in turkeys is sufficient for presumptive diagnosis. Identification of histomonads by microscopy adds confidence to the diagnosis. The organisms are most easily observed with phase-contrast microscopy with fresh specimens. Histomonads remain active and are more easily iden-

tified if the microscope stage is warmed, either with a special stage incubator or small incandescent light bulb. Tissue forms are not easily identified by microscopy.

For routine diagnostic histopathology, any of several stains, including hematoxylin and eosin or periodic acid-Schiff, may be used (18). Excellent cytologic preparations have been made from fresh cultures using Hollande's cupric picroformol and a protein-silver stain.

Where freshly killed birds are available, it is a simple matter to cultivate histomonads *in vitro* as a diagnostic aid, using Dwyer's medium (6,24). If samples are taken from freshly killed birds the test is more than 75% accurate. The medium consists of 85% Medium 199 in Hank's balanced salt solution, 5% chicken embryo extract (CEE50), and 10% horse or sheep serum, adjusted to pH 7.2. A small amount (10–20 mg) of rice powder (organically produced rice flour from a health food store) is added, and then the tubes are sealed, incubated at 40°C overnight, and observed with an inverted microscope. Cultures obtained in this way can be maintained by subculturing every 2–3 days, and can be used to infect birds experimentally, but they tend to become nonpathogenic within 6–8 weeks.

While it is not usually necessary for diagnosis, PCR tests are highly accurate in identification of *H. meleagridis.* Recent tests rely on primers based on the small-subunit RNA fraction (21).

Prevention and Control

As there are no chemotherapeutic products available for treatment of infections, and there is no commercial vaccine for histomoniasis, control measures are focused on prevention.

The primary reservoir of infection is the cecal worm ova. Thus, prevention is largely a matter of avoidance of contact of susceptible birds with sources of egg contamination and prevention of exposure to carriers.

For the protection of turkeys, exclusion of chickens from any contact is essential, because chickens may often harbor large numbers of egg-laying cecal worms. Outdoor turkey ranges can become contaminated with heterakid eggs, creating a situation in which histomoniasis recurs in turkey flocks for many years. Because of the longevity of infectious eggs, range rotation is not practical as a solution.

Rearing turkeys indoors tends to reduced outbreaks of blackhead, but exacerbates the extent and severity of outbreaks. It is most likely that outbreaks arise by the introduction of a small number of cecal worm ova into the growing facility. After introduction, the infection spreads throughout the flock by direct contact. The recent observation that histomoniasis cannot spread within a flock without direct contact between birds offers a potential method for containing outbreaks. If the growing facility is divided into subunits, even by netting or other barriers, the outbreak will be limited to the contaminated units.

Leghorn pullets and broiler breeder pullets often become infected in problem houses where worm eggs have built up in number for several years. In some areas histomoniasis is reportedly common in broilers. In some instances, disinfection may have value in killing worm eggs, but there is no experimental work to support this conclusion.

The discovery that cecal coccidiosis (*E. tenella*) interacts with histomoniasis in chickens is important because coccidia are often present in growing facilities. In experimental tests, the number of birds showing liver lesions, as well as the severity of lesions, was increased when both parasites were present, even when low infections of coccidia were used (27). These results suggest that better prevention of coccidiosis in breeder and layer pullets is important in avoiding problems with blackhead.

Chemotherapy

Management practices alone are rarely adequate to keep the disease at a low level in commercial flocks; therefore, preventive chemotherapy is sometimes practiced during the high-risk part of the growout. Presently, the only product available for the prevention of histomoniasis in poultry is nitarsone (Histostat7, Alpharma, Clifton, NJ).

Five drugs were at one time registered for treatment of outbreaks in the United States (9), including 2 arsenicals, 2 nitroimidazoles, and 1 nitrofuran (Table 28.5). However, regulatory action has removed the most useful drugs (nitroimidazoles) from the market. These products are also unavailable in other countries. Preventive use of nitarsone is usually effective in keeping blackhead at a low level, but its use in breeder stock presents additional problems. Breeder pullets and males are commonly reared on skip-a-day feeding programs, which lead to exacerbated toxicity of the arsenic. The arsenicals are not strong enough to be effective as treatment drugs and are not approved for this use. For a historical review of older literature on antihistomonal drugs, see Joyner *et al.* (17) and Joyner (16).

Because of the close association of *H. meleagridis* with bacteria, it has become common practice to treat outbreaks with antibiotics. While it is generally beneficial to administer antibiotics to combat secondary infections, there is no evidence that such treatments have a direct effect on histomoniasis (14).

Worm control is considered a central part of blackhead control programs for chickens. Frequent worming with benzamidazole type anthelmintics is known to reduce exposure to both worms and histomonads. It is important to administer wormers at least one week prior to the usual expected time of outbreaks, based on the history for each farm.

Trichomoniasis
Introduction

Trichomoniasis in birds, affecting the upper digestive tract, is caused by the flagellated protozoan *Trichomonas gallinae* (Fig. 28.13). In pigeons, it causes a condition known as *canker*. Turkeys, chickens, and a wide variety of wild birds are parasitized with varying degrees of pathogenicity (20).

Description

These intestinal flagellates are rapidly moving, pear-shaped protozoa that range in size from 5–9 μm in length and from 2–9 μm in width (Fig. 28.14). There are typically 4 free flagella arising

Table 28.5.   Feed additives or water treatments at one time registered in the United States for the prevention or treatment of blackhead disease in turkeys.[a]

Drug	Trade Name	Supplier	Use Level	Withdrawal	Approval for Chickens
			Conditions of Use		
Carbarsone[b]	Carb-O-Sep	N/A	0.025–0.037%	5	No

from a basal granule at the anterior pole of the organism. A slender axostyle usually extends well beyond the posterior end of the body. An undulating membrane originates at the anterior pole of the body and ends short of the posterior pole, with the enclosed flagellum not trailing free at the posterior end. The flagella and internal structures can be seen only with the aid of phase-contrast microscopy or special stains.

Incidence and Distribution

Squabs usually become infected with their first taste of "pigeon milk" from the crop of adults and usually remain carriers throughout life. With virulent strains, mortality may be as high as 50% before sufficient protective immunity develops. Pigeons are often blamed for transmission of trichomoniasis to turkeys and chickens. The economic impact of the disease in turkeys and chickens is difficult to assess, although infections are occasionally reported. When captive birds of prey such as falcons are allowed to feed on pigeons, infection may result in a condition known as "frounce" among falconers.

Life Cycle

T. gallinae reproduces by longitudinal binary fission. Cysts, sexual stages, or vectors are not known. The organism is transferred to squabs by infection of "pigeon milk" from adults. In chicken and turkey flocks, infection is spread by contamination of drinking water and perhaps feed.

Pathogenesis and Pathology

Nearly all pigeons are carriers of this organism. The virulence of *Trichomonas* varies widely, with some strains capable of causing mortality. At one time investigators considered trichomoniasis to be synonymous with blackhead disease. However, these investigators failed to consider that more than one parasite might produce lesions of similar appearance. Affected birds may cease to feed and become listless, ruffled in appearance, and emaciated before death. A greenish to yellowish fluid may be seen in the oral cavity and may drip from the beaks of infected birds.

A. *Tritrichomonas eberthi*. B. *Trichomonas gallinarum*. (Lund)

Gross Lesions

T. gallinae invade the mucosal surface of the buccal cavity, sinuses, pharynx, esophagus, and crop and occasionally the conjunctiva and proventriculus. The liver is frequently invaded, and occasionally other organs—but not the digestive tract below the proventriculus—are involved.

Lesions appear initially as small, circumscribed caseous areas on the surface of the oral mucosa, which may be surrounded by a thin zone of hyperemia. These may enlarge and become confluent. The buildup of caseous material may be sufficient to occlude the lumen of the esophagus partially or completely. These lesions eventually may penetrate tissue and extensively involve other regions of the head and neck, including the nasopharynx, orbits, and cervical soft tissues. In the liver, lesions appear on the surface and extend into the parenchyma as solid, white to yellow circular or spherical masses.

Histopathology

Pigeons infected with a virulent strain of *T. gallinae* had purulent inflammation with caseous necrosis as the predominant lesion (33). Trichomonads multiply in secretions and on the mucosal surface of the oropharynx. Ulceration of the mucosa with a massive inflammatory response, primarily heterophils, is well established by the fourth day of experimental infections. In the liver, focal necrotic abscesses occurred in all zones of lobules, with an inflammatory reaction characterized by mononuclear cells and heterophils. As liver lesions progressed, no intact hepatocytes remained in the center of foci; trichomonads were most numerous at the periphery.

Immunity

The relatively high incidence of infections in otherwise normal pigeons can be attributed to strain variations, acquired immunity, or both. Pigeons are immune to disease from virulent strains of trichomonads after recovery from sublethal trichomoniasis. Plasma from pigeons harboring any of 3 strains of *T. gallinae* could protect other pigeons against disease but not infection from a virulent strain.

Antigens of *T. gallinae* have been studied in regard to taxonomy with the conclusion that virulence and antigenic composition were related (7).

Diagnosis

Clinical signs and gross lesions are highly suggestive and may be confirmed by microscopic observation of organisms in direct wet smears from the mouth or crop. Histopathologic examination or cultivation of organisms in artificial media may help in cases in which the parasites are absent in fresh smears. Trichomoniasis must be differentiated from candidiasis and hypovitaminosis-A, which can produce somewhat similar lesions. History, cultivation for fungi, and histopathologic examination may prove useful in resolving problem diagnoses.

Several other species of flagellates that inhabit the avian gastrointestinal tract are frequently misidentified as *T. gallinae*. These other species of trichomonads and more distantly related flagellates have never been unequivocally demonstrated to be pathogenic for the avian host. Their recognition as harmless commensals will prevent unnecessary expenditures for therapeutic measures.
28.15. *Chilomastix gallinarum*, semidiagrammatic, illustrating details of morphology. (Boeck and Tanabe)

One trichomonad, *Tetratrichomonas gallinarum,* is a common inhabitant of the cecum of chickens and other gallinaceous birds. This trichomonad or a closely related species occasionally has been isolated from liver and blood. Although lesions have been ascribed to this organism, no confirmation of pathogenicity has come from experimental infection.

Other lower intestinal protozoa such as *Chilomastix gallinarum* (Fig. 28.15), a cyst-forming flagellate with a large cytostomal cleft but no undulating membrane, and *Cochlosoma anatis,* with a ventral sucker covering half the surface of the body, are apparently nonpathogenic. Although additional controlled experiments with flagellates found in the lower intestine are needed, for the present, they should not be considered important.

Prevention and Control

Because *T. gallinae* is transmitted from parent to squab in pigeons and by contamination of feed and water by oral fluids in the case of domestic fowl, sick birds should be removed from a flock. Drugs with activity against other related protozoa (*H. melelagridis, Entamoeba histolytica, Giardia lamblia)* are active against trichomoniasis in pigeons or turkeys, however none is approved for use in domestic birds. McLoughlin (31) found dimetridazole useful at a level of 0.05% in drinking water for pigeons. This drug is no longer available in the United States. There is no vaccine for this parasite.

Hexamitiasis
Etiology and Distribution

Hexamitiasis, or infectious catarrhal enteritis, of poults is caused by the protozoan *Spironucleus meleagridis.* There is apparently no well-known common name for this parasite other than the original generic name *Hexamita.* There is no good measure of economic losses from this parasite. However, the USDA estimated that an annual loss of $667,000 occurred from hexamitiasis in turkeys from 1942–1951 (40). Cases of hexamitiasis are encountered sporadically in diagnostic laboratories in the United States. The disease has been reported from several areas of the United States, Canada, Scotland, England, and Germany. The organism has also been found in pheasants, quail, chukar partridge, and peafowl, which may be a source of infection for range-reared turkeys. The 8 prominent flagella include 4 anterior, 2 anterolateral, and 2 posterior. The 4 anterior flagella are recurved along the body (Fig. 28.16). McNeil *et al.* (32), who named the species, described it as being 6–12.4 × 2–5 μm in size with binucleate large endosomes.

Pathology

Affected poults do not show specific signs, but a watery diarrhea occurs that may become yellowish later in the course of the disease. The poults at first are nervous and active but later tend to become listless and huddled. Convulsions and coma may occur as the terminal stage is approached.

Lesions include catarrhal inflammation and atony resulting in distention, especially in the upper small intestine. Intestinal contents are watery, and large numbers of *S. meleagridis* may be seen in the crypts upon microscopic examination. A yellowish discoloration of the liver surface was described in an outbreak in Germany.

Diagnosis

The presence of watery diarrhea and the microscopic demonstration of flagellated *S. meleagridis* in fresh smears of duodenal contents are sufficient to establish the diagnosis. Survivors may become carriers; thus, the parasites may be seen without any signs of infection. These parasites are easily distinguished from
28.16. *Spironucleus meleagridis* from the intestine of a turkey. (25)

other protozoa by their rapid, darting movement. They are small, in comparison with other flagellates.

Control and Treatment

There is no effective treatment, although butynorate (0.0375%) and chlortetracycline (0.0055%) were approved for use at one time. There is no vaccine for this parasite. The removal of carrier birds, the separation of older stock from poults, and the exclusion of other avian host species from the area of the poult flock are thought to minimize transmission. Attention to principles of good management is considered important in reducing losses to this and other parasitic diseases.

Miscellaneous Protozoa in the Digestive Tract

Several species of the genera *Entamoeba* and *Endolimax* occur naturally in the ceca or feces of various domestic fowl or can be established experimentally. Apparently, none of these are pathogenic; they exist by feeding on intestinal contents.

The amoebas have irregularly shaped trophozoites with a single nucleus with a more or less prominent endosome. They produce cysts containing 1, 4, or 8 nuclei. Phase-contrast microscopy or stained preparations is recommended for observing these organisms. A number of species have been reported (20, 30).

Miscellaneous and Sporadic Protozoal Infections

Alex J. Bermudez

Leucocytozoonosis

This parasitic disease of birds affects blood and tissue cells of internal organs. Reviews of this and other parasitic diseases have been summarized by Lund (78), Levine (73), and Fallis *et al.* (33).

Leucocytozoon was assigned to the order Haemospororina of the phylum Apicomplexa (72, 76). Similarities in life cycle and ultrastructure of some life stages of *Leucocytozoon*, *Haematroteus*, and *Plasmodium* warrant inclusion of all 3 genera in a single family, Plasmodiidae (72, 73). Approximately 67 valid species and 34 synonyms have been described. With the exception of a species observed in the teiid lizard in Brazil, all species of *Leucocytozoon* are found in birds (48).

The life cycle requires 2 hosts; sporogony is in insects, although schizogony (merogony) and gametogony are in tissues or blood cells, respectively, of the vertebrate host. *Leucocytozoon* is prevalent in areas with a suitable ecology and ethology for dipterous invertebrate hosts, simuliid flies and culicoid midges. At least 3 species of *Leucocytozoon* reported in domestic fowl are known to cause outbreaks in North America resulting in economic losses in ducks, geese, turkeys, and chickens. Outbreaks of leucocytozoonosis are sporadic in North America (2), but the disease is relatively common in the open chicken houses of southern and eastern Asia (119), the Philippines, Indonesia, and eastern Africa (24).

Leucocytozoon simondi *Mathis and Leger 1910*

Infection with *L. simondi* has been reported from 27 species of ducks and geese in United States, Canada, Europe, and Vietnam by Hsu *et al.* (48). *L. anatis* from ducks and *L. anseris* from geese are considered synonyms of *L. simondi*. Approximately 14–20% of ducks and geese along the northeastern seaboard of North America carry *Leucocytozoon* infections (8, 10). Eighty percent of geese at Seney Wildlife Refuge in Michigan had some parasitemia in 1963 just prior to the egg-laying season, and each year all goslings become infected (47).

Ducks and geese are suitable hosts for *L. simondi*, but chickens, turkeys, pheasants, and ruffed grouse are not.

Bloodsucking flies known to serve as the vector for *Leucocytozoon* in ducks include *Simulium venustum*, *S. croxtoni*, *S. euradminiculum*, and *S. rugglesi*.

Etiology

Sporogony occurs in the insect vector and may be completed in 3–4 days. Ookinetes develop following fertilization of the macrogametocyte and may be found in the stomach of the insect within 12 hours after a blood meal. Oocysts form from the ookinetes within the stomach of the invertebrate host and produce sporozoites, which migrate to the salivary glands after emerging from the oocyst. Viable sporozoites have been found in vectors up to 18 days after the last blood meal.

Schizogony takes place in internal organs of the vertebrate

host, such as liver, brain, spleen, and lungs. "Hepatic schizonts" in liver cells measure up to 45 μm when mature. Merozoites and syncytia are released from hepatic schizonts (syncytium refers to cytoplasm bounded by a plasma membrane and containing two or more nuclei). Some merozoites enter parenchymal cells of the liver and initiate another schizogonic cycle, and others enter erythrocytes or erythroblasts to develop into gametocytes. Syncytia are phagocytized by macrophages or reticuloendothelial cells throughout the body, where they develop into megaloschizonts up to 400 μm in size. Merozoites released from the megaloschizont enter lymphocytes and other leukocytes to form gametocytes.

The gametocytes of *L. simondi* found in the blood average 14.5 × 5.5 μm and usually inhabit elongate spindle-shaped host cells averaging about 48 μm in length. The parasite lies beside the nucleus of the host cell. Elongate gametocytes probably develop exclusively in leukocytes, predominantly lymphocytes and monocytes, and mature round gametocytes are found in erythrocytes. According to Allan and Mahrt (4), each *Leucocytozoon* species enters gametogony in only 1 type of host cell; therefore, the presence of 2 morphologic types in the same bird suggests a concurrent host infection with 2 species. Desser *et al.* (23) observed infections in some areas of northern Michigan that were characterized by presence of both hepatic schizonts and round gametocytes, which he attributed to different strains of *L. simondi*.

Gamonts may be differentiated with a Romanowsky stain based on the dark blue staining cytoplasm of the macrogamete with its red nucleus, and the very pale blue staining cytoplasm of the microgamont with its pale pink nucleus. The microgamonts are more delicate and subject to distortion (73).

Pathogenesis and Epidemiology

The pathogenicity of *L. simondi* in ducks and geese is well documented. An outbreak of *L. simondi* among ducks in Michigan resulted in 35% mortality. Extensive losses of young goslings, attributed to infections of *L. simondi*, are observed annually at Seney Wildlife Refuge, with mortality greater than 70% occurring every 4 years (47). However, not all *L. simondi* infections cause such severe disease. An experimental infection in anatid ducklings caused no mortality and no difference in growth rate (97).

Clinical signs vary with age and the condition of the host. Young ducklings manifest inappetence, weakness, listlessness, dyspnea, and sometimes death within 24 hours. Signs in adults appear less abruptly and consist of listlessness and low mortality. About 60% of fatalities occur 11–19 days postexposure. Some pathologic effects of the disease are anemia, leukocytosis, splenomegaly, and liver degeneration and hypertrophy. Extensive tissue damage was noted in the spleen and heart of ducks carrying megaloschizonts.

Kocan (70) described an anti-erythrocyte factor in sera from acutely infected ducks, which agglutinated and hemolyzed normal untreated erythrocytes as well as infected cells. This factor was believed to be a product of the parasite, and its action may account for the osmotic fragility of erythrocytes and anemia associated with *L. simondi* infections (79).

The greatest number of infections in northern Michigan occur in July. Gametocytes decrease in number in the blood until midwinter, when they disappear or become scarce and then reappear in the spring.

Leucocytozoon smithi *Laveran and Lucet 1905*

L. smithi was first seen in turkeys in the eastern United States by T. Smith, after whom it is named, and has since been reported in turkeys in North Dakota, Minnesota, Nebraska, California, Texas, Missouri, France, Germany, the Crimea, and Canada.

In the United States, it can be widespread in adult turkeys (105): 289 of 357 turkeys were found infected in Georgia, 60 of 67 in Florida, 4 of 12 in Alabama, and 7 of 9 in South Carolina. The incidence of infection in pen-raised and free-ranging mature wild turkeys in the Cumberland State Forest in Virginia was 100%. The incidence of infection in wild turkeys in South Carolina, Mississippi, and the midwestern states was 100%, 33%, and 3%, respectively (19, 36, 106). Economically significant outbreaks of *L. smithi* infection in turkeys are infrequent in North America (2), probably because of a transition to confinement rearing of commercial turkeys and the general shift away from raising turkeys in regions where blackflies and midges are abundant.

Etiology

L. smithi may be observed in the blood as rounded gametocytes that later become elongate, averaging 20–22 μm in length. They inhabit elongate cells averaging 45 × 14 μm, with pale cytoplasmic "horns" extending out beyond the enclosed parasite. The host cell forms a long, thin dark band along each side of the parasite. Gamonts are found only in leukocytes. The staining characteristics of the gamonts with a Romanowsky stain are similar to those of *L. simondi* (73) (Fig. 28.17A).

Intracellular schizogonous forms are found in the liver. Both schizonts and megaloschizonts were observed and illustrated by Siccardi *et al.* (98).

Several aspects of the life cycle were described in detail by Newberne and by Wehr (cited by 78); the ultrastructure of gametocytes was defined by Milhous and Solis (84). Gametocytogenesis, sporogonic development, schizonic development, fertilization, and ookinete differentiation have been described by light and electron microscopy (107, 108, 109, 110).

Pathogenesis and Epidemiology

L. smithi generally resembles *L. simondi* of Anseriformes, but turkeys are probably not susceptible to the latter. *L. smithi* is not transmissible experimentally to chickens or ducks.

Simulium occidentale, *S. aureum*, *S. meridionale*, *S. nigroparvum*, and *S. slossonae* have been listed as vectors for *L. smithi* (33, 69).

The progress of leucocytozoonosis in susceptible young turkeys may be rapid and fatal. Clinical signs include anorexia, excessive thirst, depression, somnolence, and sometimes muscular incoordination. Death may occur suddenly during the acute stage of the disease.

Heavy infections of *L. smithi* do not seem to occur in mature wild turkeys. Few signs of infection are observed in wild turkeys,
28.17.   Turkey blood containing various stages of *Leucocytozoon smithi*. A. Darkly stained macrogametocyte (upper) and lightly stained microgametocyte (lower). Giemsa stain, ×1250. B. "Round form" often found early in infection (day 16), ×140. C. Megaloschizont in turkey liver; day 9. H & E. ×1000. D. Megaloschizont turkey kidney; day 10. (21)

possibly because of local factors such as time at which suitable vectors are prevalent and the age of birds at first exposure.

Domestic hens infected with *Leucocytozoon* had decreased egg production, egg weight, and hatchability, and higher mortality than uninfected hens (63).

Recovered birds may harbor the parasite in their blood for more than 1 year (24). There is often loss of vigor, and birds may suffer moist tracheal rales and coughing. Some birds die when subjected to stress. Males showed reduced mating activity (73).

Johnson *et al.* (61) reported that death results from obstruction of the circulatory system by large numbers of parasites. The lungs, small intestine, liver, and spleen may be congested, and the liver and spleen enlarged, in affected turkeys. Lund (78) cites extensive description of pathogenesis.

Leucocytozoon caulleryi *Mathis and Leger 1909*

L. caulleryi frequently is found in chickens in southern and eastern Asia. Infections occur frequently in Japan (86). Reports of leucocytozoonosis in South Carolina, probably caused by *L. caulleryi*, are the only known cases of the disease in chickens in North America. In one survey, 13.6% of domestic yard chickens in South Carolina were infected (92). *L. andrewsi* and *L. schueffneri* are considered by some protozoologists to be synonymous with *L. caulleryi* (73).

Etiology
The domestic chicken is the only reported host for *L. caulleryi*. Insect vectors are *Culicoides arakawa*, *C. circumscriptus*, and *C. odibilis*. Akiba's discovery that the vector was a species of *Culicoides* and not *Simulium* prompted some to place *L. caulleryi* in a new genus called *Akiba* (33). Leucocytozoonosis epizootics, widespread during summer months in Japan, are serious enough to cause deaths in growing chicks and reduced egg production in hens (86).

Pathogenesis
Early schizonts occur in the lung, spleen, and thymus (48). Megaloschizonts, often readily visible on gross examination, are found in numerous tissues including the liver, spleen, kidneys, pancreas, heart, lungs, proventriculus, ventriculus, intestines, and brain (42).

Mature gamonts are round and occupy round host cells, erythrocytes, and leukocytes about 20 μm in diameter. The nucleus of the host cell reportedly disappears after infection, a characteristic that differs from other species with round gametocytes. Macrogametes (12–15 μm) stain more darkly with Romanowsky stain than microgamonts (10–15 μm) , according to Levine (73).

Serious outbreaks of *L. caulleryi* in chickens are characterized by hemorrhage in the peritoneal cavity, perirenal hemorrhage, and subdural hemorrhage (42). Extensive hemorrhage in the kidneys and other tissues occurs when merozoites are released from mega-

loschizonts. In infected laying hens, the uterus is edematous on gross examination with schizont development, granuloma formation, and inflammation of the uterus noted on histopathology (91).

Leucocytozoon sabrezi *Mathis and Leger 1910*

L. sabrezi (*L. schueffneri*, probably a synonym) has been found in domestic chickens in Southeast Asia, causing anemia, thickened oral discharge, and paralysis of the legs. Megaloschizont formation has not been reported for this parasite. Merozoites enter both erythroblasts and leukocytes to form elongate gametocytes within spindle-shaped host cells (6–7 × 4–6 μm), whose nuclei appear as thin bands beside the parasite (24). Macrogametes (22 × 6.5 μm) have a more compact nucleus and stain more darkly with a Romanowsky stain than the microgamonts (20 × 6 μm) (53). The insect vector is unknown.

Leucocytozoon schoutedeni *Rodham, Pons, Vandenbranden, and Bequaert 1913*

L. schoutedeni, which was found in 50% of chickens in East Africa (24), is unknown elsewhere. Gametocytes are round (11–13 μm) and found in round host cells (18 μm) whose nuclei surround the parasite about one-half of its length. Staining characteristics of the gametocytes have not been reported. The *Simulium* fly serves as the invertebrate host for *L. schoutedeni*.

Diagnosis

Leucocytozoon infections are diagnosed by direct microscopic observation and identification of gametocytes in stained blood or schizonts in tissue sections. Solis (102) described the high staining contrast of *Leucocytozoon* in peripheral blood films stained with brilliant cresyl blue. A variety of serologic tests including the agar gel precipitation test, indirect IFA, ELISA test and latex agglutination test have been developed for detecting antibodies to *L. caulleryi* (54, 57).

Treatment and Control

Drug treatment of leucocytozoonosis has had limited success. No effective treatment has been found for *L. simondi*. Pyrimethamine (1 ppm) and sulfadimethoxine (10 ppm) administered simultaneously reportedly will prevent, but not cure, infections of *L. caulleryi*. Halofuginone has been used for treatment in Asia. Clopidol in feed effectively controlled *L. smithi* according to Siccardi *et al.* (98).

Control requires elimination of the insect vector from the environment of the vertebrate host. A large-scale aerial treatment program using an organophosphate insecticide (2% temephos granules) for control of larval *Simulium* substantially reduced adult and larval blackfly populations and reduced the level of *L. smithi* blood parasitemia in turkeys in one study (68).

Repellents sprayed within houses to discourage entrance of the insect vector lowered mortality and incidence of disease but did not completely prevent infection in the flock (33).

The control of *L. caulleryi* by vaccination using an oil-adjuvanted rR7 vaccine has shown promising results in both laboratory and field trials (55, 56). This vaccine uses a recombinant R7 protein (rR7) from second-generation *L. caulleryi* schizonts.

Avian Malaria

Parasites of the genus *Plasmodium* (phylum Apicomplexa) cause the presence of pigment in infected erythrocytes of the host. Schizogony occurs in blood, and gametocytes are found in mature erythrocytes. All species of *Plasmodium* are transmitted by mosquitoes. These characteristics distinguish them from *Haemoproteus* and *Leucocytozoon* species and other members of the family Plasmodiidae.

About 65 species of *Plasmodium* from more than 1000 different birds have been described, but only 35 are considered valid (9, 72). Species pathogenic for domestic fowl are found mostly in Asia, Africa, and South America. Malaria outbreaks have been recorded in North American birds of the orders Anseriformes, Passeriformes, and Columbiformes.

Etiology

Although many species of *Plasmodium* can be introduced into various domestic fowl, only a few appear to be natural parasites of these birds. *P. gallinaceum* occurs in jungle fowl and domestic hens; *P. juxtanucleare* parasitizes domestic hens and turkeys; *P. durae* and *P. griffithsi* occur in turkeys; *P. lophurae* of the fire-backed pheasant can also parasitize chickens and has been host-adapted to other domestic fowl and ducks; *P. fallax* of guinea fowl has been adapted to various domestic fowl; *P. hermani* will infect domestic and wild turkeys and bobwhite quail (31, 39).

Other species found primarily in passerine birds that can infect domestic fowl or have been experimentally transmitted to them include *P. relictum*, *P. elongatum*, *P. cathemerium*, and *P. circumflexum* (66).

Life Cycle

Only a general outline of the malarian life cycle can be given here. Consult Garnham (40) for information on the life cycles of various species. Greiner *et al.* (45) presented color plates of 24 species.

Avian plasmodia develop in culicine mosquitoes of the genera *Culex* and *Aedes*, and rarely in *Anopheles*. Gametocytes from an avian blood meal are taken up by the mosquito, after which gamete formation, oocyst development and sporogony occur. Infective sporozoites entering the avian host from the bite of a mosquito invade cells of the reticuloendothelial system and typically progress through two generations of primary exoerythrocytic schizonts: cryptozoites and metacryptozoites. Merozoites produced by the second generation are released into the bloodstream and invade erythrocytes. An interchange of parasites between blood and reticuloendothelial tissues may occur, resulting in secondary exoerythrocytic schizonts (phanerozoites) in many tissues, especially spleen, kidney, and liver endothelial cells. These may be responsible for subsequent heavy parasitemias.

The trophozoite inside an erythrocyte is known as the ring form because of its appearance. Romanowsky staining shows a band of blue cytoplasm surrounding a vacuole and a peripheral red-stained nucleus. The characteristic malarial pigment, visible in stained smears, is formed as the parasite consumes and metabolizes the host cell hemoglobin. Nuclear division (schizogony)

leads to formation of multiple nuclei, which bud off to form merozoites. The host cell ruptures to release merozoites for infection of other erythrocytes. After several asexual cycles, some merozoites differentiate into gametocytes and await ingestion by a suitable mosquito. The species of avian plasmodia vary in numbers of merozoites formed in exoerythrocytic and erythrocytic stages, in timing of the life cycle, and in morphology of various stages.

Pathology and Pathogenesis

The pathologic effects in avian hosts range from no apparent signs to severe anemia and death. *P. gallinaceum*, *P. juxtanucleare*, and *P. durae* are the most pathogenic for domestic fowl and may cause 90% mortality. Intense and severe anemia and generalized hypoxia may occur in acute *P. gallinaceum* malaria (66). A similar situation occurs in ducks affected with *P. lophurae*. Severe anemia may also occur in *P. juxtanucleare* infections.

Other pathologic changes occur in avian malaria. The exoerythrocytic stages of *P. gallinaceum* may block capillaries in the brain, resulting in death due to central nervous system dysfunction. Also, *P. durae* produces exoerythrocytic schizonts in the capillaries of the brain, sometimes producing high mortality (49).

Zoonotic Disease

Human malaria is an extremely important worldwide public health concern, however, no avian *Plasmodium* species has been reported to be capable of causing infection in humans (22).

Immunity

Immunologic factors, such as antigen-antibody complex and hemagglutinins, and such conditions as splenomegaly, anemia, and nephritis have been studied extensively in *P. gallinaceum* infections (82, 103).

Treatment and Control

The life cycle of the malaria parasite must be broken by the eradication of mosquitoes or by isolation of the flock from the vector by suitable housing. Although avian models have been used extensively in chemotherapeutic studies, information on potential preventative medications or treatments is limited. Studies with *P. durae* suggest that halofuginone is a possible preventive, and a combination of sulfachloropyrazine and sulfamonomethoxine could be used in treatment (49). Penguins are extremely susceptible to *Plasmodium* infection and have been treated successfully with a combined treatment of chloroquine and primaquine phosphate (43).

Haemoproteus Infections

Haemoproteus infections are characterized by schizogony (merogony) in visceral endothelial cells, gametocyte development in circulating erythrocytes, and the presence of pigment in granules in infected erythrocytes. Transmission is by various biting dipterans of the families Hippoboscidae and Ceratopogonidae (58). Characteristics of *Haemoproteus* are similar enough to *Plasmodium* and *Leucocytozoon* that the genera are placed in the same family, Plasmodiidae. Infections occur throughout tropical and temperate areas of the New and Old Worlds wherever vector species and avian hosts coexist.

There are about 128 species of *Haemoproteus* that have been reported from birds, mostly in wild waterfowl, raptors, passerines, and some other families of birds (72, 75). In surveys of wild birds, *Haemoproteus* species are the most commonly identified blood parasite. Many of the reported species become synonymous as life cycles are defined and cross-transmission studies are conducted, as shown by Bennett and coworkers (8, 116).

Species found in domestic poultry and pet birds include *Haemoproteus meleagridis*, in domestic and wild turkeys (44); *H. columbae* and *H. saccharovi* in pigeons and doves; and *H. nettionis* in waterfowl (78).

Etiology

H. columbae of pigeons and doves is the most extensively studied of these parasites. Sporogony occurs in 2 families of flies. Sporogony is completed in 6–7 days in the ceratopogonids or in 7–14 days in the hippoboscids. Schizonts (meronts) of various sizes and numbers of merozoites occur in the pulmonary vascular endothelium in alveolar septa of pigeons. The merozoites invade erythrocytes and mature into gametocytes (3). Further development requires ingestion by a suitable vector (arthropod) in a blood meal.

Vectors include the hippoboscid *Pseudolynchia canariensis* for *H. columbae* and the ceratopogonid *Culicoides* for *H. nettionis* (70). Vectors for *H. meleagridis* include *C. edeni*, *C. hinmani*, *C. arboricoli*, *C. knowltoni*, and *C. haemoproteus* (5).

Atkinson (5) studied experimental infections of *H. meleagridis* in turkeys and partially defined the life cycle. He observed ookinetes, oocysts, sporozoites, and megaloschizonts, with at least 2 generations of schizogony. First-generation schizonts matured 5 and 8 days postinfection (PI) and produced elongate merozoites. Second-generation megaloschizonts developed after 8 and 17 days in cardiac and skeletal muscles and yielded spherical merozoites that developed into erythrocytic gametocytes (Fig. 28.18).

Pathogenesis and Pathology

Signs from experimental infections with *H. meleagridis* in turkeys include severe lameness, diarrhea, severe depression, emaciation, and anorexia (5). Anemia and enlarged livers occasionally are attributed to infections. Necropsy of wild turkeys revealed myopathy associated with megaloschizonts. Skeletal muscles contained numerous fusiform cysts oriented in parallel order with muscle fibers (6). Pigeons infected with *H. saccharovi* had enlarged gizzards. Muscovy ducks (*Carina moschata*) infected with *H. nettionis* suffered lameness, dyspnea, and sudden death with hemorrhage on the heart as well as edematous lungs and swollen firm livers, spleens, and kidneys, although this species was nonpathogenic for other species of ducks (64).

Diagnosis

The diagnosis of *Haemoproteus* infection requires microscopic examination of stained blood smears. Both restriction enzyme based methods and PCR asays have been developed which can
28.18. *Haemoproteus columbae*. Pigeon blood; (a, b) Macrogametocyte in erythrocyte. (c) Microgametocyte. (d, e) Normal erythrocyte. (Drake and Jones)

distinguish between *Haemoproteus* spp., *Plasmodium* spp., and *Leucocytozoon* spp. (7, 46).

Treatment and Control

Control of insect vectors may be of use in local situations (66). However, complete life cycles are not known for most species, precluding specific control recommendations. No drugs are approved for commercial use, although atebrin and plasmochin have marginal effects against *H. columbae* in experimental treatment

Trypanosomiasis

Although trypanosomes have been reported from many species of wild and domestic birds, their pathologic significance appears to be minimal or nil. Even the taxonomic grouping of these organisms is unclear.

Several species have been named, including *Trypanosoma avium*, *T. numidae*, *T. calmetti*, and *T. gallinarum*. The possibility that the latter 3 are synonyms of *T. avium* cannot be ruled out in absence of a rigorous taxonomic study (32). The ATCC lists two trypanosomes from avian species, *T. avium* and *T. bennetti* (72).

T. avium and its life cycle were described by Molyneaux (87), who summarized vector relationships for all avian trypanosomes and listed culicine mosquitoes and simuliids as known vectors.

Sarcocystosis

Sarcocystosis, previously called sarcosporidiosis, is caused by apicomplexan protozoa of the genus *Sarcocystis* Lankester 1882. The disease is recognized by the presence of elongated cysts (sarcocysts) located in muscles. The nature of the causative organism was unclear until discovery that coccidian oocysts are shed by the final host after eating flesh from another animal containing sar-

cocysts. These parasites are closely related to the *Eimeria* and other apicomplexans.

Sarcocystosis is not economically important to the poultry industry, but it occurs extensively in wild ducks and other birds. Many infected game birds are discarded by hunters for aesthetic reasons. Sarcocystosis from birds does not appear to be a public health hazard. The parasites are killed by cooking and storage at subfreezing temperatures. Mild signs were reported, however, by infected human volunteers given cysts from mammalian sources (72).

The apicomplexan nature of *Sarcocystis*, a controversial subject for the past century, and the historic aspects of sarcocystosis were reviewed by Spindler (104), Levine (73), Long (77), and Melhorn and Heydorn (83). Odening (93) provided a review of the taxonomy of *Sarcocystis* species, and Tenter (112) evaluated molecular methods used to clarify the taxonomy of this genus.

Incidence and Distribution

Avian sarcocystosis is found throughout the world in individual birds but is rare in domestic chickens. A study in northwest Ethiopia found that 6.6% of the chickens examined had sarcocysts within skeletal muscle specimens (118) but this high incidence of infection does not occur in modern poultry production systems. Two isolated cases of sarcocystosis in wild turkeys were reported in the southeastern United States (29, 111). The incidence is as high as 40% in ducks and 93% in grackles (34), and is influenced by species, age, and geographic location of the host. Sarcocystosis occurs more often in puddling than in diving ducks.

Etiology

Sarcocystis horvathi (*S. gallinarum*, *S. horvathi*) is the etiologic agent in chickens (74) and *S. rileyi* (*Balbiani rileyi*, *S. anatina*) in ducks. *Sarcocystis falcatula* has been described in numerous passerine, psittacine, and columbid species (74). Based on microscopic differences in the wall substance of microcysts, however, at least 5 different species of *Sarcocystis* are present in birds (25). These are two-host parasites, with a mammalian host serving as the definitive host.

Sarcocystis is classified in the phylum Apicomplexa, suborder Eimeriorina (74) and the family Sarcocystidae (72), and is characterized as multiplying by endodyogeny. Cysts or pseudocysts containing zoites are formed in parenteral cells of the host. It appears to have strong host specificity (73). The classification of *Sarcocystis* is based on discovery of its coccidial nature with a disporocystid (a tetrazoic isosporanlike oocyst), an obligatory two-host life cycle (often carnivore-herbivore), reproduction by endodyogeny, and characteristic ultrastructure (80, 100).

Morphology

Sarcocysts (third-generation meronts) of *S. rileyi*, also called Miescher's tubule, are elongate, with their long axis parallel to the muscle fibers (Fig. 28.19). They are whitish and smooth walled and appear cylindroid or spindle shaped when removed from the musculature. They are 1.0–6.5 × 0.48–1.0 mm (104). They have double-layered walls, an inner spongy fibrous layer,

28.19. Sarcocytosis in wild mallard; a severe, naturally occurring infection. (U.S. Dept Interior)

and an outer dense limiting membrane (73). Sarcocysts are divided into compartments, each of which contains numerous banana-shaped cystozoites (bradyzoites), also called Rainey's corpuscles. Cystozoites are 8–15 μm in length and 2–3 μm in width. Other developmental stages of *S. rileyi* are less well defined. The ultrastructure of *Sarcocystis* was described by Melhorn and Heydorn (83).

Life Cycle
Obligatory two-host life cycles have been described from 86 species of *Sarcocystis* (93). Two vertebrate hosts are required in the life cycle of all these species, usually a carnivorous predator or scavenger and the prey or food animal. Sexual reproduction occurs in the predator (definitive host) and asexual reproduction in the prey (intermediate host). The intermediate host becomes infected by fecal contamination from an infected definitive host.

Sarcocystis from shoveler ducks (*Anas dypeata*) were transmitted to the striped skunk (*Mephitis mephitis*) (20, 117). When muscle containing sarcocysts was eaten by skunks, sporocysts (1.4 × 12.4 μm) were shed sporadically from 19–63 days PI.

Shoveler ducks orally administered sporocysts developed microcysts (80 × 16 μm) in skeletal muscle 85 days later and macrocysts (1–3 × <1 mm) 154 days PI (20). The opossum was susceptible to infection with tissue cysts from ducks (31). In another study (101), the transmission of *S. falcatula* was demonstrated with the opossum (*Didelphis virginiana*) serving as the definitive host. Although asexual parasites were not found in ducks (*Anas platyrhynchos*) given fecal sporocysts from opossums, the intermediate host spectrum of some avian species of *Sarcocystis* is apparently quite broad (16). Sarcocysts from grackles and cowbirds are also infective to the opossum.

Levine (74) lists the chicken as the intermediate host and the dog as the definitive host for *S. horvathi*. The life cycle for *S. horvathi* is not completely defined.

The life cycle of *Sarcocystis* spp. is summarized as follows: In cardiac, smooth, or skeletal muscle tissues are eaten by a definitive host, releasing cystozoites that penetrate the intestinal wall and develop into macrogametocytes and microgametocytes in subepithelial tissues. Oocysts (containing 2 sporocysts, each with four sporozoites) are produced and are shed in feces as fully sporulated sporocysts. Sporozoites are released when sporocysts are ingested by the intermediate host, and invade the mucosa of the intestine. Schizogony (merogony) occurs in endothelial cells of various organs. After several asexual generations, the merozoites develop into young cyst stages, containing metrocytes and later cystozoites, and mature into the third-generation meronts (sarcocysts) in myocardial, skeletal, and smooth muscle tissues (80, 101).

Pathogenicity
The pathogenicity of sarcocystosis in birds is variable. The presence of sarcocysts in the skeletal muscle and heart of waterfowl is often an incidental finding, with no clinical disease being evident. In contrast some avian species develop serious or fatal sarcocystosis as the protozoa undergo schizogeny in the endothelium of the infected intermediate avian host (94). Isolated cases of sarcocystosis reportly cause severe debility and death in wild turkeys and backyard chickens (29, 90, 111). Similar fatal disease has commonly been reported in psittacine birds where pulmonary hemorrhage and edema are the cause of death (94). Box and Duszynski (14) attributed death of 4 of 12 sparrows and morbidity of 3 of 6 canaries to experimental sarcocystosis.

Pathogenesis and Epidemiology
Naturally occurring and experimental sarcocystosis has been reported in 59 species and 11 orders of birds, including domestic ducks, chickens, and wild turkeys (13, 29, 104).

Transmission, Carriers, and Vectors
Attempts at direct transmission of *S. rileyi* to young ducks by oral, intramuscular (IM), and intravenous (IV) administration of cystozoites and cohabitation with infected ducks were unsuccessful, emphasizing the requirement of a second host (105).

Sporocyst-contaminated food is the common source of infection for the intermediate host (birds); infection in the carnivorous

definitive host (mammal) results from ingestion of sarcocyst-infected tissues of the intermediate hosts. Cystozoites from sarcocysts in confined migratory ducks were found to be viable for 3 years. Thus, intermediate hosts may serve as an available source of infection for prolonged periods over a widespread area. Sarcocytosis appears to be most prevalent in hosts that frequently drink from shallow or stagnant water (puddling ducks, cattle, sheep, or swine) (104).

Incubation Period

Infections are seldom found in juvenile grackles (34) or in juvenile ducks, suggesting a long incubation period. Microcysts and macrocysts were found in ducks 85 and 154 days PI, respectively (20), and macrocysts were observed in sparrows and canaries 70 days PI (15).

Clinical Signs

Sarcocysts usually are found in the skeletal muscles of birds. Spindler (104) reported that very heavy infections may cause signs of disease, and ducks may fly low and slowly. Adverse signs were not observed in experimentally infected ducks (20). Box and Duszynski (14) noted labored breathing and morbidity in canaries and sudden death in sparrows given oocysts. Psittacine birds with acute sarcocystosis likewise develop marked respiratory signs prior to death (94). Chickens with *Sarcocystis*-associated encephalitis exhibit distinct neurologic signs (90).

Gross Lesions

Sarcocysts running lengthwise in the musculature of the breast, thigh, neck, or esophagus are the usual lesions associated with avian sarcocytosis. Lung consolidation and splenomegaly were observed in infected canaries (14), and pulmonary edema and hemorrhage, hepatomegaly, and splenomegaly have been described in psittacine birds (90, 94). Lesions have not been seen in definitive hosts with experimental infections.

Histopathology

Fatty degeneration of muscles, enlargement and rupture of parasitized muscle fibers, and inflammatory responses around sarcocysts in muscles were reported (104). *Sarcocystis*-associated encephalitis has been described in chickens, turkeys, and other nondomesticated avian species (29, 90, 111). Systemic sarcocystosis has been described in a wild turkey with inflammatory changes associated with protozoal schizonts and merozoites in the heart, lung, and liver (29).

Immunity

Active and passive immunity have not been demonstrated. Animals have been immunized against sarcocystosis by repeated injections of untreated or formalin-treated toxin. Serum from immunized animals gives protection to other animals against the toxin (104).

Zoonotic Disease

While human cases of sarcocystosis do occur, they are typically asymptomatic and have been exclusively associated with the consumption of raw or undercooked beef or pork. (1).

Diagnosis

Diagnosis is based on the identification of sarcocysts or cystozoites in tissues. Large sarcocysts are seen easily in gross specimens; smaller cysts and cystozoites can be identified by histologic examination of muscle tissue. *Sarcocystis* schizonts and merozoites can be differentiated from other systemic protozoal infections (*Toxoplasma* and *Neospora*) by immunohistochemistry (81, 90). Molecular techniques using PCR amplification and restriction endonuclease digestion are also be used in the identification of *Sarcocystis* species (28). Infections of *Sarcocystis* may be diagnosed in the definitive host by identification of sporocysts in feces.

Serology

Sarcocystis reacts with cytoplasm-modifying antibody in the Sabin-Feldman dye test but cross-reacts with *Toxoplasma* (104). An indirect fluorescent antibody test in which cystozoites were used as the antigen was successful (114). Munday and Corbould (89) devised a complement-fixation test using an antigen prepared from sarcocysts and found that a titer of 1:10 was indicative of sarcosporidial infections. Serologic reactions have not been applied extensively in the diagnosis of sarcocystosis in birds.

Prevention and Control

Chemotherapy of avian sarcocystosis has no practical application at this time. The lack of chemotherapeutic or biologic control agents places the burden of control on prevention by breaking the infection cycle. Modern poultry production systems prevent the occurrence of sarcocystosis as the avian intermediate host is not exposed to the oocyst-contaminated excreta of the definitive host.

Toxoplasmosis

Toxoplasmosis is a parasitic disorder of mammals, birds, and reptiles affecting primarily the central nervous system but sometimes also the reproductive system, skeletal muscles, and visceral organs. The majority of infections are inapparent or latent, with overt toxoplasmosis resulting at times of stress or immunosuppression.

Only sporadic cases of toxoplasmosis in chickens and turkeys have been reported (26, 41, 95, 99). Studies of avian tissues using the mouse inoculation test and histologic examination indicate that a somewhat higher incidence of infection exists than is apparent based on the observation of clinical disease. Nevertheless, the disorder is uncommon in chickens and is of little significance to the health of commercial poultry.

Toxoplasmosis is a significant zoonotic disease and a human health problem of increasing importance due to a growing immunodeficient population (104). Humans are typically exposed to the disease by the ingestion of oocysts shed by felids, congenital infection, or the consumption of raw or undercooked meat products (113). Serologic prevalence of *Toxoplasma* infection in humans typically ranges between 10% and 80% and varies markedly based on environmental conditions and cultural dietary habits (113). An average seroprevalence of 14% was reported in

the United States (37). A multi-country case-control study of the source of *Toxoplasma* infection in pregnant women revealed that the greatest risk factors were ingestion of undercooked meats, soil contact, and travel outside of Europe and North America (21). Poultry products were not implicated as a significant risk factor in this study.

The true nature of *Toxoplasma* as close relatives of *Eimeria* was not known until 1969. The literature presents extensive overviews of history and current knowledge of toxoplasmosis (26, 37, 58, 62, 73, 113).

Etiology

A single species, *Toxoplasma gondii*, is the cause of toxoplasmosis in all hosts. Synonyms for the agent in avian hosts are *T. avium* and *T. paddae*.

T. gondii is a coccidian with sexual stages similar to *Isospora* (50). Endodyogeny, however, is unique to *T. gondii*. *Toxoplasma* is classified in the family Sarcocystidae, along with *Sarcocystis*, in the suborder Eimeriorina and phylum Apicomplexa (72).

Numerous *Toxoplasma* isolates have been designated strains based on differing pathogenicity in different hosts rather than on immunologic variation, although the latter may occur with some strains.

Free *T. gondii* zoites are crescent shaped (4–6 × 2–3 μm), with one extremity more rounded than the other and a nucleus near the rounded end. No pseudopods, cilia, or flagella are present. Ultrastructure of developmental stages was reviewed by Levine (73) and Ferguson *et al.* (38).

Life Cycle

Both schizogonic and gametogenic developmental cycles are known to occur in the intestinal epithelium of some members of the cat family (Felidae). Both an "enteroepithelial" cycle and an "extraintestinal" cycle have been described.

The enteroepithelial cycle occurs only in cats, resulting from infection by encysted organisms (bradyzoites), free or intracellular individual organisms (tachyzoites), or oocysts (35). The prepatent period is 24 days or longer if oocysts are ingested, 5–10 days after ingestion of tachyzoites, and only 3–5 days if bradyzoites are the source of infection. Asexual development (schizogony) occurs in the intestinal epithelium.

The sexual phase also occurs only in intestinal epithelial cells of Felidae. Gametocytes develop throughout the small intestine but more commonly in the ileum. Microgametocytes (7–10 × 5–8 μm) give rise to 12–32 microgametes (2–5 μm). Following fertilization of the macrogamete (13 μm), oocysts develop and detach unsporulated from the intestinal epithelium. Oocysts are shed for 7–20 days. Sporulation is complete in 1–5 days, depending on the environmental temperature and oxygen and results in the development of 2 sporocysts (6–8 × 5–7 μm), each containing 4 sporozoites.

In birds and other nonfelines, only the extraintestinal (tissue) cycle of *T. gondii* is known. After ingestion, *T. gondii* tachyzoites reproduce by endodyogeny within parasitophorous vacuoles of many cell types. Tachyzoites may spread to the brain, eye, heart, liver, lungs, and nucleated red blood cells of birds.

Eight or more tachyzoites are produced in a host cell. A final generation of tachyzoites develops into tissue cysts, in which bradyzoites multiply by endodyogeny (113). Encysted bradyzoites develop intracellularly in the brain, heart, eyes, and skeletal muscles but are walled off as immunity develops. Cysts may persist for the life of the host or, if immunity wanes, bradyzoites may be released and a proliferation of tachyzoites renewed. The tissue cycle may reverse again and cysts form from tachyzoites (59, 62, 113).

Pathogenesis and Epidemiology

Infective oocyts of *T. gondii* are produced only by members of the Felidae (domestic cats, ocelots, pumas, jaguarundi, bobcats, and Asian leopards) (62). More than 63 species of birds and 27 species of other animals become infected from ingestion of oocysts and develop cysts in tissues without passing oocysts in the feces (99). Naturally occurring infections have been diagnosed in the chickens, turkeys, ducks, and many wild birds (17, 41, 78, 95). Ruiz and Frenkel (96) isolated *T. gondii* from 54% of chickens that were reared in small backyard poultry flocks in Costa Rica. In contrast, Kuticic (71) found that only 0.4 % of commercial chickens cultured positive for *T. gondii* in Croatia. Presumably, commercial chickens have little exposure to *T. gondii* oocysts, in contrast with free-range birds.

Transmission, Carriers, and Vectors

T. gondii has been reisolated from Japanese quail, bluejays, crows, turkeys, and chickens after experimental infections (27, 85). Tachyzoites and bradyzoites may be spread to birds by carnivorous ingestion, and sporulated oocysts are spread by cat feces.

The question of congenital infection occurring in chicks from naturally infected parents remains unresolved. Jacobs and Melton (60) found that 12 of 62 pools of reproductive tract tissues from chickens were infected with *T. gondii*, but the parasite could not be isolated from any of 108 eggs from these hens. In another study, 1 of 327 eggs from hens with chronic toxoplasmosis was positive. Iannuzzi and Renieri (52) concluded that toxoplasmas did not survive in unembryonated eggs and was not a factor in transmission. However, Caballero-Servin (18) reported successful transovarian transmission of the parasite by experimentally infecting hens, which resulted in embryonic mortality and congenital malformation of 18% of the surviving chicks.

Coprophagous arthropods such as flies and cockroaches can serve as transport hosts for the *Toxoplasma* (115). Earthworms ingest *Toxoplasma* oocysts and are a source of infection for chickens (96).

Course of the Disease

During the 1950s, several cases were reported that involved 12–50% of the chickens within a flock (12, 26). Clinical signs in affected chickens included anorexia, weight loss, pale combs, spasms, paralysis, and a loss of eyesight (26). In a recent case report, chickens affected with *T. gondii*-induced peripheral neuritis were emaciated and had difficulty standing (41). A wild turkey with systemic toxoplasmosis was emaciated, weak, and readily captured (95).

Susceptibility of chickens to *T. gondii* may vary with age of host, strain of infective agent, and route of infection. Oral inoculation with 10^3 or 10^5 *Toxoplasma* oocysts (30, 65) produced no clinical signs in 4-week-old chickens. Further, chickens inoculated with tachyzoites by intravenous or oral route showed no clinical disease or adverse production effects (65). Turkeys were also resistant to the oral inoculation of *Toxoplasma* oocysts (27).

Inoculation of chicks with tissue cysts by abnormal routes such as intracerebral (IC)(12) or intraperitoneal (IP) routes (67) produced clinical signs. Inoculation with tissue cysts IV, IP, IM, and SC also produced parasitemia and chronic infections in older birds. Clinical signs in experimentally inoculated chickens include anorexia, emaciation, paleness and shrinking of the comb, drop in egg production, whitish feces, diarrhea, incoordination, ataxia, trembling, opisthotonos, torticollis, blindness, and high mortality (11, 12, 67, 78).

Gross Lesions

Gross lesions include enlargement of liver and spleen, necrotic hepatitis, pericarditis, myocarditis, ulcerative enteritis, lung congestion, and encephalitis (12, 78).

Histopathology

In chickens inoculated by IC and IM routes, *Toxoplasma* tissue cysts were found in the cerebrum, brain stem, optic chiasma, and most frequently, around ventricles and in molecular and Purkinje layers of the cerebellum. Free trophozoites were seldom found, and then only in the brain. *Toxoplasma* cysts were found in the myocardium, pancreas, and testes of chickens infected intramuscularly (12).

Coagulation necrosis and diffuse sinusoidal congestion were observed in the liver. The myocardium, pancreas, and testes were diffusely infiltrated with lymphocytes, plasma cells, and heterophils. In the brain, infection caused lymphocytic lesions and plasma cell-cuffing of blood vessels; lymphocytic infiltration of choroid villi; ependymal proliferation of the lateral ventricle; thickening of leptomeninges; and gliosis of the lateral ventricle and around vessels of the cerebrum, brain stem, and cerebellum (12).

Oral inoculation of chickens with *Toxoplasma* oocysts produced focal necroses in the spleen, liver, and intestine and a mixed leukocyte infiltration (30). Lymphocytic foci were also noted in the myocardium, skeletal muscle and liver. Of the 12 chickens inoculated, only one developed lesions in the brain with perivascular leukocyte infiltration, gliosis, and one tissue cyst noted in the cerebrum (30).

Zoonotic Disease

Toxoplasmosis can affect numerous mammalian hosts, including humans, following the consumtion of oocytes shed by infected felids or uncooked meat containing infective *T. gondii* bradyzoites (1). Prevention of infection is by the sanitary disposal of cat feces and the thorough cooking of meat. Most postnatal infections are inapparent while congenitally acquired toxoplasmosis causes both severe disease and sequelae (1).

Diagnosis

T. gondii may be isolated and identified by injecting suspensions of infected tissues into various species of laboratory animals, chicken embryos, or cell cultures. Inoculation of mice IP or IC with suspensions of brain and heart are preferred methods of isolation (26). Mice inoculated with virulent strains die within a few days. Less virulent isolates may not produce mortality, and can only be detected serologically, or by examination for cysts 8–10 weeks after inoculation.

Impression smears of peritoneal fluids or tissues stained with Giemsa or tissue sections of brain, liver, spleen, lung, lymph nodes, and eye often suffice for direct microscopic observation of *Toxoplasma*.

Toxoplasma can be grown in the chorioallantoic cavity of 6–12-day-old embryonated chicken eggs. Embryos succumb 7–10 days PI with hemorrhage and nodular lesions in skin and viscera. Numerous yellow-white plaques 0.5–3.0 mm in diameter develop on the chorioallantoic and amniotic membranes. Smears of the chorioallantoic membrane and yolk sac stained with Wright's stain reveal numerous free and intracellular toxoplasmas.

Toxoplasma must be differentiated from other protozoa such as *Sarcocystis* and *Neospora*. Immunohistochemical stains capable of distinguishing between these species are available in several laboratories (29, 81, 90). A reliable PCR technique has been developed to detect *T. gondii* in formalin-fixed, paraffin-embedded tissue (51). The use of PCR testing in diagnosis of toxoplasmosis in fresh tissues was reviewed by Morgan (88).

Serology

Historically, avian toxoplasmosis serology testing was considered impractical because most avian species do not seroconvert using the human dye test. However, the modified agglutination test and ELISA test detected antibodies within 2 weeks of inoculation of chickens, and at 68 days post-inoculation (30). The latex agglutination test was judged insensitive in detecting *T. gondii* antibodies, and no antibodies were detected by the dye test or the indirect hemagglutination test. Other workers have used an ELISA test to demonstrate seroconversion in chickens and pigeons within 2 or 3 weeks of inoculation, respectively (11).

Treatment, Prevention, and Control

Chemotherapy has not been used to control avian toxoplasmosis. Prevention of avian toxoplasmosis requires management practices that eliminate the source of infective tachyzoites and oocysts by preventing exposure to rodents, coprophagous arthropods, and especially cats. Oocysts disseminated throughout the premises are resistant to common laboratory detergents, acids, and alkalis and are, therefore, difficult to destroy. However, they may be destroyed by ammonia, drying, and a temperature of 55°C (73).

V Noninfectious Diseases

Chapter 29
Nutritional Diseases

Kirk C. Klasing

Poultry require the presence of at least 36 nutrients in their diet in appropriate concentrations and balance (Table 29.1). Commonly available feedstuffs are usually deficient in many nutrients, and diets must be supplemented with the deficient nutrients, usually from purified sources. Errors in the formulation or milling may sometimes result in deficient or toxic levels of one or more nutrients. Severely deficient or toxic levels often are expressed as characteristic pathologies to organs and tissues. Marginally inadequate supplies often result in suboptimal growth, impaired resistance to infectious diseases, decreased egg production, or lowered hatchability. Frequently, it is the task of the veterinarian to determine whether an ailment is nutritional in its origin or whether nutrition is a contributing factor to a specific clinical problem. It may be difficult to recognize a partial nutritional deficiency because nonspecific signs may be brought about by a number of causes, including infectious diseases and toxicants.

The quantitative nutrient requirements of the young growing chick and turkey and for light breeds of laying hens are quite well established (Table 29.1); however, the requirements of growing chicks and poults after the first few weeks of age and the requirements of male and female broiler and turkey breeding fowls for many nutrients have not been determined experimentally.

Food substances of importance in nutrition of poultry are water, proteins and amino acids, carbohydrates, fats, vitamins, and essential inorganic elements.

Water

Water holds a unique position in nutrition mainly due to its physical properties. Because of its solvent and polar properties, it acts as a transport medium for other nutrients and products of metabolism and enhances cell reactions. Because of its high specific heat, it can absorb the heat of reactions produced in the oxidation of carbohydrates and fats with little rise in temperature. Water evaporates readily, removing many calories from the body as latent heat of vaporization. These and many other functions explain why the animal can exist much longer without food than without water.

Unlike larger farm animals, chickens and turkeys must have access to a continuous water supply, because they drink only small amounts at a time. An insufficient amount results in decreased growth, egg production, and resistance to heat stress.

The quantity of water consumed by chicks is correlated directly with the salt content of their diet (5, 179). Sodium and potassium in the form of bicarbonate salts cause similar increases in water intake of broiler chicks. Chlorine and phosphorus also increase water intake, but not as much as sodium or potassium and calcium has little effect (12, 179). Excess dietary protein and deficiencies of amino acids result in increased water intake (12). The effect of protein is presumably due to increased excretion of nitrogen and minerals such as phosphorus and sulfur that are constituents of protein.

Proteins and Amino Acids

Commercial diets usually are formulated using a "least cost" approach, and meeting the protein and amino acid requirements impacts greatly the cost of the diet. For this reason, the limiting amino acids in the diet are typically supplied with very little margin of safety. The protein requirement represents the collective need for 10 absolutely essential amino acids (arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine), 2 amino acids (cysteine and tyrosine) that can be synthesized from essential amino acids, 2 amino acids that are essential for the young chick (glycine or serine and proline), plus additional amino acids to satisfy the nitrogen requirement for synthesis of nonessential amino acids, purines, pyrimidines, and other nitrogenous compounds.

Practical ingredients usually are limiting in one or more amino acids. Grains such as corn, milo, and wheat are most deficient in lysine; whereas soybean meal is most deficient in methionine. It is often cost effective to supply these limiting amino acids in the form of synthetic amino acids, especially lysine and methionine. Other amino acids such as threonine, tryptophan, arginine, and isoleucine can become limiting when unusual protein sources are used or when the dietary protein level is reduced. Diets that are devoid of animal byproducts are often fortified heavily with feed grade amino acids.

In contrast to the specific signs that may occur as a result of vitamin or mineral deficiencies, the effects of essential amino acid deficiencies are nonspecific: reduced growth, reduced feed consumption, decreased egg production and egg size, and loss of body weight in adults. The decrease in feed intake occurs within hours of consumption of a deficient diet and is due to a distortion in plasma and tissue amino acid levels. Marginal amino acid deficiencies often result in increased food intake or the maintenance of food intake, with concomitant reduction of body weight gain and lean tissue growth resulting in increased body fat. Severe deficiencies also result in altered body composition.

Table 29.1.   Nutrient requirements of poultry.[1]

Nutrient	Unit	Required Level			
		Egg-laying strain from 0–6 wk	White-egg layers at 100 % production	Broiler from 0–3 wk	Turkey from 0–4 wk
Crude protein	%	18.00	15.00	23.00	28.00
Arginine	%	1.00	0.70	1.25	1.60
Glycine + serine	%	0.70	–	1.25	1.00
Histidine	%	0.26	0.17	0.35	0.58
Isoleucine	%	0.60	0.65	0.80	1.10
Leucine	%	1.10	0.82	1.20	1.90
Lysine	%	0.85	0.69	1.10	1.60
Methionine	%	0.30	0.30	0.50	0.55
Methionine + cystine	%	0.62	0.58	0.90	1.05
Phenylalanine	%	0.54	0.47	0.72	1.00
Phenylalanine + tyrosine	%	1.00	0.83	1.34	1.80
Threonine	%	0.68	0.47	0.80	1.00
Trytophan	%	0.17	0.16	0.20	0.26
Valine	%	0.62	0.70	0.90	1.20
Linoleic acid	%	1.00	1.00	1.00	1.00
Calcium	%	0.90	3.25	1.00	1.20

Pyridoxine	mg/kg	3.00	2.50	3.50	4.50

[1]Requirements are taken from NRC (1994) and are based on diets with standard energy contents and a dry matter of 90%.

Some amino acids have additional effects. Methionine deficiency may exacerbate choline or vitamin B_{12} deficiencies owing to its role in methyl group metabolism. Lysine deficiency causes impaired pigmentation of bronze turkey poults, the biochemical basis of which is unknown (75), and can result in stunting and retarded development in chicks (Fig. 29.1). Arginine deficiency tends to cause the wing feathers to curl upward, giving the chick a distinct ruffled appearance. Several other amino acids have been reported to affect feather growth and structure (75, 159).

When animals are provided with dietary protein in excess of their requirements, the surplus protein is catabolized, and the nitrogen released is converted to uric acid. A large excess of protein may cause hyperuricemia and exacerbate articular urate deposition ("articular gout") in birds that are genetically susceptible
29.1. Lysine deficiency. Stunting and retarded development are apparent in this chick (right) fed a diet without sufficient lysine when compared with the normal control chick (left) fed adequate lysine. (Swayne)

(15, 178). Excesses of individual amino acids due to feed mixing errors are especially toxic. Methionine is the most toxic of the amino acids and also the amino acid most likely to supplemented to a poultry diet. The relative order of toxicity of amino acids for growing chickens fed a corn and soybean diet is methionine > phenylalanine > tryptophan > histidine > lysine > tyrosine > threonine > isoleucine > arginine > valine > leucine (59, 80). Acute toxicity of individual amino acids manifests as a severe decrease in food intake and usually can be diagnosed by high levels of the toxic amino acid in the blood. Oxidation of excess methionine results in the release of sulfate, which generates two moles of acid. Oxidation of phosphorylated amino acids and dibasic amino acids also contributes to metabolic acidosis. Thus, high levels of dietary protein or of methionine cause metabolic acidosis and may contribute to a variety of problems in poultry, including poor bone mineralization, thinning of eggshells, and poor growth.

Carbohydrates

This food component is the primary source of metabolizable energy in practical poultry diets. Starch and sucrose are used readily by the chick. Intestinal lactase activity is low in chickens; this limits the amount of lactose that can be tolerated. Milk by-products, such as whey, are excellent sources of B vitamins, and although beneficial at low levels, excessive levels in the diet cause growth depression and severe diarrhea. The latter condition, characteristic of lactose intolerance in many species, is caused by influx of water into the lower digestive tract and by microbial fermentation of undigested lactose.

Fats

Fats are important in the diet of poultry as concentrated sources of energy and sources of the essential nutrient linoleic acid. Linoleic acid cannot be synthesized but can be converted to

arachidonic acid by poultry. Both fatty acids are important constituents of cell organelles, membranes, and adipose tissue and have additional physiologic roles as precursors of prostaglandins. Lack of these fatty acids in the diet of young chicks results in suboptimal growth and enlarged fatty livers (90). Essential fatty acid deficiency in laying hens results in lowered egg production, egg size, and hatchability (133).

Reduced concentrations of arachidonic acid and increased concentrations of eicosatrienoic acid in tissue and egg lipids are a characteristic sign of essential fatty acid deficiency.

Unsaturated fatty acids may undergo oxidative rancidity, with multiple effects: Essential fatty acids are destroyed; aldehydes that are formed may react with free amino groups in proteins, reducing amino acid availability; and the active peroxides generated during rancidification may destroy activities of vitamins A, D, and E and water-soluble vitamins such as biotin. Producers of vitamin A supplements have enhanced the stability of this vitamin by mechanical means, wherein minute droplets of vitamin A are enveloped in a stable fat, gelatin, or wax, forming a small bead that prevents most of the vitamin from coming into contact with oxygen until it is digested in the intestinal tract. The addition of synthetic antioxidants to poultry feeds provides further protection of vitamin A and other essential nutrients.

Vitamins

The term vitamin refers to a heterogeneous group of fat-soluble and water-soluble chemical compounds essential in nutrition that bear no structural or necessary functional relationship to each other. All recognized vitamins with the exception of vitamin C are dietary essentials for poultry. Although amounts of various vitamins needed in poultry diets range from parts per million to parts per billion, each is required for normal metabolism and health.

A marked deficiency of a single vitamin in the diet of a chick or poult results in failure of the metabolic process in which that particular vitamin is concerned. This causes a vitamin-deficiency disease, which in some instances exhibits characteristic macroscopic or microscopic changes. In several instances, a single disease may result from a deficiency of any one of several nutrients. Chondrodystrophy ("perosis"), for example, occurs in young chicks or poults when the diet is deficient in manganese or any one of the following vitamins: choline, nicotinic acid, pyridoxine, biotin, or folic acid. Chondrodystrophy is an anatomic deformity of leg bones of young chickens, turkeys, pheasants, and other birds, which is characterized by decreased linear bone growth, enlargement of the tibiometatarsal joint, twisting or bending of the distal end of the tibia and proximal end of the metatarsus, with secondary varus or valgus deformation of the legs, and, finally, slipping of the gastrocnemius tendon from its condyles. This last lesion causes complete crippling in the affected leg; if both legs are affected, death usually results because the chick or poult cannot secure food and water. Analysis of the diet may be the only way to determine whether a specific nutritional deficiency is responsible for the condition.

Vitamins A and D and riboflavin are most likely to be deficient

if special attention is not given to provide them when feed is formulated. Because of extraction and purification of many common ingredients, however, and the tendency to omit animal proteins and high-fiber ingredients such as alfalfa meal and wheat mill by-products from diets, amounts of several other vitamins have decreased to sometimes deficient levels. These are vitamins E, B_{12}, and K; pantothenic acid, nicotinic acid, biotin, and choline. Poultry rations usually are formulated to contain more than adequate amounts of all vitamins, providing margins of safety to compensate for possible losses during feed processing, transportation, and storage, and variations in feed composition and environmental conditions.

Vitamin A

Vitamin A is essential in poultry diets for growth, optimal vision, and integrity of mucous membranes. Because epithelial linings of alimentary, urinary, genital, and respiratory systems are composed of mucous membranes, these are the tissues in which lesions of vitamin A deficiency are most readily observed. Vitamin A aldehyde, or retinal, is a component of visual pigments in sensory cells of the retina within which cis-trans isomerization of the isoprenoid side chain plays an essential role in the detection of light. Vitamin A, as retinoic acid, functions in morphogenesis during embryonic development, the maintenance of epithelial tissues, mucus production, bone growth, immunity, and a variety of other essential processes. Most dietary vitamin A is in the form of retinol and retinal, which are oxidized by cells to retinoic acid. Retinoic acid mediates the effects of vitamin A by regulating gene expression.

Vitamin A Deficiency
Clinical Signs and Signalment. When adult chickens or turkeys are fed a diet severely deficient in vitamin A, signs and lesions usually develop within 2–5 months, depending on the amount stored in liver and other tissues of the body. As deficiency progresses, chickens become emaciated and weak, and their feathers are ruffled. Egg production decreases sharply; the length of time between clutches increases; and hatchability is decreased. A watery discharge from the nostrils and eyes is noted, and eyelids are often stuck together. As the deficiency continues, milky white, caseous material accumulates in the eyes. At this stage of the disease, eyes fill with this white exudate to such an extent that it is impossible for the chicken to see unless the mass is removed; in many cases, the eye is destroyed. Most signs in adult turkeys are similar to those in chickens (16, 88).

Marginal deficiencies of vitamin A may cause epithelial damage in the oropharynx and esophagus without accompanying growth depression (16). More severe deficiencies result in keratinization of intestinal enterocytes, a decrease in the number of goblet cells, decreased alkaline phosphatase activity, decreased expression of brush-border enzymes, and blunting of villi. Impaired growth rate of deficient broiler chicks appears to be secondary to diminished digestive function (200). The incidence and severity of blood spots in eggs of chickens is increased in vitamin A deficiency. The amount of vitamin A required to minimize blood spot incidence may be slightly higher than the re-

quirement for good production and health of the laying hens (87, 154). Vitamin A deficiency also results in abnormal embryonic development (201).

Vitamin A-deficiency signs in chicks and poults are cessation of growth, drowsiness, weakness, incoordination, emaciation, and ruffled plumage. If deficiency is severe, they may show ataxia not unlike that of vitamin E deficiency (87), although the 2 conditions can be differentiated by histologic examination of the brain (3). Periorbital edema may occur (Fig. 29.2A). In acute vitamin A deficiency, lacrimation usually occurs, and a caseous material may be seen under the eyelids. Xerophthalmia may not be observed because in acute deficiency, chicks often die of other causes before the eyes become affected. Increased testes weight, spermatogenesis, and comb development may occur in young cockerels marginally deficient in vitamin A (140). Vitamin A-deficient cocks have decreased sperm counts, reduced sperm motility, and a high incidence of abnormal sperm (148).

Pathology. Vitamin A-deficiency lesions first appear in the pharynx and are confined largely to mucous glands and their ducts. The original epithelium is replaced by a keratinizing epithelium (i.e. squamous metaplasia) that blocks ducts of the mucous glands, causing them to become distended with secretions and necrotic materials. Squamous metaplasia can be found in nasal mucosa (Fig. 29.2B). Small white nodules are found in the nasal passages, mouth, esophagus, and pharynx and may extend into the crop. Nodules range in size from microscopic lesions to 2 mm in diameter (Fig. 29.2C). As the deficiency progresses, lesions enlarge, are raised above the surface of the mucous membrane, and have a depression in the center. Small ulcers surrounded by inflammatory products may appear at the site of these lesions. This condition resembles certain stages of fowl pox, and the 2 conditions can be differentiated only by microscopic examination. Bacterial and viral infections often occur because of breakdown of the mucous membrane.

Clinical signs and lesions of vitamin A deficiency of the respiratory tract are variable; it is difficult to differentiate this condition from infectious coryza, fowl pox, and infectious bronchitis. In vitamin A deficiency, thin diphtheritic membranes and nasal plugs usually are limited to the cleft palate and its adjacent epithelium. They may be removed easily without bleeding. Atrophy and degeneration of the respiratory mucous membrane and its glands occur. Later, the original epithelium is replaced by a stratified squamous keratinizing epithelium. In early stages of vitamin A deficiency in chickens, turbinates are filled with seromucoid water-clear masses that may be forced out of the nodules and cleft palate by application of slight pressure. The vestibule becomes plugged and overflows into paranasal sinuses. Exudate may also fill sinuses and other nasal cavities, causing swelling of one or both sides of the face. Mucous membranes, cleared of inflammatory products, appear thin, rough, and dry.

Similar lesions frequently may be found in the trachea and bronchi. In early stages, these may be difficult to see. As the condition progresses, the mucous membrane is covered with a dry, dull fine film that is slightly uneven, whereas a normal membrane is even and moist. In some cases, small nodule-like parti-

cles may be found in or beneath the mucous membrane in the upper part of the trachea.

Chronic vitamin A deficiency causes damage to the kidney tubules, which leads to azotemia and visceral urate deposits (e.g., "visceral gout") in severe cases (178).

Histopathology. The first histologic lesion of vitamin A deficiency is atrophy and deciliation of columnar-ciliated epithelium of the respiratory tract (174). Nuclei often present with marked karyorrhexis. A pseudomembrane formed by the atrophying and degenerating ciliated cells may hang as tufts on the basement membrane; later these are sloughed. During this process, new cylindric or polygonal cells may be formed singly or in pairs and appear as islands beneath the epithelium. These new cells proliferate, and their nuclei enlarge, containing less chromatin as they develop. Cell boundaries are less clearly defined; finally, the columnar ciliated epithelial lining of nasal cavities and communicating sinuses, trachea, bronchi, and submucous glands are transformed into a stratified squamous keratinizing epithelium. Lesions in glands of tongue, palate, and esophagus (Fig. 29.2D) are similar to those of the respiratory tract (175).

Histopathologic examination of tissues from nasal passages of chicks serves as a sensitive indicator of borderline deficiencies of vitamin A (101). Chicks receiving suboptimal levels show lesions that resemble in basic character, but not in severity, those described by Seifried (174) for complete deficiency of vitamin A.

According to Wolbach and Hegsted (221, 222), vitamin A deficiency in young chicks and ducks causes marked retardation and suppression of endochondral bone growth. The proliferating zone is reduced. Hypertrophied cells accumulate, surrounded by uncalcified matrix. Vascular invasion of the epiphyseal cartilage is reduced and exhibits irregular patterns such as branching. The number of endosteal and periosteal osteoblasts is decreased, leading to impaired bone growth and thinning of bone cortex. Bone remodeling is inhibited. Disproportionate growth of brain and spinal cord relative to that of the axial skeleton appears to cause compression of brain tissue. Increased cerebrospinal fluid pressure is one of the earliest signs of vitamin A deficiency (224).

An increased frequency of atretic ovarian follicles containing hemorrhages either throughout the follicle or between the theca interna and granulosa cell layer has been observed in chickens exposed to vitamin A deficiency over a period of 5–8 months (25). Vitamin A deficiency has been reported to decrease hatchability of chicken and turkey eggs and to increase mortality of chicks and poults that do hatch (10, 87). Thompson *et al.* (195) produced a severe vitamin A deficiency in developing embryos by supplementing breeder diets with retinoic acid. This form of vitamin A permits egg production but does not support embryonic development. Embryos die—always in the same stage of development. The complete trunk and head are formed, and the head is rotated slightly to one side. No differentiation of major blood vessels occurs, and an expanded area of vasculosa is seen forming a "blood ring" at the sinus terminalis.

Treatment of Deficiency. Poultry found to be severely deficient in vitamin A should be given a stabilized vitamin A preparation at a level of approximately 10,000 IU vitamin A/kg of ration. Absorption of vitamin A is rapid; therefore, chickens or turkeys not in advanced stages of deficiency should respond promptly, except for blindness, which may be permanent.

Hypervitaminosis A
Baker *et al.* (20) reported that the administration of 200 mg retinyl acetate per kg of body weight per day to growing chickens adversely affects skeletal development. Chicks have lighter and shortened tibiae exhibiting widened epiphyseal growth plates with irregular tunneling by blood vessels. Widening results from increased numbers of hyperplastic chondrocytes. Bones exhibit reduced osteoblastic activity and increased bone and blood alkaline phosphatase activity. Ventricular dilation and brain swelling are also observed.

Tang *et al.* (191) administered 330 or 660 IU vitamin A per kg body weight per day to commercial broilers. Chicks had an unsteady gait and were reluctant to walk within a few days of treatment with excess vitamin A. They became anorexic by 9 days and developed conjunctivitis, adhesions of the eyelids, and encrustations around the mouth. Tibiae had widened epiphyseal growth plates due primarily to accumulation of hypertrophic chondrocytes. These investigators reported other abnormalities of the tibia including hyperosteoidosis and metaphyseal sclerosis. Frontal bones of the skull were thinner and more porous and exhibited thickened osteoid seams.

Signs of hypervitaminosis A in leghorn chicks differed from those of broiler chicks administered similar levels of vitamin A (191). The epiphyseal growth plates in tibiae from leghorn chicks were normal in width but contained a narrower proliferative or maturation zone and a wider hypertrophic zone. Osteoid seams were normal. Leghorns had normal parathyroid morphology, whereas parathyroid hyperplasia was observed in broiler chicks.

It must be noted that the reported histopathology of hypervitaminosis A is not entirely consistent among laboratories. The nature of the cell population contributing to widening of the epiphyseal growth plate differed in the preceding studies (20, 191). Wolbach and Hegstead (220, 223), moreover, reported that vitamin A excess caused narrowing of the growth plate in their early studies involving young chicks and ducks.

Vitamin D
Vitamin D is required by poultry for proper metabolism of calcium and phosphorus in the formation of normal skeleton, hard beaks and claws, and strong eggshells. It functions in the regulation of calcium metabolism by stimulating the intestinal absorption of calcium, influencing osteoblast and osteoclast activity, and increasing renal tubular reabsorption of calcium in response to metabolic demands for calcium.

Vitamin D can be synthesized from 7-dehydrocholesterol in the skin under the influence of ultraviolet light. Although this synthesis can reduce the dietary requirement for vitamin D to some extent (62), it is not sufficient to satisfy the requirements of fowl under normal conditions of poultry and egg production. Poultry diets commonly are supplemented with cholecalciferol (vitamin D_3); however, 25-hydroxycholecalciferol is also some-

times used and has a slightly higher bioavailability when fed at low levels (11). The plant source of vitamin D activity, ergosterol (vitamin D_2), is not efficiently used by poultry (41) and is not usually used as a supplement.

The metabolically active form of vitamin D is formed by 2 enzymatic hydroxylations of cholecalciferol (vitamin D_3), the first yielding 25-hydroxycholecalciferol in the liver, and the second yielding 1,25-dihydroxycholecalciferol in the kidneys (8, 55). The second hydroxylation is tightly regulated by calcium status, being activated by low blood calcium, phosphate or parathyroid hormone. 1,25-dihydroxycholecalciferol is much more potent in promoting calcium absorption and bone mobilization than its precursors, vitamin D_3 and 25-hydroxycholecalciferol. Many other hydroxylation products of 25-hydroxycholecalciferol have been identified. In particular, 24R,25-dihydroxyvitamin D_3 appears to be an essential vitamin D_3 metabolite for both normal bone integrity and healing of fracture in chicks (176).

Vitamin D Deficiency

Clinical Signs and Signalment. In confined laying hens, signs of deficiency begin to occur as soon as 2 weeks after they are deprived of vitamin D. The first sign is a marked increase in the number of thin-shelled and soft-shelled eggs, followed soon after by marked decrease in egg production. Biochemical indicators include a rapid decrease in the concentrations of 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol in the blood, followed soon thereafter by a decrease in blood calcium concentration (176, 197, 199). Egg production and eggshell strength may vary in a cyclic manner. Several cycles of decreased egg production and shell strength may each be followed by periods of relatively normal production and shell strength.

Individual hens may show temporary loss of the use of the legs, with recovery after laying an egg that is usually shell-less. During periods of extreme leg weakness, hens show a characteristic posture that has been described as a "penguin-type squat." Later, beak, claws, and keel become very soft and pliable. The sternum usually is bent, and ribs lose their normal rigidity and turn inward at the junction of the sternal and vertebral portions, producing a characteristic inward curve of the ribs along the sides of the thorax.

Vitamin D metabolism has been implicated in problems of eggshell quality. Soares *et al.* (180) reported that 2 strains of chickens that had been selected for divergence in eggshell strength and thickness differed in their blood concentrations of 1,25-dihydroxycholecalciferol: The strain having higher eggshell quality also had significantly higher concentrations of the vitamin D metabolite. When hens of a commercial strain of leghorns received 30 μg of vitamin D_3 or 5 mg of 1-α-hydroxycholecalciferol (a putative synthetic precursor of 1,25-dihydroxycholecalciferol), the latter resulted in greater tibial calcium and phosphorus content, tibial breaking strength, and eggshell mineralization. Bar *et al.* (21) reported that the inclusion of 2 or 5 μg/kg of 1,25-dihydroxycholecalciferol in the diet of aging hens increased shell weight and density in the first egg of the clutch and decreased the rate of decline of both measures in subsequent eggs of the clutch. Other studies (197, 198, 199) confirm that 1,25-dihydroxychole-

calciferol supports egg production and is effective in promoting eggshell mineralization and minimizing eggshell breakage when it is used at a concentration of 5 μg/kg in the diet of leghorn hens.

Hatchability is reduced markedly by vitamin D deficiency. Chicks and poults that do not hatch have a high incidence of chondrodystrophy in which the upper or lower mandible is shortened to the extent that occlusion of the mandibles is abnormal (183, 186). The synthetic vitamin D analogues 25-hydroxycholecalciferol, 1-α-hydroxycholecalciferol, and 1,25-dihydroxycholecalciferol support adequate egg production and eggshell strength, but only 25-hydroxycholecalciferol is effective in supporting hatchability (1, 8). Evidence strongly suggests that the other 2 analogues are poorly transported into the egg (8, 64, 181). Manley and coworkers (127) reported that the addition of 1100 ICU of 25-hydroxy-cholecalciferol to diets of turkey hens that already contained 2200 ICU of vitamin D_3 improved the hatchability of fertile eggs. This interesting observation appears at odds with other evidence that 900 IU of vitamin D_3 per kilogram of diet is adequate for hatchability of turkey eggs (183).

In addition to retarded growth, the first sign of vitamin D deficiency in chicks or poults is rickets, characterized by severe fragility and bending of long bones due to poor mineralization. Between 2 and 3 weeks of age, beaks and claws become soft and pliable, and birds walk with obvious effort and take a few unsteady steps before squatting on their hocks, which they rest upon while swaying slightly from side to side. Feathering is poor. A marked increase in serum phosphatase is perhaps the first indicator of a borderline rachitic condition.

Pathology. In laying and breeding chicken and turkey hens receiving deficient vitamin D, characteristic changes observed on necropsy are confined to bones and parathyroid glands. The latter become enlarged from hypertrophy and hyperplasia. Bones are soft and break easily. Well-defined knobs are present on the inner surface of the ribs at the costochondral junction (rachitic rosary) (Fig. 29.2E). Many ribs show evidence of pathologic fracture in this region. In chronic vitamin D deficiency, marked skeletal distortions become apparent. The spinal column may bend downward in the sacral and coccygeal region; the sternum usually shows a lateral bend and an acute dent near the middle of the breast. These changes reduce the size of the thorax with consequent crowding of vital organs. The beak may be soft and pliable (Fig. 29.2F).

The most characteristic internal signs of vitamin D deficiency in chicks and poults are a bending of the ribs at their juncture with the spinal column and a bending of the ribs downward and posteriorly (Fig. 29.2E). Poor calcification can be observed at the epiphysis of the tibia or femur (Fig. 29.3). Bones of vitamin D-deficient chicks have reduced calcium content with an increased proportion of osteoid, and a greater proportion of bone mineral is present as a low-density amorphous form of calcium phosphate (57).

Vitamin D deficiency results in widening of the epiphyseal plate, hypertrophy, and softening of bone. Enlargement of the epiphyseal plate initially is due to widening of the proliferating and hypertrophic zones; as the deficiency progresses, it may be
29.3. Effects of nutrient deficiencies on tibiotarsal bones of broiler chickens. (Swayne) A. Control fed an adequate diet. B. Phosphorus deficiency. Prominent wide zone of hypertrophy. C. Calcium/phosphorus deficiency. Widened zone of proliferation. D. Lysine deficiency. Hypoplasia.

primarily the former (83, 92, 123). Long and coworkers (123) noted that the hypertrophic zone exhibits irregular contours—wider in some areas and narrower in others—among and within affected birds. The widening of the proliferating zone appears to be the result of delayed chondrocyte hypertrophy rather than increased chondrocyte replication (109). As the deficiency progresses, the columns of chondrocytes in the degenerating hypertrophic zone of the epiphyseal plate become shortened and thickened and exhibit an irregular pattern of invasion by metaphyseal blood vessels. Irregular patterns of cartilage and bone development occur in the primary and secondary spongiosa (92, 123). Porosity of cortical bone, sometimes leading to fractures (Fig. 29.2G), increases due to resorption of bone in haversion canals. Fractures also may occur elsewhere (Fig. 29.2H). Decrease in trabecular bone volume due to increased osteoclast resorbing activity contributes to diminished mechanical strength of long bones (103). Increasing the dietary calcium level to levels twice those normally required maintains normal epiphyseal cartilage width and metaphyseal bone histomorphology and mineralization in chicks fed vitamin D deficient diets (103).

The histopathology of rickets differs significantly depending on the cause of the disease (109, 121, 122, 123). Refer to the section on calcium and phosphorus for further information on this topic.

Another skeletal disorder, tibial dyschondroplasia, frequently is observed in broiler chickens (refer to Chapter 31 for a description of the pathology). It has been produced experimentally by decreasing the ratio of calcium to phosphorus in the diet (60, 155) or by altering the ratio of these nutrients and increasing the dietary concentration of anions, such as chloride (79). This condition persists even when experimental diets contain generous levels of vitamin D_3 (212). The incidence and severity of tibial dyschondroplasia were reduced or prevented when the diets were supplemented with 1,25-dihydroxycholecalciferol (61, 63, 155), suggesting that the metabolic conversion of vitamin D_3 to 1,25-dihydroxycholecalciferol is not sufficient under some conditions to meet the need for this metabolite for normal bone development.

Commercial sources of 25-dihydroxycholecalciferol have become available, and this vitamin D metabolite has intermediate activity for prevention of tibial dyschondroplasia (209).

Treatment of Deficiency. Hooper *et al.* (89) found that feeding a single massive dose of 15,000 IU vitamin D_3 cured rachitic chicks more promptly than when generous levels of the vitamin were added to feed. This single oral dose protected cockerels against rickets for 8 weeks and pullet chicks for 5 weeks. In giving massive doses to rachitic chicks, it should be remembered that excess vitamin D can be harmful. The dose should be scaled to the degree of deficiency, and excessive amounts of vitamin D should not be added to feed.

Hypervitaminosis D
The relative toxicity of vitamin D and its metabolites follows the same pattern as their bioactivity: $D_2 < D_3 < 25$-dihydroxycholecalciferol $< 1,25$-dihydroxycholecalciferol. Elevated rates of calcium absorption and mobilization from the bone cause elevated

levels of calcium in body fluids, resulting in soft-tissue calcification, cellular degeneration, and inflammation. Vitamin D toxicity is exacerbated by high levels of dietary calcium or phosphorus, especially in the growing chick. In broiler chicks, pathology can be detected at 30,000 IU/kg of vitamin D_3 when fed throughout the growth period. Lesions include atrophy of parathyroid gland associated with the proliferation of connective tissues, Ca deposits in basal areas of the aortic valve and renal tubular lumina, and epithelial calcification in blood vessel walls that in the brain caused vacuolization and necrosis (42). Hens are generally more resistant to vitamin D toxicity than growing chicks, but toxic levels can be transferred to the egg causing excessive mobilization of eggshell calcium and late embryonic death. Very high levels of vitamin D_3—4 million IU or more/kg diet—rapidly induce renal damage from dystrophic calcification of kidney tubules. Calcification may be less often observed in the aorta and other arteries. A moderate excess of vitamin D has been reported to increase the incidence of eggshell pimpling (74). The latter appears to be due to excessive localized calcareous deposits on and within the eggshell that when scraped off the shell, often expose the underlying eggshell membranes. In laying hens, 25-dihydroxycholecalciferol becomes toxic at around 825 μg/kg feed (192).

Vitamin E
Vitamin E deficiency produces encephalomalacia, exudative diathesis, and nutritional myopathy (muscular dystrophy) in chicks; enlarged hocks and dystrophy of the ventricular musculature in turkeys; and nutritional myopathy in ducks. Vitamin E also is required for normal embryonic development in chickens, turkeys, and probably ducks.

In its alcoholic form, vitamin E is a very effective antioxidant. It is an important protector in feeds of the essential fatty acids and other highly unsaturated fatty acids as well as vitamins A and D_3, carotenes, and xanthophylls. Diets that contain high levels of unstabilized polyunsaturated fatty acids become depleted of vitamin E and are most likely to cause deficiencies. Selenium (Se) at dietary concentrations of 0.04–0.1 ppm has been shown to prevent or cure exudative diathesis in vitamin E-deficient chicks (170, 171, 172). Selenium at 0.1–0.2 ppm effectively prevents myopathies of ventriculus and heart in young poults (173).

Vitamin E plays multiple roles in poultry nutrition. It is required not only for normal reproduction but also as nature's most effective antioxidant for prevention of encephalomalacia, in a specific role interrelated with action of selenium for prevention of exudative diathesis and turkey myopathies, and in another role interrelated with selenium and cystine for the prevention of nutritional myopathy. Vitamin E has a low level of toxicity for poultry, and problems with excess levels are often due to induction of a deficiency in another fat-soluble vitamin—like vitamin A or K.

Clinical Signs, Signalment, and Pathology of Deficiency
No outward signs occur in mature chickens or turkeys receiving very low levels of vitamin E over prolonged periods. However, hatchability of eggs from vitamin E-deficient chickens or turkeys is reduced markedly (93). Embryos from hens fed rations low in vitamin E may die as early as the fourth day of incubation or con-

siderably later, depending on the severity of the deficiency. Turkey embryos may have bilateral cataracts that can cause blindness (66). Testicular degeneration occurs in males deprived of vitamin E for prolonged periods (4).

Encephalomalacia in Chicks. Encephalomalacia is a nervous syndrome characterized by ataxia or paresis (Fig. 29.4A), backward or downward retractions of the head (sometimes with lateral twisting), forced movements, decreasing coordination, rapid contraction and relaxation of the legs, and finally complete prostration and death. Even under these conditions, complete paralysis of wings or legs is not observed. The deficiency usually manifests itself between day 15 and 30 of the chick's life, although it has been known to occur as early as day 7 and as late as the day 56. Dietary long-chain polyunsaturated fatty acids, especially C18:2n6, increase the severity of encephalomalacia (70).

The cerebellum, striatal hemispheres, medulla oblongata, and mesencephalon are affected most commonly in the order named (147). In chicks killed soon after the appearance of signs of encephalomalacia, the cerebellum is softened and swollen, and the meninges are edematous (Fig. 29.4B). Minute hemorrhages are often visible on the surface of the cerebellum. The convolutions are flattened. As much as four-fifths of the cerebellum may be affected, or lesions may be so small they cannot be recognized grossly. A day or two after signs of encephalomalacia appear, necrotic areas present a green-yellow opaque appearance. One or two days later, the cerebellum may become pale and shrunken (Fig. 29.4C).

In the corpus striatum, necrotic tissue is frequently pale, swollen, and wet and in early stages becomes sharply delineated from remaining normal tissue. The greater portion of both hemispheres may be destroyed. In other cases, lesions are apparent only on microscopic examination. Medullary lesions are not so readily noted in a macroscopic examination.

Histologically, lesions include circulatory disturbances (ischemic necrosis), demyelination, and neuronal degeneration (Fig. 29.4D,E). Meningeal, cerebellar, and cerebral vessels are markedly hyperemic, and a severe edema usually develops. Capillary thrombosis often results in necrosis of varying extent. In the normal chick cerebellum, myelinated tracts exhibit a strongly positive reaction with Luxol fast blue; whereas in affected chicks, the staining reaction is markedly diminished, diffusely or locally accentuated. Degenerative neuronal changes occur everywhere but are most prominent in Purkinje cells and in large motor nuclei. Ischemic cell change is most frequently encountered. Cells are shrunken and intensely hyperchromatic, and the nucleus is typically triangular. Peripheral chromatolysis with the Nissl substance packed along the periphery of the cell nucleus is also common.

Signs of encephalomalacia in turkey poults are similar to those observed in chicks (97). Poults with paresis usually do not have brain lesions but have poliomyelomalacia (Fig. 30.4F).

Exudative Diathesis in Chicks. Exudative diathesis is an edema of subcutaneous tissues (Fig. 29.5) associated with abnormal permeability of capillary walls. In severe cases, chicks stand with

29.5. Exudative diathesis in chicks.(Scott)

their legs far apart as a result of accumulation of fluid under the ventral skin. This green-blue viscous fluid is seen easily through the skin, because it usually contains some blood components from slight hemorrhages that appear throughout the breast and leg musculature and in the intestinal walls. Distention of the pericardium and sudden deaths have been noted. Chicks suffering from exudative diathesis show a low ratio of albumin to globulins in blood (73).

Onset of exudative diathesis coincides with appearance of peroxides in tissues. Plasma activities of selenium-dependent glutathione peroxidase decrease sharply (141). Intracellular and extracellular isozymes of glutathione peroxidase catalyzes the neutralization of hydrogen peroxide and lipoperoxides that can cause oxidative damage to structural elements of the cell, particularly membrane lipids. Noguchi *et al.* (141) proposed that vitamin E in the capillary membranes and the selenium-containing enzyme glutathione peroxidase of plasma protect the capillary membrane against oxidative damage. This may explain the dual role of vitamin E and selenium in the prevention of exudative diathesis and other vitamin E/selenium-responsive diseases (172, 189). Another selenium-dependent enzyme, phospholipid hydroperoxide glutathione peroxidase, probably also is involved in the protection of membranes from oxidative damage.

Nutritional Myopathy (Muscular Dystrophy) in Chickens, Ducks, and Turkeys. When vitamin E deficiency is accompanied by a sulfur amino acid deficiency, chicks show signs of nutritional myopathy—particularly of the breast muscle—at about 4 weeks of age. The condition is characterized by light-colored streaks of easily distinguished affected bundles of muscle fibers in the breast (Fig. 29.4G). A similar dystrophy occurs throughout all skeletal muscles of the body in vitamin E-deficient ducks.

The initial histologic change is hyaline degeneration. Mitochondria undergo swelling, coalesce, and form intracytoplasmic

globules. Later, muscle fibers are disrupted transversely. Extravasation separates groups of muscle fibers and individual fibers. The transuded plasma usually contains erythrocytes and heterophilic leukocytes. In more chronic conditions, reparative processes dominate the picture. There is a pronounced proliferation of cell nuclei and also fibroplasia, leaving a scar in the degenerate muscle.

Vitamin E and selenium deficiency in chickens and especially in turkeys may result in an extreme myopathy of the ventriculus (gizzard) (Fig. 29.4H) and heart muscles (173).

Enlarged Hock Disorder in Turkeys. Turkeys receiving diets low in vitamin E and also containing readily oxidizable fats or oils may develop characteristic hock enlargements and bowed legs at approximately 2–3 weeks of age (169). If poults are allowed to continue on these diets, hock enlargements usually disappear by the time the poults are 6 weeks of age, only to reappear in more severe form when they reach 14–16 weeks, especially in toms raised on wire or slat floors. Creatine excretion is increased, and muscle creatine levels are reduced. The need for vitamin E may be related to a protection of biotin that otherwise might be destroyed in the presence of rancidifying fats or oils.

Treatment of Deficiency
If not too far advanced, exudative diathesis and nutritional myopathy in chicks are readily reversed by the administration of proper levels of vitamin E and selenium by injection, by oral dosing, or in feed. Encephalomalacia may or may not respond to treatment with vitamin E, depending on the extent of damage to the cerebellum. Ventricular myopathy in turkeys is prevented by supplementing deficient diets with vitamin E or selenium. It is not affected by the dietary level of sulfur amino acids.

Vitamin K

Vitamin K is required for synthesis of prothrombin. It is a cofactor in the posttranslational carboxylation of glutamic acid in prothrombin, osteocalcin, and several other calcium binding proteins. The product, a-carboxyglutamic acid, is anionic at physiologic pH and functions in the binding of Ca to protein during blood clotting. In the absence of vitamin K, an abnormal prothrombin lacking α-carboxyglutamic acid is secreted into the blood by the liver (71). Because prothrombin is an important part of the blood-clotting mechanism, deficiency of vitamin K results in markedly prolonged blood-clotting time (95); an affected chick or poult may bleed to death from a slight bruise or other injury. Vitamin K deficiency reduces the α-carboxyglutamic acid content of bone in laying hens and growing chicks (111).

Clinical Signs, Signalment, and Pathology of Deficiency
Signs of vitamin K deficiency occur most frequently 2–3 weeks after chicks are placed on a vitamin K-deficient diet. Presence of sulfaquinoxaline in feed or drinking water may increase incidence and severity of the condition. Large hemorrhages appear on the breast, legs, and wings, and/or in the abdominal cavity. Chicks show an anemia that may result partly from loss of blood but also from development of a hypoplastic bone marrow.

29.6.   Typical stargazing pose displayed by chick suffering from thiamin deficiency. (Scott)

Although blood-clotting time is a fairly good measure of vitamin K deficiency, a more accurate one is obtained by determining prothrombin time. Inadequate vitamin K in breeder diets causes increased embryo mortality late in incubation. Dead embryos appear hemorrhagic.

Treatment of Deficiency
Within 4–6 hours after vitamin K is administered to deficient chicks, blood clots normally, but recovery from anemia or disappearance of hemorrhages cannot be expected to take place promptly.

Thiamin (Vitamin B$_1$)

Thiamin is converted in the body to an active form, thiamin pyrophosphate, which is an important cofactor in oxidative decarboxylation reactions and aldehyde exchanges in carbohydrate metabolism. Deficiency of thiamin leads to extreme anorexia, polyneuritis, and death.

Clinical Signs, Signalment, and Pathology of Deficiency
Polyneuritis is observed in mature chickens approximately 3 weeks after they are placed on a thiamin-deficient diet. In young chicks, it may appear before 2 weeks of age. Onset is sudden in young chicks but more gradual in mature birds. Anorexia is followed by loss of weight, ruffled feathers, leg weakness, and an unsteady gait. Adult chickens often show a blue comb. As the deficiency progresses, apparent paralysis of muscles occurs, beginning with the flexors of the toes and progressing upward, affecting the extensor muscles of legs, wings, and neck. The chicken characteristically sits on its flexed legs and draws back the head in a "stargazing" position (Fig. 29.6). Retraction of the head is due to paralysis of the anterior muscles of the neck. The chicken soon loses the ability to stand or sit upright, and it topples to the floor, where it may lie with the head still retracted.

The body temperature may drop to as low as 35.6°C. A progressive decrease in respiration rate occurs. Adrenal glands hypertrophy more markedly in females than males. Apparently, the degree of hypertrophy determines the degree of edema, which occurs chiefly in the skin. The epinephrine content of the adrenal
29.7.   Duodenum from thiamin-deficient chick, with severe dilation of crypts of Lieberkühn (left). Control (right). ×30. (Scott)

gland increases as the organ hypertrophies. Atrophy of genital organs is more pronounced in males than females. The heart shows a slight degree of atrophy; the right side may be dilated, the auricle being more frequently affected than the ventricle. Atrophy of the stomach and intestinal walls may be sufficiently severe to be easily noted.

Crypts of Lieberkühn in the duodenum of deficient chicks become dilated (Fig. 29.7) (78). Mitosis of epithelial cells in the crypts decreases markedly; in advanced stages of deficiency the mucosal lining disappears, leaving a connective tissue framework. Necrotic cells and cell debris accumulate in the enlarged crypts. Exocrine cells of the pancreas show cytoplasmic vacuolation with the formation of hyaline bodies.

Treatment of Deficiency
Chickens suffering from thiamin deficiency respond in a matter of a few hours to oral administration of the vitamin. Because thiamin deficiency causes extreme anorexia, supplementing feed with the vitamin is not a reliable treatment until after chickens have recovered from acute deficiency.

Riboflavin (Vitamin B₂)

Riboflavin is a cofactor in many enzyme systems in the body. Examples of riboflavin-containing enzymes are NAD- and NADP-cytochrome reductases, succinic dehydrogenase, acyl dehydrogenase, diaphorase, xanthine oxidase, L- and D-amino acid oxidases, L-hydroxy acid oxidases and histaminase, some of which are vitally associated with oxidation-reduction reactions involved in cell respiration.

Clinical Signs, Signalment, and Pathology of Deficiency
When chicks are fed a diet deficient in riboflavin, they grow very slowly and become weak and emaciated; their appetite is fairly good; diarrhea develops between the first and second weeks. Chicks do not walk except when forced to, and then they frequently walk on their hocks with the aid of their wings. Leg paralysis may be more prevalent than curled-toe paralysis (46). Toes are curled inward when both walking and resting (Fig. 29.8). Chicks are usually found in a resting position. The wings often droop as though it were impossible to hold them in the normal position. Leg muscles are atrophied and flabby, and the skin

29.8.   Curled-toe paralysis (riboflavin deficiency). Typical signs include poor growth, reluctance to stand or walk, sitting on hocks, and toes curled inward. (Swayne)

29.9.   Curled-toe paralysis. Peripheral neuropathy characterized by axonal swelling and degeneration, Schwann cell activation and proliferation, and myelin degeneration. ×70. (Swayne, Barnes)

is dry and harsh. Young chicks in advanced stages of deficiency do not move around but lie with their legs sprawled out.

Riboflavin deficiency in young turkeys is characterized by poor growth, poor feathering, leg paralysis (165), and by encrustations in the corners of the mouth and on the eyelids. Severe dermatitis of the feet and shanks—marked by edematous swelling, desquamation, and deep fissures—appears in some deficient poults (131).

In severe cases of riboflavin deficiency, chicks show marked swelling and softening of sciatic and brachial nerves (35). Sciatic nerves usually undergo the most pronounced changes, sometimes reaching a diameter 4–5 times normal size. Histologic examination of affected nerves shows degenerative changes in myelin sheaths of the main peripheral nerve trunks (Fig. 29.9). This may be accompanied by axis cylinder swelling and fragmentation. Schwann cell proliferation, myelin changes, gliosis, and chromatolysis occur in the spinal cord. Fine structural examination of the sciatic nerve reveals that redundant folds and loops of myelin form symmetric or asymmetric expansions of the sheath resulting in segmental demyelination (35). In cases of curled-toe paralysis, degeneration of the neuromuscular end plate and muscle tissues is often found. Riboflavin is probably also essential for myelin metabolism of the main peripheral nerve trunks. No gross dystrophy develops, although muscle fibers are in some cases completely degenerated. The sciatic nerve exhibits myelin degeneration in one or more branches. Similar changes are apparent in the brachial nerve trunks. Chicks fed riboflavin-deficient diets develop pancreatic and duodenal lesions as described for thiamin deficiency in addition to the more classic nervous signs (78).

A deficiency of riboflavin in the diet of hens results in decreased egg production, increased embryonic mortality, and an increase in size and fat content of the liver. Hatchability of eggs decreases within 2 weeks after hens are fed a riboflavin-deficient diet but improves to near normal levels within 7 days after adequate amounts of riboflavin are added to the diet.
Embryos that fail to hatch from eggs of hens fed diets low in this vitamin are dwarfed and show a high incidence of edema, degeneration of Wolffian bodies, and defective down. The down is referred to as "clubbed" and results from failure of the down feathers to rupture the sheaths, causing feathers to coil in a characteristic way.

Riboflavin is transported to the egg by riboflavin-binding protein (RfBP). Chickens that are genetically unable to produce RfBP lay eggs that support embryonic development until 13 or 14 days of incubation (208). However, they lack sufficient riboflavin to complete embryogenesis. At day 10 of incubation, embryos become severely hypoglycemic and begin to accumulate intermediates of fatty acid oxidation. The major metabolic consequence of riboflavin deficiency appears to be a severe impairment of fatty acid oxidation due to an 80% reduction in the activity of medium-chain acyl-CoA dehydrogenase. The nervous system of embryos that fail to hatch from eggs laid by hens fed riboflavin-deficient diets has degenerative changes very much like those described in riboflavin-deficient chicks (65).

Treatment of Deficiency

Two 100-μg doses of riboflavin should be sufficient for treatment of riboflavin-deficient chicks or poults, followed by incorporation of an adequate level in the ration. When the curled-toe deformity is of long standing, however, irreparable damage has occurred and administration of riboflavin no longer cures the condition.

Pantothenic Acid

Pantothenic acid is a component of coenzyme A, which is involved in the formation of citric acid in the Krebs cycle, synthesis and oxidation of fatty acids, oxidation of keto acids resulting

from deamination of amino acids, acetylation of choline, and many other reactions.

Clinical Signs, Signalment, and Pathology of Deficiency
Signs of pantothenic acid deficiency in chicks are difficult to differentiate from those of biotin deficiency; deficiencies of either result in dermatosis, broken feathers, chondrodystrophy, poor growth, and mortality. Pantothenic acid-deficient chicks are characterized by retarded and rough feather growth. Chicks are emaciated, and definite crusty scablike lesions appear in corners of the mouth. Eyelid margins are granular, and small scabs develop on them. Eyelids frequently are stuck together by a viscous exudate; they are contracted, and vision is restricted. There is slow sloughing of the keratinizing epithelium of the skin. Outer layers of skin between the toes and on bottoms of the feet sometimes peel off; small cracks and fissures appear at these points. These cracks and fissures enlarge and deepen, so chicks move about very little. In some cases, skin layers of the feet of deficient chicks cornify and wartlike protuberances develop on the balls of the feet.

Necropsy shows the presence of a pasty substance in the mouth and an opaque gray-white exudate in the proventriculus (157). The liver is hypertrophied and may vary in color from a faint to dirty yellow. The spleen is atrophied slightly. Kidneys are somewhat enlarged. Nerves and myelinated fibers of the spinal cord show myelin degeneration (153). These degenerating fibers occur in all segments of the cord down to the lumbar region.

Pantothenic acid is required in the diet of breeding hens for normal hatchability of eggs (72). Beer *et al.* (24) observed that the peak day of embryonic mortality depends on the degree of pantothenic acid deficiency and that borderline deficiencies produce extremely weak chicks that fail to survive unless injected immediately with pantothenic acid (200 μg intraperitoneally). Subcutaneous hemorrhage and severe edema are signs of pantothenic acid deficiency in the developing chicken embryo (24).

Pantothenic acid deficiency in chicks produces duodenal and pancreatic lesions as described under thiamin deficiency (but of lesser extent), dermatosis, and severe ataxia progressing to inability to stand. In addition, there is pronounced lymphocytic necrosis and lymphoid depletion in the bursa of Fabricius, thymus, and spleen (78).

Treatment of Deficiency
Pantothenic acid deficiency appears to be completely reversible, if not too far advanced, by oral treatment or injection with the vitamin followed by restoration of an adequate level in the diet.

Nicotinic Acid (Niacin)
Nicotinic acid is the vitamin component in 2 important coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), that are extensively involved in carbohydrate, fat, and protein metabolism. They are especially important in metabolic reactions that furnish energy. One or both coenzymes take part in the anaerobic and aerobic oxidation of glucose, glycerol synthesis and catabolism, fatty acid synthesis and oxidation, and oxidation of acetyl coenzyme A via the Krebs cycle.

Niacin-Tryptophan-Pyridoxine Interrelationships
Tryptophan pyrrolase catalyzes the initial reaction in the major metabolic pathway of tryptophan catabolism. Picolinic carboxylase regulates an important branch point in the pathway at which an intermediate either enters a sequence of reactions resulting in its degradation to carbon dioxide, water, and ammonia or enters a biosynthetic pathway leading to NAD synthesis. Picolinic carboxylase catalyzes the first reaction in the degradative pathway, whereas the first reaction in the NAD pathway occurs nonenzymatically. High picolinic carboxylase activity limits the synthesis of NAD from tryptophan.

Key enzymes in the metabolism of tryptophan require vitamin B6 as a cofactor and limit the overall pathway in vitamin B6 deficiency. Briggs *et al.* (30, 31) first showed that niacin requirements of chicks and hens depend on the level of tryptophan in the diet. When tryptophan is marginally adequate, chickens can synthesize approximately 1 mg of niacin from 45 mg of dietary tryptophan (18, 39, 58). Ducks, in contrast, are much less efficient: approximately 1 mg niacin can be synthesized from 180 mg of dietary tryptophan (40). This difference in efficiency of conversion of tryptophan to niacin is reflected in a markedly higher niacin requirement for ducks than chicks. It has been attributed to relatively high picolinic carboxylase activity in ducks (40, 58).

Clinical Signs, Signalment, and Pathology of Deficiency
The main lesion of nicotinic acid deficiency in young chicks, turkeys, and ducks is an enlargement of the hock joint (chondrodystrophy) and bowing of the legs (39, 58). The main difference between this condition and the chondrodystrophy of manganese or choline deficiency is that in nicotinic acid deficiency, the Achilles tendon rarely slips from its condyles. Scott (169) showed that both nicotinic acid and vitamin E are required for prevention of the disorder in turkeys. Briggs (30) described further signs of nicotinic acid deficiency as inflammation of the mouth, diarrhea, and poor feathering. Hock disorders and lesions of the mouth are prominent lesions in ducks and chicks, respectively (39). Niacin/tryptophan deficiency in chicks produces duodenal and pancreatic lesions comparable to those of thiamin deficiency (78).

Ringrose *et al.* (158) observed reduced feed consumption and body weight, decreased rate of egg production, and reduced hatchability of eggs when hens were fed a semipurified diet based on casein and gelatin as the sources of protein and lacking in supplemental niacin. No signs of pathology were observed. Although no evidence has been obtained of any need to supplement practical diets of mature chickens (2) with nicotinic acid, niacin supplementation was reported to increase egg size with turkey breeders (82).

Treatment of Deficiency
Supplementing a deficient ration with required amounts of nicotinic acid has little or no effect on cases that have progressed to the extent that the tendon has slipped from its condyles (chondrodystrophy) or on advanced cases of enlarged hock disorder in adult tom turkeys. Excessive supplementation should be avoided because levels above 0.75% dietary niacin cause decreased bone thickness dimensions and bone strength (96).

Pyridoxine (Vitamin B$_6$)

Pyridoxine is required in several enzymes, particularly those involved in transamination and decarboxylation of amino acids. The coenzymes are pyridoxal phosphate and pyridoxamine phosphate.

Clinical Signs, Signalment, and Pathology of Deficiency

Severely pyridoxine-deficient chicks show depressed appetite, poor growth, chondrodystrophy, and characteristic nervous signs. Chicks show jerky, nervous movements of the legs when walking and often undergo extreme spasmodic convulsions that usually terminate in death. During these convulsions, chicks may run aimlessly about, flapping their wings and falling to their sides or rolling completely over on their backs, where they perform rapid jerking motions with their feet and heads. These signs may be distinguished from those of encephalomalacia (vitamin E deficiency) by the relatively greater intensity of activity of the chicks during a seizure, which results in complete exhaustion and often death.

Gries and Scott (77) observed that chicks fed very low levels of pyridoxine (up to 2.2 mg B$_6$/kg diet) combined with a high protein level (31%) have classic nervous signs. Intermediate levels (2.5–2.8 mg B$_6$/kg diet) combined with 31% protein cause severe chondrodystrophy but no nervous signs. The consequence is bone curvature. If the diet contains 22% protein, even the lowest levels of pyridoxine (1.9 mg/kg diet) fail to induce nervous signs, chondrodystrophy, or even lowered growth rate. The function of pyridoxine in amino acid metabolism is reflected in an increased requirement when high levels of protein or methionine are fed (168). A pyridoxine deficiency causes a defect in collagen fibers in cortical bone and articular cartilage matrix and increased solubility of proteoglycans and collagen (128). These structural defects apparently cause chondrodystrophy and osteoarthritis in deficient chicks.

Clinical signs of pyridoxine deficiency in ducklings are reported to include poor growth and food consumption, hyperexcitability, weakness, microcytic hypochromic anemia, convulsions, and death (227).

In adult birds, pyridoxine deficiency causes marked reduction of egg production and hatchability, as well as decreased feed consumption, loss of weight, and death. The injection of pyridoxine into the fertile egg has increased the hatchability of eggs from turkey breeders that had received in their diets more than twice the concentration of pyridoxine estimated as the requirement by the National Research Council. This suggests that the requirement of breeders under some conditions may be higher than the dietary level of pyridoxine used under practical conditions.

Biotin

Biotin is a cofactor in carboxylation and decarboxylation reactions involving fixation of carbon dioxide. These reactions have important roles in anabolic processes and in nitrogen metabolism.

Clinical Signs, Signalment, and Pathology of Deficiency

In biotin deficiency, the dermatosis of the feet and skin around the beak and eyes is similar to that of pantothenic acid deficiency. Thus, in making a differential diagnosis, it is usually necessary to examine composition of the diet.

Chondrodystrophy is a sign of biotin avitaminosis in growing chickens and turkeys. Biotin deficiency signs in chicks include various other abnormalities of the tibia. Bain *et al.* (17) reported that chicks fed a purified diet devoid of biotin had shortened tibiae, higher bone density and bone ash, and an abnormal pattern of bone modeling: The median side of the mid-diaphyseal cortex was thicker than the lateral side in chicks fed the biotin-free diet, whereas the opposite pattern existed for chicks fed the same diet supplemented with adequate biotin. This raises the possibility that biotin may have a role in various deformities of the limb (17). Changes in tibial concentrations of fatty acids that are prostaglandin precursors correlate with bone abnormalities in biotin-deficient chicks, suggesting that altered prostaglandin synthesis may be a contributing factor in altered bone modeling patterns of the tibiotarsus in biotin deficiency (204).

Biotin is essential for embryonic development (47, 48). Embryos from hens fed biotin-deficient diets developed syndactylia, an extensive webbing between the third and fourth toes. Many embryos that fail to hatch are chondrodystrophic—characterized by reduced size, a parrot beak, severely crooked tibia, shortened or twisted tarsometatarsus, shortened bones of the wing and skull, and shortening and bending of the scapula. Two peaks of embryonic mortality may occur: one during the first week and a second during the last 3 days of incubation.

Robel and Christensen (160) reported that the injection of 87 μg of D-biotin into eggs of large white turkey hens that had been held under commercial conditions resulted in approximately 4–5% higher hatchability of their eggs. The reason for the improvement is not known; however, the authors suggest that biotin levels or biotin availability in the egg may have been low.

Fatty liver and kidney syndrome (FLKS) is a biotin-responsive condition that has been observed in broiler chicks. Chicks exhibit depressed growth; fatty infiltrations of liver, kidney, and heart; decreased plasma glucose; increased plasma-free fatty acids; and increased ratio of C16:1 to C18:0 fatty acids in liver and adipose tissue (150, 210). High dietary protein or fat reduces or eliminates mortality, whereas high protein or fat increases the signs of biotin deficiency. Fasting exacerbates FLKS and its associated mortality (210). Fasting decreases blood glucose concentrations and increases plasma-free fatty acids. Pyruvic carboxylase, a biotin-containing enzyme, is decreased in activity in FLKS biotin deficiency (150). It has been suggested that biotin deficiency impairs gluconeogenesis as a result of low activity of this enzyme, leading to increased conversion of pyruvate to fatty acids. Chicks having FLKS frequently do not have the characteristic signs of biotin deficiency. This may be a temporal phenomenon wherein the changes in tissue metabolism leading to FLKS occur rapidly in biotin-depleted chicks, but the classic signs of biotin deficiency require a longer period of time to develop (32).

Biotin has been suspected of having a role in "acute death syndrome" (or "sudden death syndrome") in broiler chickens. Biotin deficiency alters the unsaturated fatty acid profile in tissue lipids in such a manner as to suggest that it impairs the conversion of

linoleic acid to arachidonic acid (203). The latter is a precursor of the prostaglandins, prostocyclin I2 and thromboxane A2, which have marked effects on the vascular system. The concentration of biotin in liver was reported to be depressed in chicks that exhibited acute death syndrome (108). The role of biotin in acute death syndrome, however, remains obscure.

Biotin bioavailability for chickens and turkeys varies greatly among practical feed ingredients (69, 134, 211). Biotin is no more than 10% available in some grains but almost completely available in others. This is an important consideration in formulating diets to satisfy the biotin requirements of poultry.

Treatment of Deficiency
Patrick *et al.* (149) and Jukes and Bird (98) reported that injection or oral administration of a few micrograms of biotin was sufficient to prevent biotin deficiency signs in chicks and turkey poults.

Folic Acid (Folacin)
Folic acid is a part of the enzyme system involved in single-carbon metabolism. It is involved in synthesis of purines and the methyl groups of such important metabolites as choline, methionine, and thymine. Folic acid, therefore, is required for normal nucleic acid metabolism and formation of the nucleoproteins required for cell multiplication.

Clinical Signs, Signalment, and Pathology of Deficiency
Folic acid deficiency in chicks is characterized by poor growth, very poor feathering, anemia, and chondrodystrophy. Folic acid is required for pigmentation in feathers of Rhode Island red and black leghorn chicks. Thus, folic acid, lysine, copper, and iron appear to be required for prevention of achroma of feathers in colored poultry.

A deficiency in the breeding diet of chickens or turkeys causes a marked increase in embryonic mortality. Embryos die soon after pipping the air cell. According to Sunde *et al.* (186, 187, 188), a deformed upper mandible and bending of the tibiotarsus are lesions of embryonic deficiency. Poults show a characteristic cervical paralysis and die within 2 days after the onset of these signs unless folic acid is administered immediately. Poults show only a slight anemia.

Folic acid deficiency in chicks causes megaloblastic arrest of erythrocyte formation in bone marrow, which results in a severe macrocytic anemia as one of the first signs in chicks. White cell formation also is reduced, causing a marked agranulocytosis.

Folic Acid-Choline Interrelationship
Folic acid has a central role in methyl group metabolism. Young *et al.* (229) observed that when a diet for chicks is deficient in folic acid, an increase in the dietary level of choline reduces, but does not completely prevent, the incidence and severity of chondrodystrophy. A growth depression has been observed in chicks fed a practical diet that was low in folic acid and marginally deficient in methionine and choline. Supplementation of the diet with folic acid or methionine and choline stimulated growth under these conditions (152).

Treatment of Deficiency
A single intramuscular (IM) injection of 50–100 µg pure pteroyl-glutamic (folic) acid causes a peak reticulocyte response within 4 days in severely anemic folic acid-deficient chicks (161). Hemoglobin values and growth rates return to normal within 1 week. Addition of 500 µg folic acid/100 g feed caused recovery comparable to that obtained with injection of the vitamin.

Vitamin B$_{12}$ (Cobalamin)
Vitamin B$_{12}$ is involved in nucleic acid and methyl synthesis and carbohydrate and fat metabolism. One of its main enzyme functions involves isomerization of methylmalonyl coenzyme A to form succinyl CoA.

Clinical Signs, Signalment, and Pathology of Deficiency
Vitamin B$_{12}$ deficiency results in slow growth, decreased efficiency of feed utilization, mortality, and reduced egg size and hatchability. Specific signs for vitamin B$_{12}$ deficiency have not been demonstrated in growing or mature poultry. Vitamin B$_{12}$ deficiency has been reported to cause myelin degeneration in chicks. Some investigators have detected increased total phospholipids and decreased levels of galactolipids from deficient chicks, suggesting impaired myelin maturation (102). Chondrodystrophy may occur in vitamin B$_{12}$-deficient chicks or poults when their diets lack choline, methionine, or betaine as sources of methyl groups. Addition of vitamin B$_{12}$ may prevent chondrodystrophy under these conditions because of its effect on the synthesis of methyl groups.

Vitamin B$_{12}$-deficient embryos have a peak in mortality at day 17 of incubation, reduced size, myoatrophy of the legs, diffuse hemorrhages, chondrodystrophy, edema, and fatty liver (139, 145).

Treatment of Deficiency
Peeler *et al.* (151) showed that IM injection of 2 µg vitamin B$_{12}$/hen increased hatchability of eggs from vitamin B$_{12}$-deficient hens from approximately 15–80% within 1 week. Addition of 4 mg vitamin B$_{12}$/ton breeding ration is sufficient to maintain maximum hatchability and to produce chicks having sufficient stores of the vitamin to prevent any deficiency during the first few weeks of life. Similar injections of young chicks followed by supplementation of the chick ration also will correct the deficiency.

Choline
Choline is present in acetylcholine and body phospholipids. It acts as a methyl source in synthesis within the body of methyl-containing compounds such as methionine, creatine, carnitine, and N-methylnicotinamide. Choline per se does not act as a methyl donor but first must be oxidized to the compound betaine, which then can donate 1 of its 3 methyl groups to a methyl-acceptor such as homocysteine or glycocyamine for formation of methionine or creatine, respectively.

Clinical Signs, Signalment, and Pathology of Deficiency
In addition to poor growth, the most consistent lesion of choline deficiency in chicks and poults is chondrodystrophy (Figs. 29.10

29.10. Choline deficiency. Stunting; poor feathering; and short, thick, bowed legs typical of chondrodystrophy are seen in a bird that had been fed a choline-deficient diet. (Swayne)

29.11. Choline deficiency. Chondrodystrophy and deformity of tibiotarsus from broiler chicken given a diet lacking adequate choline. (Swayne)

and 29.11). Young turkeys have a high requirement for choline and, therefore, will show a high incidence of severe chondrodystrophy unless special care is taken to supplement the diet with choline. Chondrodystrophy is first characterized by pinpoint hemorrhages and a slight puffiness about the hock joint, followed by an apparent flattening of the tibiometatarsal joint caused by rotation of the metatarsus. The metatarsus continues to twist and may become bent or bowed until it is out of alignment with the tibia. When this condition exists, the leg cannot adequately support the weight of the bird. The articular cartilage is deformed and the Achilles tendon (tendo calcaneous) slips from its condyles.

When laying pullets that have received high-choline rearing diets are fed severely deficient diets, the percentage of fat in the liver increases. In livers of choline-deficient chickens, fat content is higher in females than males. Choline deficiency is, however, rare in adult chickens and turkeys fed practical rations. Nesheim *et al.* (138) showed that pullets fed high choline levels during the 8–20-week growing period are more likely to show fatty livers when placed on purified low-choline laying diets than pullets fed minimum levels during the same growth period. These results indicate that maturing chickens can synthesize choline but will not fully develop this ability if given diets containing ample amounts.

Treatment of Deficiency
If choline deficiency is noted in chicks or poults before severe signs of chondrodystrophy have developed, the deficiency can be cured by supplementing the ration with sufficient choline to meet the requirements. After the tendon has slipped in chicks or poults suffering from choline deficiency, the damage is irreparable.

Essential Inorganic Elements

Essential mineral elements are as important as amino acids and vitamins in maintenance of life, well-being, and production in poultry. Bone and eggshell owe their rigidity to calcium salts. Electrolytes regulate osmotic pressure and acid-base balance and exert specific effects on the ability of muscles and nerves to respond to stimuli. Minerals also are necessary as catalysts or for activation of many enzymes of the body and some are necessary components of macromolecules.

The minerals essential for maintenance of well-being are calcium; phosphorus; sulfur; magnesium; potassium; sodium; chlorine; and the trace elements manganese, iron, copper, zinc, iodine, molybdenum, chromium and selenium (142). Arsenic, boron, fluoride, nickel, rubidium, vanadium, and some rare earth minerals may also have essential functions, but mechanistic information is lacking. Analyses of individual mineral constituents in the body of chickens show that major portions of calcium, phosphorus, magnesium, and zinc are present in bones. Other essential elements are distributed largely in muscles, other soft tissues, and body fluids.

Calcium and Phosphorus
Calcium (Ca) and phosphorus (P) are closely associated in metabolism, particularly in bone formation. The major portion of dietary calcium is used for bone formation in growing chicks or poults and for eggshell formation in mature hens. Calcium also is essential for clotting of blood, and it is required along with sodium and potassium for normal contraction of cardiac muscle. Calcium is an integral constituent of cell signaling and regulatory pathways.

In addition to its role in bone formation, phosphorus is an essential component of purine nucleotides and other phosphorylated compounds involved in the transfer or conservation of free energy in biochemical reactions. It is an integral component of

many macromolecules and is involved in the regulation of many cellular and metabolic processes. Phosphorous also plays a critical role in the maintenance of acid-base balance.

Calcium and Phosphorus Deficiency

The utilization of calcium and phosphorus depends on presence of an adequate amount of vitamin D in the diet. In vitamin D deficiency, the deposition of these minerals in bones of growing chicks and poults is reduced; bones become depleted of mineral; and the quantity of calcium in eggshells is decreased.

According to Long and associates (121, 122, 123), deficiencies of calcium and phosphorus in the diet of growing broiler chicks cause rickets that differs in histopathology from the rickets of vitamin D deficiency. Tibiae from chicks that had been fed a diet containing 0.3% Ca from the time of hatching showed, by 2 weeks, a widening of the proliferating prehypertrophic zone of epiphyseal cartilage and irregular contours in the boundary between the zones of proliferating and hypertrophic cartilage (123). Irregular cartilage columns and elongated epiphyseal vessels were present. By 4 weeks, the epiphyseal growth plate had widened and, in some cases, extended as a cartilaginous plug into the metaphysis. Histologically, the proliferating and hypertrophic zones were irregular and often contained areas of nonviable cells. The hypertrophied zone was markedly widened in some chicks by 4 weeks. Metaphyseal blood vessels invaded along the lateral, but not the apical, region of the cartilaginous plug; cartilage columns of the metaphysis were thickened and irregular. The investigators note that the pathology is similar to that of tibial dyschondroplasia.

According to Long *et al.* (121), phosphorus deficiency (0.2% available dietary P) and calcium excess (2.24% Ca and 0.45% available P) resulted in similar abnormalities of the tibia. Several histologic abnormalities were observed, but most conspicuous was a marked lengthening of the cartilage columns of the degenerating hypertrophied epiphyseal cartilage and metaphyseal primary spongiosa. Some chicks were unable to stand at 4 weeks, displaying a spraddle-legged posture. Folding fractures and bowing or rotation of the tibiotarsus were frequently observed.

Julian (100) observed that phosphorus-deficient chicks had increased respiratory rates and were polycythemic. Blood CO_2 and O_2 were decreased, presumably due to poor rib strength and infolding, which interfered with respiratory movements of the rib cage. Birds died of right ventricular failure, often accompanied by ascites.

In laying hens, calcium deficiency results in reduced egg production and thin-shelled eggs as well as a tendency to deplete calcium content of the bones, first by complete removal of the medullary bone, followed by a gradual removal of the cortical bone. Finally, bones become so thin that spontaneous fractures may occur, especially in vertebrae, tibia, and femur. This condition may be associated with a syndrome commonly termed "cage layer fatigue" (156). Although a marginal calcium deficiency has often been found to be a triggering agent in cage layer fatigue, the syndrome apparently is not due to a simple deficiency of calcium but also involves other etiologic factors not yet identified.

The phosphorus in plant-base feedstuffs is poorly available be-

cause much of it is present in phytic acid and is not released by digestive enzymes. The availability of phosphorus can be increased by the inclusion in the diet of phytase of microbial or plant origin.

Excess Calcium

Shane *et al.* (177) fed leghorn pullets diets containing 3.0% Ca and 0.4% P from 8–20 weeks of age. Nephrosis and visceral urate deposition (e.g., "visceral gout") were observed in the high calcium treatment by 16 weeks of age. Wideman *et al.* (213) provided replacement pullets diets containing excess (3.25%) or adequate (1.0%) levels of calcium in combinations with moderate (0.6%) or low (0.4%) available phosphorus from 7–18 weeks of age. All birds received a commercial layer diet during the laying period. Pullets fed on the 3.25% Ca diets developed a high incidence of urolithiasis by 18 weeks, which persisted or increased in the laying period through 51 weeks of age. Low levels of dietary phosphorus during the rearing period exacerbated the effect of excess calcium.

Magnesium

Magnesium (Mg) is essential for carbohydrate metabolism and for activation of many enzymes, especially those involved in phosphorylation reactions. It is essential for bone formation, about two-thirds being present in bone chiefly as a carbonate. Eggshells contain about 0.4% Mg.

Deficiency

Almquist (7) observed that chicks fed a magnesium-deficient diet grew slowly for approximately 1 week and then ceased growing and became lethargic. When disturbed, these chicks frequently passed into a brief convulsion accompanied by gasping and finally into a comatose state sometimes ending in death. Magnesium deficiency signs of poults are similar to those of chicks (185). Hypomagnesemia and hypocalcemia are associated with severe magnesium deficiency in chicks. Tibiae have decreased magnesium and increased calcium content and exhibit abnormalities (185, 205, 206) including thickening of trabeculae, increased retention of cartilage cores, and the occurrence of elongated and inactive osteocytes in the metaphysis. Deficient chicks have thickening of the cortex, the presence of elongated inactive osteocytes, and enlargement of Haversion canals within the diaphysis. The epiphyseal plate, however, appears normal. The parathyroid appears hyperactive, perhaps in response to the hypocalcemia that is characteristic of magnesium deficiency (206).

Excess Magnesium

Ordinary feeds supply enough magnesium in practical poultry diets to meet requirements. It is possible, however, that under certain conditions rations may contain excess magnesium, producing detrimental effects including reduced growth rate and bone ash in chicks and decreased egg size, eggshell thinning, and diarrhea in hens (43, 132, 184). The maximum tolerable level of magnesium in the diets of poultry is about 0.5% for growing birds and 0.75% for laying hens (142). Diets with low levels of phosphorus enhance the sensitivity of hens to toxicosis (85).

29.12.   Characteristic sign of chloride deficiency. (Leach)

29.13.   Sodium excess. Cardiomegaly, especially involving the right ventricle, ascites, and fibrin masses in the body cavity and on the liver capsule, occurred in this chicken given excess sodium. (Swayne)

Sodium and Chlorine (Salt)

Sodium (Na) as chloride (Cl), carbonate, and phosphate is found chiefly in blood and body fluids. Sodium is connected intimately with maintenance of membrane potentials, cellular transport processes, and the regulation of the hydrogen ion concentration of blood. Chloride, the major mineral anion in extracellular fluid, plays a role in fluid, ionic balance, and acid-base balance.

Clinical Signs and Signalment of Deficiency

Animals receiving diets deficient in sodium not only fail to grow but also develop softening of bones, corneal keratinization, gonadal inactivity, adrenal hypertrophy, changes in cellular function, impairment of food utilization, and decrease in both plasma and special fluid volumes. Cardiac output drops; mean arterial pressure falls; the hematocrit increases; elasticity of subcutaneous tissue decreases; adrenal function is impaired; and a state of shock results, which if uncorrected, terminates in death.

Chicks fed a diet containing no added salt show retarded growth with decreased efficiency of food utilization. Lack of salt in the diet of laying hens results in an abrupt decrease of egg production and reduced egg size, loss of weight, and cannibalism.

Salt deprivation in turkeys impairs egg production and hatchability (81). Leach and Nesheim (115) observed that chicks fed a purified diet containing 0.24% Na and 0.4% potassium required 0.12% chlorine. They produced chloride deficiency by feeding young chicks a purified diet containing 190 mg Cl/kg diet. Chicks exhibited extremely poor growth rate, high mortality, hemoconcentration, dehydration, and reduced blood chloride. In addition, deficient chicks showed nervous signs characteristic of Cl deficiency. When startled, they fell forward with their legs outstretched behind them and lay paralyzed for several minutes, then appeared quite normal until frightened again (Fig. 29.12).

Excess Salt

Large amounts of salt in the ration are toxic to chickens and turkeys. The lethal dose is approximately 4 g/kg body weight. Young chicks appear to be more susceptible to toxic effects of salt than are older chickens. Poultry are much less tolerant to salt supplied via the water than by the diet. Signs of salt intoxication include inability to stand, intense thirst, pronounced muscular weakness, and convulsive movements preceding death. There are lesions in many organs, particularly hemorrhages and severe congestion in the gastrointestinal tract, muscles, liver, and lungs. Excess sodium results in ascites, right ventricular hypertrophy, and right ventricular failure in broiler chickens (Fig. 29.13) (99, 202, 225) and contributes to spontaneous cardiomyophathy in turkeys (68). Matterson *et al.* (129) fed day-old poults graded quantities of salt for 23 days and observed 25% edema and 25% mortality at 4.0% salt but none at 2.0%. Swayne *et al.* (190), however, described a case of accidental salt poisoning in 5–11-day-old poults in which a diet contained 1.85% salt. Signs included respiratory distress, ascites, hydropericardium, hydrothorax, and sudden death. High levels of salt also cause the excretion of dilute urine and wet litter.
Potassium

Potassium is found primarily in the cellular compartment of the body; soft tissues of the chicken contain more than 3 times as much potassium as sodium. As a major cation in intracellular fluid, potassium has an essential role in the maintenance of membrane potential and cellular fluid balance. Potassium participates directly in numerous biochemical reactions and is necessary for normal heart activity, reducing contractility of the heart muscle and favoring relaxation.

Clinical Signs and Signalment of Deficiency

The main effect of potassium deficiency is overall muscle weakness characterized by weak extremities, poor intestinal tone with distention, cardiac weakness, and weakness of the respiratory

muscles and their ultimate failure. Severely affected individuals may exhibit tetanic seizures followed by death. Low levels of potassium in laying diets cause decreased egg production and eggshell thinning (113). A low potassium level in the vital organs of animals may occur during severe stress. Plasma potassium is elevated, causing the kidney (acting under influence of the adrenocortical hormone) to discharge potassium into the urine. During adaptation to stress, the muscle will begin to retrieve its lost potassium. As liver glycogen is restored, potassium returns to the liver. This may result in temporary prolongation of the general potassium deficiency throughout the body. High temperature results in increased loss of potassium in the urine (54).

An all-vegetable diet low in potassium produced low plasma potassium concentrations and a high incidence of sudden death syndrome at the onset of egg production in broiler breeder pullets that had undergone restricted feeding (91). The hypothesis that low dietary potassium leads to this syndrome, however, has not been subjected to testing.

Dietary Balance of Macrominerals

Studies in many laboratories during the past 2 decades have determined that the balance among dietary minerals has a profound effect on acid-base balance and certain developmental, metabolic, and physiologic functions in poultry (135). Balance has been expressed in several ways. One expression is dietary undetermined anion (dUA), sometimes referred to as mineral cation-anion balance (13). It is defined as follows: dUA = (Na+K+Ca+Mg) – (Cl+P+S), in which all values are expressed in milliequivalents per kg of diet and valences are assumed to be +1 for Na and K, +2 for Ca and Mg, –1 for Cl, –1.75 for P and –2 for S. P and S are assumed to be inorganic. Trace minerals are excluded because of their insignificant contributions to the overall mineral balance. Another term, dietary electrolyte balance, emphasizes the balance among the strong electrolytes (Na+K-Cl).

A positive value of dUA represents the net dietary concentration of organic anions. If the value is negative, a very unusual condition, it is a measure of the net hydrogen ion content of the diet. Minerals differ in their chemical properties and metabolism. Therefore, although dUA provides an indication of the qualitative effect, it is not an accurate predictor of the quantitative effect of the diet on acid-base balance.

Diets rich in mineral anions, particularly Cl, tend to cause metabolic acidosis and result in disturbances of Ca metabolism, increased incidence and severity of tibial dyschondroplasia in immature fowls, and reduced eggshell calcification in laying hens. Effects on tibial development (60, 79, 116, 167) and eggshells (14) are exacerbated when calcium is limiting.

A dietary combination of excessive calcium and low phosphorus results in the excretion of an alkaline urine (213), as would be predicted from dUA. The urolithiasis observed in replacement pullets by Wideman *et al.* (213) under these conditions may be due in part to the increased pH of urine. Alkaline conditions favor the precipitation of divalent mineral salts. Growing chicks given high levels of sodium bicarbonate develop visceral urate deposition (e.g., "visceral gout") that is especially pronounced in the kidney, which displays urate granulomas (tophi) in renal interstitium and tubular necrosis (137). Increasing the dietary acid load has been used to reduce uroliths (213) in poultry and some mammals (29). The potentially adverse effects of low dUA on bone development and eggshell quality should be considered before such treatment is attempted.

High levels of dietary electrolytes also increase fecal moisture and can cause problems with wet litter. Increasing dietary concentrations of sodium, potassium or phosphorus causes linear increases in the water intake of the laying hens and linear increases in the moisture content of their excreta. Each 1 g/kg increase in dietary mineral increased the moisture content of the excreta by 9.0, 12.0 and 5.6 g/kg for sodium, potassium and phosphorus, respectively (179). Various sodium salts ameliorate heat stress in chickens, at least in part by increasing water intake (6, 29).

Manganese

Manganese (Mn) is an activator of several enzymes and is required for normal growth and reproduction and prevention of chondrodystrophy. In addition to its chondrodystrophy-preventing properties, manganese is necessary for formation of normal bones. Wilgus *et al.* (218) observed that leg bones of chicks fed chondrodystrophy-producing diets frequently were thickened and shortened. Manganese deficiency impairs endochondral bone growth. Cells of the epiphyseal growth plate are arranged irregularly and the extracellular matrix is greatly reduced (112). Manganese is essential for the activity of glycosyltransferases; a deficiency of manganese impairs the synthesis of the glycosaminoglycan molecules that are components of proteoglycans in the cartilage of the epiphyseal growth plate (114, 120). Bone of manganese-deficient ducks, consequently, contains a reduced concentration of hexosamine (114). Manganese also has been reported to be necessary for maximum eggshell quality.

Lyons and Insko (126) found that manganese deficiency resulted in very low hatchability of fertile eggs and chondrodystrophy in embryos. The peak of mortality for such embryos occurred on day 20 and 21 of incubation. Chondrodystrophic embryos were characterized by very short, thickened legs, short wings, parrot beak, globular contour of head, protruding abdomen, and retarded down and body growth. Marked edema was noted in about 75% of these embryos. The manganese content of eggs producing chondrodystrophic embryos was less than that of normal eggs.

Chicks hatched from eggs produced by hens fed a diet deficient in manganese sometimes exhibit ataxia, particularly when excited (38). The head may be drawn forward and bent underneath the body or retracted over the back. Ataxic chicks grow normally and reach maturity but fail to recover completely. They also retain the short bones characteristic of embryos and newly hatched chicks from manganese-deficient dams (37).

Manganese is generally considered to be one of the least toxic minerals and poultry tolerate diets with up to 2,000 mg/kg without signs of toxicosis (142).

Iodine

Traces of iodine (I) are required for normal functioning of the thyroid gland in poultry as in other animals. Thyroxine contains

approximately 65% I and acts as an important regulating agent in body metabolism. When the intake of iodine is suboptimal, the thyroid tissue enlarges and goiter results.

Wilgus *et al.* (217) reported that iodine deficiency results in an enlarged thyroid and, in some cases, lower body weight in growing chicks. They observed congenital goiter in hatchlings from hens receiving 0.025 ppm I in the ration. Rogler *et al.* (162) observed mortality late in incubation. Hatching time was delayed. Embryo size was reduced and yolk sac resorption was retarded. Use of 0.25% iodized salt in chicken and turkey rations should prevent development of iodine deficiency. This would supply 0.175 ppm in addition to that contained in the diet. Christensen and Ort (45) reported that dietary supplements of iodine increased the permeability of eggshells and the hatchability of turkey eggs.

Iodine deficiency in poultry has been largely prevented by widespread use of iodine either in iodized salt or as part of the trace mineral premix. Some egg producers feed high levels of iodine in order to enrich eggs and provide added value. Levels of dietary iodine of 12 mg/kg and above decrease egg weight, albumen index and Haugh units (226). Lichovnikova *et al.* (119) observed decreased egg production, size, and Haugh units at 6.01 mg of iodine/kg diet. Iodine reduces the growth rate of chicks at 900 mg/kg and this effect is mitigated by dietary bromine (19). High levels of iodine also reduce male fertility. Iodine toxicosis is normalized within about 7 days of returning birds to a diet with normal iodine levels (118).

Copper

Copper (Cu) is essential for formation of hemoglobin. In the absence of copper, dietary iron is absorbed and deposited in the liver and elsewhere but hemoglobin synthesis does not occur. Copper deficiency in chicks results in anemia, characterized by reduced numbers of circulating erythrocytes, and impaired feather pigmentation in colored breeds of fowl (75).

Copper is a component of several enzymes that participate in redox reactions. Lysyl oxidase is a copper-containing enzyme that catalyzes oxidation of lysine residues in formation of the cross-linking structure desmosine in elastin (164). Copper deficiency decreases the cross-linking. This weakens the structure of elastin, leading to aortic rupture in poultry. Thinning of the tertiary bronchial mantle in lungs may also result from decreased cross-linking of elastin (33); however, observations on birds fed high levels of cadmium appear inconsistent with this view (117). Copper deficiency has been reported to decrease cross-linking in bone collagen and to increase bone fragility (146, 163). Copper is a component of superoxide dismutase, cytochrome oxidase, and ceruloplasmin—all of which have decreased activities in copper-deficient chicks (28, 107). A copper deficiency also causes hypertriglyceridemia, hypercholesterolemia, and prolonged prothrombin time (104). A deficiency of copper in laying hens causes reduced egg production, increased egg size, and abnormal eggshell calcification. Eggshell abnormalities include shell-less eggs, misshapen eggs, wrinkled eggshells, and reduced eggshell thickness. The palisade layer of the eggshell appears normal; however, the mammillary layer has enlarged mammillary knobs and increased spacing between knobs. This may be related to an abnormal structure of eggshell membranes caused by a decrease in lysine cross-linking (23).

Relatively high levels of copper (100 to 200 mg/kg diet) are often fed to poultry because of an antibiotic-like effect that improves growth and efficiency. Growth promoting levels of copper decrease the number of lymphocytes in the lamina propria of the intestines and also decrease the numbers of intraepithelial lymphocytes (9).

Excess Copper

Excessive dietary levels of copper have been reported to cause abnormalities of the ventriculus. Fisher *et al.* (67) reported that dietary copper levels ranging from 205–605 ppm resulted in a rough thickened ventricular lining in broiler chicks, the severity of the lesion increasing as the copper level of the diet increased. The highest copper level caused markedly thickened and folded linings having a warty appearance. Histologic examination revealed thickening of the koilin layer, sloughing of epithelial cells into the area under the koilin layer and the inclusion of clusters of sloughed cells within the koilin layer. Wight *et al.* (216) observed similar lesions in chicks receiving 2000 and 4000 ppm copper. They noted ventricular erosions and fissures in the ventriculus lining, hemorrhages under the koilin layer, and a mucoid material adhering to the mucosa of the proventriculus. Chiou observed liver pathology, including proliferation of bile ducts and infiltration of lymphocytes, and elevated serum creatine kinase, aspartate amino transferase, and lactate dehydrogenase in laying hens fed 800 ppm copper (44). Ducks are more sensitive to copper toxicosis than chickens (142).

Iron

Iron (Fe) is an essential component of heme, the porphyrin nucleus of hemoglobin and the cytochromes, and is a component of several enzymes including catalase, peroxidase, phenylalanine hydroxylase, tyrosinase, and proline hydroxylase.

Iron deficiency results in a hypochromic, microcytic anemia and reduced concentration of nonheme iron in plasma and prevents normal feather pigmentation in breeds having colored plumage (52, 86). A deficiency in laying hens also causes anemia in the developing chick embryo and reduced hatchability (136). Chicks that survive incubation are weak and listless; however, they recover when given supplemental iron.

The hemoglobin level of hens falls with the beginning of egg production, but this apparently is not related to the iron or copper content of the diet. Since the hemoglobin level rises rapidly with onset of broodiness, it is more probable that low levels prevailing in egg production are caused by changes in hormone activity rather than iron or copper deficiencies. A deficiency of iron has been reported to decrease the synthesis of niacin from tryptophan in chicks (144).

Characteristic signs of chronic iron toxicosis include decreased growth and efficiency of gain. Cao *et al.* (36) observed slightly decreased growth in day old chicks fed practical diets supplemented with 400 mg iron/kg diet as $FeSO_4$ and 800 mg/kg resulted in poor growth. However, if iron supplemented diets
29.14.   Enlarged hocks in poult caused by zinc deficiency. (Young)

were introduced after day 5, performance of chicks fed 800 mg/kg supplemental iron was normal. The liver, heart, and pancreatic beta cells are most affected by iron overload (142).

Zinc

Traces of zinc (Zn) appear to be necessary for life in all animals. It is a constituent of the enzyme carbonic anhydrase and is an activator or a cofactor of more than 299 enzymes. Zinc stabilizes "zinc finger" structural motifs, which are involved in protein-DNA interactions that regulate gene expression.

Clinical Signs and Signalment of Deficiency

Deficiency of zinc results in retarded growth; poor feathering; enlarged hocks (Fig. 29.14); short, thickened long bones (chondrodystrophy); scaling of the skin and dermatosis, particularly on the feet; and an awkward arthritic gait (143, 228). Zinc-deficient chicks exhibit increased hematocrit, which is due to redistribution of body water rather than altered water intake (26, 27).

Histologic lesions include hyperkeratinization of skin of the shank and feet and parakeratosis of the esophagus. Nucleoli of the crop epithelium are enlarged and contain increased amounts of RNA. Alkaline phosphatase and alcohol dehydrogenase, two zinc-containing enzymes, exhibit reduced activities in the crop and esophagus (215). Severe epiphyseal growth plate lesions are characterized by reduced cellularity and abnormally shaped cells in areas remote from blood vessels. Changes in growth plate cellularity are due to decreased chondrocyte proliferation and increased cell apoptosis (108). Reduced alkaline phosphatase activity is also observed in epiphyseal cartilage. Starcher *et al.* (182) found that activity of the zinc-dependent enzyme collagenase is reduced in the tibia during zinc deficiency. They suggest that effects of zinc on bone may be the re-

sult of decreased bone collagen turnover. Lymphoid organs become depleted of lymphocytes and reticular cells of the thymus become necrotic (51). The effect of deficiency is greatest on the bursa, followed by thymus, and then spleen. Bettger *et al.* (26, 27) reported evidence of an interrelationship between vitamin E and zinc. Leg abnormalities, arthritic gait, and epidermal lesions were reduced by vitamin E and exacerbated by polyunsaturated fatty acids.

Ducks exhibit poor growth and epidermal lesions of the feet, particularly interdigital webs (214). Pathology of the epidermis is evident in the interdigital web, mucous membrane of the tongue, and epithelium in other parts of the gastrointestinal tract. Hyperkeratosis and acanthosis characterize the tongue and interdigital web lesions. Intercellular spacing between prickle cells and basal cells is increased and number of desmosomes is diminished. Prickle cells have an abnormal structure, enlarged nuclei and nucleoli, and decreased content of free ribosomes, tonofilaments, and other structures. Lymphoid organs are affected similarly to those of chickens (50).

The zinc requirement of poults is higher than for chicks. Thus, poults are more likely to show enlarged hocks and poor feathering of zinc deficiency unless special supplements are added to the diet. The most dramatic embryonic abnormalities resulting from nutritional deficiency appear when the breeding diet contains excess calcium and phosphorus, is high in phytic acid, and is deficient in zinc. Zinc-deficient embryos may have only a head and complete viscera but no spinal column beyond a few vertebrae, and no wings, body wall, or legs (106).

Excess Zinc

Excessive dietary levels of zinc (e.g., 20,000 ppm as zinc oxide) induce molt in laying hens (49). Zinc results in abrupt decline in egg production and onset of molt followed by rapid resumption of egg laying after dietary zinc concentrations are returned to normal. Excess zinc results in inanition, which is presumably responsible for initiating the molt (130). High levels of zinc result in accumulation of zinc in tissues and pathologic changes in the ventriculus, thyroid and pancreas. Chicks exhibit a rough, pale ventricular lining, which may show evidence of fissures and, less frequently, ulceration (56, 216). Histologic examination reveals epithelial desquamation and infiltration of inflammatory cells. Pancreases exhibit dilated acinar lumina and degenerative changes in acinar cells. The latter include loss of zymogen granules, vacuolization of the cytoplasm, the presence of hyaline bodies and other electron-dense debris (216). Follicular cell hypertrophy and hyperplasia occur in the thyroids (105).

Large excesses of dietary zinc such as those used to induce a molt result in reduced activity of the selenium-dependent enzyme, plasma glutathione peroxidase. Selenium administration restores glutathione peroxidase activity but fails to prevent pathologic changes in the ventriculus and pancreas (216). Lesser excesses of zinc (i.e., up to 2000 ppm) did not affect plasma or hepatic glutathione peroxidase activity, but interfered with exocrine function of the pancreas and reduced the plasma and tissue concentrations of a-tocopherol in chicks fed a purified diet but not in chicks fed a practical diet (124, 125).
29.15. Pancreas from selenium-deficient chick. Acini consist of degenerating cells forming central lumen with extensive interstitial fibrosis (left). Control (right). ×250. (Scott)

Selenium

Selenium has been shown to be an essential mineral element for both chicks and poults. It is a constituent of the enzymes, glutathione peroxidase and phospholipid hydroperoxide glutathione peroxidase, which serve to protect tissues against oxidative damage, and it is a component of iodothyronine 5′-deiodinase, an enzyme that is involved in the conversion of thyroxine to its active form (34).

Clinical Signs and Signalment of Deficiency

Selenium prevents development of exudative diathesis in young chickens and myopathy of ventriculus and heart in young turkeys (170, 171, 173). Selenium-deficient ducklings have reduced plasma glutathione peroxidase activity and exhibit low body weight gain and increased mortality. Ducklings that succumb to selenium deficiency may exhibit necrosis of several tissues including the ventriculus, heart, skeletal muscle and smooth muscle of the intestine, and show signs of hydropericardium and ascites (53). Vitamin E and selenium have a mutual sparing effect in prevention of these diseases (see Vitamin E). Pheasants display degenerative cardiomyopathy, vacuolar degeneration of hepatocytes, and centrilobular hepatic necrosis (110).

Chicks severely deficient in selenium exhibit poor growth and feathering, impaired fat digestion, pancreatic atrophy, and fibrosis (193, 194), and reduced activity of selenium-dependent glutathione peroxidase activity in the pancreas (207). Selenium deficiency depresses growth of broilers by inhibiting hepatic 5′-deiodinase activity, which causes lower plasma 3,5,3′-triiodothyronine concentration (94). Replenishing triiodothyronine normalizes growth and feed efficiency. Gries and Scott (76) performed a time-sequence study of pancreatic lesions, which began at 6 days of age with vacuolation and hyaline body formation in the exocrine pancreas. As the deficiency progressed, cytoplasm degenerated until acini were represented by rings of cells with a central lumen embedded in fibrous tissue (Fig. 29.15).

Treatment

Addition of 0.1 ppm Se as Na_2SeO_3 to the diet caused complete pancreatic acinar regeneration within 2 weeks and a marked clinical recovery. Injecting chicks displaying exudative diathesis with 15 μg selenium greatly improved clinical signs within 6 days (22). High dietary levels of vitamin E (15–20 times the amount needed for prevention of other vitamin E-deficiency diseases) protect against the pancreatic degeneration caused by selenium deficiency (207). High plasma tocopherol levels were maintained by feeding 100 IU vitamin E/kg and bile salts to enhance its absorption. This greatly reduced incidence of exudative diathesis, which did not appear until the pancreas in chicks had degenerated severely.

Excess

Excess inorganic selenium interferes with sulfur metabolism due to the formation of sulfur-selenium complexes and the substitution of selenium for sulfur in cysteine. Excess organic selenium, usually as selenomethionine, is incorporated readily into proteins because $tRNA_{met}$ does not distinguish selenomethionine from methionine and selenomethionine is readily incorporated into proteins in place of methionine. These aberrations result in impaired protein synthesis, impaired function of proteins, and mutagenesis. A decrease in growth rate occurs with 5 mg/kg selenium in broiler chicks (196). Salyi *et al.* (166) reported an incidence of acute selenium toxicity in broiler chicks that was evident by watery diarrhea, weakness, somnolence, and cerebellar edema. Hepatic lesions include vacuolic degeneration, pyknosis of cells of the mononuclear phagocytic system (MPS), hemorrhagic dystrophy, and parenchymal atrophy. Kidneys had diffuse tubulonephrosis, followed by the necrosis of tubular epithelium. Myocardial and skeletal myodegeneration and damage of the bursa of Fabricius were also observed.

The developing embryo is particularly affected by high selenium (219). Hatchability is typically poor and those that hatch are often deformed, often with legs, toes, wings, beaks, or eyes that are rudimentary or completely lacking. Down is often wiry

and sparse (84). Chicks consuming excessive levels of selenium display slow growth, pectoral muscle atrophy, hepatotoxicity, edema, and claw and feather loss.

Public Health Significance

Poultry products are an important part of the human diet and supply highly bioavailable forms of nutrients. Levels of vitamins and minerals in meat and eggs are highly dependent on the levels in the diet. Birds fed diets that are deficient in vitamins or minerals do not supply intended levels of nutrition to human consumers. Animals deficient in nutrients are often immunocompromised, resulting in increased incidence of infectious diseases and, in some cases, evolution of more pathogenic disease organisms.

Often animals can serve as buffers for high levels of minerals or other nutrients found in plants and other foodstuffs, thereby reducing human exposure to potentially toxic nutrients. However, levels of some nutrients (e.g. selenium, iodine, copper, fluoride, and vitamin A) may accumulate in meat or eggs to levels that might adversely affect human health (142). Prompt diagnosis and correction of toxicities is important for safeguarding the human food supply.

Chapter 30

Developmental, Metabolic, and Other Noninfectious Disorders

Rocio Crespo and H. L. Shivaprasad

Introduction

The diseases and conditions discussed in this chapter represent a heterogeneous group; in some cases the etiology is quite clear, whereas in others it is questionable or unknown. They vary in economic importance and frequency of occurrence. Emphasis has been placed on metabolic diseases of economic importance to the modern poultry industry. Diseases have been classified by body system primarily affected; however, the initial part of this chapter covers diseases that are not associated with a specific body system conditions such as cannibalism, environmental disease, or amyloidosis.

Feather Pecking and Cannibalism

Feather pecking is a behavior expressed by dominant birds at subordinates. Feather pecking may vary from pecking to plucking the feathers of subordinate birds. Birds with damaged feathers have poor thermoregulation and greater energy demands than unaffected birds (356). The egg production in affected laying hens usually drops. If the feathers are severely damaged, hemorrhage may occur, which then attracts even more pecking. Appearance of blood on the exposed skin may lead to the death of the bird due to cannibalistic behavior from the other birds in the flock or the bird has to be culled due to the severity of the injuries.

There is a recognized individual and strain difference in the incidence of feather pecking, which implies a genetic component. Traditionally, light breeds of the Mediterranean class have been much more prone to feather pecking than the heavier breeds of the American and Asiatic classes (471). Today, cannibalism is more common in the modern brown hybrids than in the white layer lines (409). Recent studies have demonstrated genetic links between feather pecking and feather pigmentation (237).

Vent pecking appears to be a separate behavior. It generally occurs soon after birds have come into lay and may be linked to hormonal changes (294, 409). It is more common when birds in floor systems lay their eggs on the floor in crowded areas. It occurs immediately after oviposition, and exposure of the mucous membrane stimulates pecking by other birds. Vent pecking is responsible for at least 80% of all prolapses (153). It has been also

hypothesized that vent pecking may be the initiating lesion that triggers the onset of salpingitis in the oviduct and perhaps egg peritonitis (349).

Etiology

There is not general agreement in the causes of feather pecking. Feather pecking may reflect redirected ground pecking; however, it is not clear whether it is related to foraging behavior (food searching and food consumption) or dust bathing (409). Other possible causes of feather pecking may be fearfulness (46, 196) and may also be related to accelerated sexual maturity and increased egg production (73). Feather pecking has been also associated with early sexual maturation, fast growth, and weak bones (211). This study also found that victims grew faster, had lower corticosterone levels, and were less active in a restraint test. Feather pecking is more common in females than males (211), and the presence of males is an important factor in reducing the problem (153). Some of the conditions reported to stimulate feather pecking are bright light, pelleted feed or compressed feed, high-density rearing systems, nutritional and mineral deficiencies, and irritation from external parasites (200, 339). Although feather pecking and feather damage are more severe in hens housed in cages than in floor systems, cannibalism is less likely to occur in hens housed in cages than it is in hens housed in pens (29, 411). Since feather pecking and cannibalism tend to reoccur within the same group or in adjacent cages, it is suggested that it may be a learned behavior (450).

Prevention

Outbreaks of feather pecking and cannibalism occur unpredictably in birds, despite the measures taken to reduce their risk. Feather pecking and cannibalism can best be prevented by providing adequate diet, supplying with mash diets rather than pelleted feed, rearing the birds on floor litter rather than slats, reducing light intensity, providing perches as a refuge for pecked birds, and avoiding overcrowding (15, 215, 409). Environmental enrichment with pecking devices can reduce many of the harmful effects of pecking and allows the birds to exercise their natural behavior (216). Avoid selecting pecking devices that can increase social pecking such as plastic rods or shoe laces; also do not use systems that may be ignored by birds such as beads or motorized devices. Simple devices such as hanging white or yellow strings are particularly attractive stimuli to chickens (217). Inclusion of oat hulls and other insoluble dietary fiber in diets decreases the

incidence and severity of feather pecking (184). Beak trimming has been recommended as a means for controlling feather pecking and cannibalism (200); however, it may not be totally effective. In addition, there is an increasing public concern that break trimming may cause chronic pain (74). Beak trimming also may stimulate the growth of neuromas in the stump of the beak if done after 5 weeks of age (197). Plastic devices have been used in preventing feather pecking in gamebird rearing (15, 135), but so far these devices are not satisfactory for use in domestic fowl (410).

Environmental Disease

Heat Stress

All classes of poultry experience heat distress when high temperatures accompanied by high humidity rise above their comfort zone. Birds, unlike mammals, do not have sweat glands. When the environmental temperatures are between 28°C and 35°C (82°F and 95°F), birds utilize non-evaporative cooling (radiation, conduction, and convection) as major means of heat dissipation. Birds manipulate non-evaporative cooling in two ways: 1) increasing the surface area by relaxing the wings and hanging them loosely at their sides, and 2) increasing the peripheral blood flow (492). As the environmental temperature approaches the body temperature of the bird (41°C or 106°F), the rate of respiration increases and the bird open-mouth breathes in order to increase evaporative cooling or water evaporation. If panting (open-mouth breathing) fails to prevent body temperature from rising, birds become listless, then comatose, and soon die due to respiratory, circulatory, or electrolyte imbalances (448).

Increased respiration rate alters the acid-base balance since the CO_2 concentration in the blood decreases (34). The higher blood pH reduces the amount of ionized calcium in the blood, which is needed for eggshell formation. In consequence, laying flocks experience an increase in the number of thin-shell eggs. Panting or open-mouth breathing in heat stressed birds may lead to an increased incidence of respiratory infections, since the natural filters of the nasal passages are bypassed. Another sign of heat stress in a flock is reduced feed intake. In growing birds, fasting will decrease growth rate. In laying flocks reduction of feed intake will result in reduction of egg size, egg production and egg quality.

The extent of the losses from heat stress are determined by the age, environmental history, the maximum temperature to which the bird is exposed, the duration of the high temperatures, the rate of temperature change, and the relative humidity of the air (163).

Every effort should be made to prevent or alleviate heat stress in the flock. Increased air circulation in the house can be done by running ventilation equipment at full capacity. Cooling the air inside the house can be accomplished by using sprinklers or spraying down the floor, walls, ceiling, and outside roof with cool water during times of extremely high temperature. During periods of high temperature, adequate drinking water should be available. Techniques aimed at lowering water temperature of heat-distressed birds will aid in heat dissipation.

Several diet manipulations have been tested in heat stress

birds. Egg production improves by increasing the intake of protein relative to energy, but energy requirements increase in severe heat stress (12). Addition of vitamins (A, C, and E) and electrolyte supplements may help in preventing heat stress (439), possibly by replenishing the minerals and correcting the acid/base balance. However, there is still controversy regarding the effect of some these nutrients. For instance, addition of vitamin E in the diet has shown a beneficial effect in layers (31, 463), but other researches have found no effect with addition of this vitamin to the diet (447, 451). Some drugs, such as nicarbazin or monensin (404, 451), have deleterious interactions when administered to heat stressed birds; while others, such as virginiamycin (451), may alleviate heat distress.

Preventive measures consist of installation of fans and foggers, proper construction of ventilating ducts, insulation of the buildings and water pipes, roof overhangs to prevent the sunlight from shining into the house and use of white or aluminum paint on the outside to reflect heat. In southern climates where low production and mortality from heat are constant problems, installation of foggers and sprinklers or evaporative coolers is essential. Also, enhancement of adaptability of birds to heat stress conditions, such as early thermal conditioning should be considered (91).

Asphyxiation

Asphyxiation is generally caused by birds crowding or piling in a corner. It may occur when birds are moved to new quarters, when they are frightened, or in young birds when they are chilled. Asphyxiation also may happen when power fails or ventilation system is faulty in controlled-environment houses that have no windows. The history of the case often indicates that mortality occurs only at night and the flock in general looks healthy. Asphyxiation of baby chicks can occur in chick boxes that are piled too high without an air space between each box, in boxes that do not have sufficient ventilation holes, or in boxes placed in a closed compartment such as the trunk of a car. Necropsy of birds that have asphyxiated usually does not reveal specific gross or histologic lesions to make a positive diagnosis, but a thorough examination will eliminate other possible causes of death. In birds that have smothered, there is congestion of the trachea and lungs, and in older birds feathers will be worn off where birds have been trampled.

Asphyxiation of chicks in the brooder house can be controlled by putting a circle of corrugated cardboard around the hover for the first week of life and gradually widening the diameter as chicks get older. This will prevent piling in a corner during the night. When birds are moved to new quarters, the use of a dim light or lantern the first few nights will decrease the possibility of smothering. Birds transferred to new quarters should be checked late in the evening for signs of piling. Frequent observation of the flock is very important the first few days after acquiring a group of new chicks or grown birds.

Dehydration

Dehydration is generally caused by failure of birds to find water, inability to reach the water, failure to provide adequate amount of water, or in some cases by a deterring factor in the water. Chicks can survive several days without water but will die beginning on

the 4th or 5th day. Mortality will reach its peak during the 5th or 6th day and terminate abruptly if water is provided. Chicks that are not drinking will have succumbed by this period, and survivors are those that have found the water and are drinking. Laying birds need a constant water supply or production will drop. Birds will die if the water restriction is severe. Dehydration can be detected by the chick's inability to "peep" during the later stages, insufficient weight for size and age, and dehydrated and wrinkled skin on the shanks. Other changes are blue discoloration of the beak, dry and dark breast musculature, dark kidneys, accumulation of urates in the ureters, visceral urate deposition ("visceral gout"), and darkening of the blood. Signs and lesions in older birds are similar to those in chicks, and weight loss is much more noticeable. To prevent dehydration in chicks, water fountains should be placed at the edge of the hover directly on the litter without any platform. When a large type or automatic drinkers replace a small drinker, the old type should be kept for a few days and gradually moved toward the new source of water supply to accustom birds to the change. Faulty electrical heating devices used to prevent freezing may cause an electrical charge in the water, and birds will not drink.

Incubation and Hatchery Related Problems

It is a common misunderstanding in the poultry industry that health problems in birds begin with hatching. Incubation conditions have a profound effect on chicken survival and quality. Poor incubation causes major losses to the industry, not only due to low hatchability or increased early mortality (146); but also due to growth depression, unevenness of the flock, increased susceptibility to infectious agents, and increased incidence of leg problems (370). It is important to identify the problem in order to minimize the losses in a flock. Temperature, humidity, ventilation, and egg turning are critical factors for hatching good quality chickens and turkeys. Embryos or recently hatched birds are more susceptible to chilling or overheating than older birds. The most typical complaint caused by high incubation temperature, and sometimes from low humidity, is "unhealed navels." Unhealed navel is a broad term that includes black buttons, strings, and ectopic viscera. Temperatures of 3 degrees higher than normal during the last week of incubation are also associated with increased number of late dead embryos, unevenness in the flock, skin necrosis, and high incidence of leg problems including slipped tendons. Effects of low incubation temperature are more pronounced during the first week of incubation. Some of the effects of low temperature include high incidence of late dead, pipped alive, increased residual albumen, unsteady gait, and high incidence of spraddle leg deformities. Low temperature while in the hatcher induces increased number of navel abnormalities such as improper closure of the navel, bloody navels, and urates attached to the yolk sac. Starvation and dehydration may occur when birds are accidentally held in hatching machines for long periods.

Early chick mortality has also been associated with rupture of the yolk sac. Late hatching chicks may have a higher incidence of ruptured yolk sac. Because of the dry conditions in the hatcher the yolk sac may adhere to the wall of the abdomen reducing its mobility and increasing its susceptibility to injury during hatchery manipulations. Also, during sexing the handler may squeeze the birds too firmly, increasing the incidence of ruptured yolk sacs (418). If the humidity during incubation is higher than normal, the hatchlings may have large yolk sacs. These yolk sacs are not well suited to withstand standard handling practices at the hatchery and consequently there is an increased incidence of yolk sac ruptures (268).

Prevention can be achieved by establishing standards for the hatchery and maintenance of equipment, especially ventilation systems. Environmental temperature, humidity and pressures in every room should be taken on a daily basis and variations in these parameters should be minimized. Diagnostic work of the unhatched eggs left in the hatching trays should be done to establish specific causes of mortality or poor performance in the flock and to solve hatching problems. Optimizing incubation conditions and handling birds with care during sexing can minimize the incidence of ruptured yolk sac (17, 268).

Starve-out

Mortality in young birds, between 1 and 10 days of age, that is not from infectious diseases is commonly referred to as starve-out because it is generally associated with lack of water and nutrient intake. Management and environmental factors including temperature, light, and water and feed quality may contribute to early mortality. Under commercial hatchery conditions, birds may be 24–48 hour old before they are removed from the hatchery, and additional time is spent in processing and transportation to the farm. As a result, most birds are delivered when they are 50 hours old or older, and will do well if they are placed in brooders and given adequate feed and water. However, mortality up to 6.14% has been reported in birds if they are placed at 72 hours after hatching. Mortality increased to as high as 35.14% if they were not placed until 120 hours after hatching (132). As soon as the birds are placed in the brooders, they should be encouraged to eat and drink. There are no specific gross lesions associated with starve-out. In general, the starve-out birds are smaller, dehydrated, and have dark shanks. The crop, proventriculus, and gizzard may contain litter material, but not feed. Infectious diseases should be ruled out before making a diagnosis of starve-out.

Management practices that delay or discourage birds from eating and drinking should be avoided in order to prevent starve-outs. The optimal temperature in the house at placement and during the first week is crucial for encouraging birds to seek for water and feed. The birds must have adequate light to easily find the feeders and drinkers. Drinkers and feeders should be adequately spaced and easily accessible. The feed should be palatable. If the crumbles or pellets are too large, the birds will not be able to eat them. If the feed is too fine, it will stick to the beaks of the birds. If the feed or water is too warm the chicks will not eat or drink. Some hatcheries inject the birds subcutaneously with a glucose solution to prevent starve-outs. However, no differences were found in the total mortality between fasted and glucose treated poults at 2 wk of age (304).
30.1. Layer chickens with severe myositis and muscle atrophy secondary to vaccination. Bar = 1 cm.

Problems Related with Vaccination

Killed vaccines and bacterins usually employ an oil adjuvant to stimulate a localized inflammatory reaction and improve the immune response. When oil-emulsion bacterins are administered subcutaneously into the neck, the adjuvant may infiltrate into the adjacent tissues causing dermatitis, neuritis, and myositis (2). Neurological and/or musculoskeletal problems, which impair the birds' ability to eat, have been documented when a killed vaccine is delivered subcutaneously in the neck and/or too close to the skull. Killed vaccines administered intramuscularly into the breast or leg muscles (Fig. 30.1) may produce severe granulomatous myositis near the site of injection (98). The birds may refuse moving due to muscle damage, lose weight and have reduced production; besides, the meat may be downgraded at the processing plant due to trimming of affected areas. Live or attenuated vaccines and bacterins also have been reported to cause pathologic changes in the birds. In young chickens, in ovo and subcutaneous live vaccines given at the hatchery have been associated with neurologic signs, pyogranulomatous myositis, neuritis, and meningomyelitis (Fig. 30.2). Since these vaccines do not have irritant substances, the tissue reaction is thought to be a misdirected vaccine (168, 424). Bacterial contamination of the hatchery's vaccine equipment has caused nervous symptoms and increased mortality in young birds (298). To minimize the inflammatory reaction in the tissues, manufacturer recommendation should be followed in vaccinating birds and vaccinating crew should be trained in injecting the bacterins and vaccines into the correct site. Vaccine equipment should be maintained clean and disinfected to avoid bacterial infections.

Amyloidosis

Amyloidosis is a well-recognized pathologic disorder in birds, characterized by deposition of proteinaceous material between cells in various tissues and organs of the body. Once the deposition of amyloid has started the progression of this disease is irre-
30.2. Histologic section of meninges around the spinal cord (bottom) of a 2-day-old broiler chicken that was vaccinated in the neck. Note the nonsuppurative meningitis, most likely associated with misdirected vaccination. H & E, bar = 10 μm

versible, because these proteins have low solubility and are relatively resistant to proteolytic digestion (239). There are more than 15 biochemical types of amyloid protein recognized in mammals (69); however, only amyloid A (AA) has been detected in birds (251, 310). Amyloidosis caused by AA is frequently associated to an underlying infectious or inflammatory condition (238). Landman *et al.* (251) have published an excellent review of amyloidosis in birds. Among the domestic avian species, waterfowl are most susceptible to amyloidosis. Birds of all ages are susceptible to amyloidosis, but it is most common in adults, although it can occur in ducks as young as 4 wk of age (420).

Clinical Signs and Pathology

No specific clinical signs or gross lesions are associated with systemic amyloidosis. Clinical signs in ducks may include anorexia, lethargy, loss of weight, decreased egg production in layers, swollen abdomen, and increased mortality in the flock. In Brown egg-laying type chickens locomotor problems due to

swollen joints and weight loss can be encountered. But often the birds with amyloidosis are submitted for necropsy after being found dead with no prior clinical signs.

Brown egg-laying type chickens are particularly susceptible to amyloid arthropathy caused by *Enterococcus faecalis* (252, 253) and by *Mycoplasma synoviae* (MS)(250). Amyloid arthropathy associated with MS has also been reported in turkeys (427), but the disease has not been reproduced experimentally. Other bacteria such as *E. coli, Salmonella enteritidis* and *Staphylococcus aureus* have also been associated with amyloidosis in chickens (249). The authors also have observed amyloidosis associated with *M. gallisepticum*. Another condition in which amyloidosis is frequently encountered in mature chickens is hepatitis-splenomegaly syndrome, which results from infection by hepatitis E virus (see "Hepatitis E Infections" in Chapter 14). Amyloidosis associated with mycobacteriosis is a common finding in waterfowl and other birds in zoological collections (164, 303). Management and genetic factors may also play an important role in the incidence of amyloidosis especially in ducks raised commercially.

Amyloid deposition may be found in any tissue; the most commonly affected organs are liver, spleen, intestine and kidney. Gross lesions may be none or minimal when amyloid deposits are present in small amounts. When present in significant amounts the lesions include severe ascites ("water belly") most common in ducks and diffusely enlarged heavy liver with firm to rubbery consistency and pale or brown or grey smooth surfaces (Fig. 30.3.). Cut surfaces of the liver may have a smooth waxy appearance and the capsule may be thickened due to fibrosis. Occasionally the livers of some affected birds may have multiple hyperplastic nodules of various sizes that may have the normal color of the liver. Spleen can be severely enlarged and mottled white (Fig. 30.4). Kidneys and adrenals may be enlarged and pale. Brown egg-laying type chickens with amyloid arthropathy may have enlarged joints with presence of orange-yellowish material in the joints (Fig. 30.5).

During the gross examination, application of Lugol's iodine to a suspected organ brings out the amyloid as distinctly brown material. If this is followed by application of dilute sulfuric acid, amyloid will change from brown to blue. Microscopically, amyloid appears as homogenous eosinophilic material deposited extracellularly in many organs (Fig. 30.6a). When amyloid is stained with Congo red it appears as brownish-orange and emits apple green birefringence under polarized light (Fig. 30.6b and 30.6c). Amyloid A can also be extracted and identified from formalin-fixed tissues using the Shtasrburg method (433).

Treatment and Prevention

There is no treatment for amyloidosis. Adequate management to prevent chronic infections or stress in birds would reduce the incidence of amyloidosis. Deposition of amyloid interferes with the normal functions of the affected tissue and it can be life threatening. Thus, treatment of the underlying inflammatory disease or stress factor should start as soon as possible to prevent or stop the progressive deposit of amyloid in the tissues. In a recent study, deposition of AA in the joints of chickens was enhanced by feeding a high dose vitamin A, while methylpred-

nisolone (an antiinflammatory drug) and pentoxifylline had an inhibitory effect (415).

Diseases of the Skeleton

Dyschondroplasia

Dyschondroplasia is restricted to the abnormal persisting accumulation of cartilage from the growth plate in which maturation of prehypertrophic and hypertrophic chondrocytes is retarded or stunted. It is a common defect associated with the growth plates of meat-type chickens, ducks, and turkeys. It is characterized by an avascular plug of abnormal cartilage in the growth plate of long bones. It is most commonly recognized in the proximal tibiotarsus, and, hence, the condition is often described as tibial dyschondroplasia. Dyschondroplasia also occurs, but is less severe, in the proximal and distal femur, the distal tibia, the proximal tarsometatarsus, and the proximal humerus (363). Reviews on the condition have been written by Farquharson and Jefferies (134), Orth and Cook (338), Thorp (454), and Whitehead (474).

Clinical Signs and Pathology

In many broiler chicken flocks up to 30% of birds may have lesions of dyschondroplasia characterized by abnormal masses of cartilage below the growth plate, primarily in the proximal tibiotarsus (Fig. 30.7), but also at other sites. In turkey flocks the incidence of dyschondroplasia has been reported as high as 79% (470). Most birds show no clinical signs. If masses of cartilage are large, birds may exhibit reluctance to move, stilted gait, and bilateral swelling of the femoral-tibial joints often associated with bowing of the legs. The abnormal masses of cartilage in the proximal tibia tend to be cone shaped. In mild cases, these cones of abnormal cartilage mainly develop below the posterior medial part of the growth plate. In severe cases, masses of cartilage develop from the whole growth plate and fill the whole metaphysis. Severity of the tibial dyschondroplasia lesions has been correlated with the degree of anterior bowing of the tibiotarsus and lameness in broiler chickens (272). The concave surfaces of such bones have hypertrophied cortices. This is considered an adaptive change (122). A high association between leg deformities and tibial dyschondroplasia also has been described in turkeys (470). Fractured fibulae have been associated with tibial dyschondroplasia and bowing of the tibia (363). These fractures occur at the iliofibularus, but are not always associated with abnormal tibiotarsal curvature (106). Dyschondroplasia in the femoral head in broiler chickens has been associated with a widened and shortened femoral neck and, in some cases, with fractures of the femoral head (99–101).

In a survey of leg weakness in broiler chicken flocks processed at 7 wk of age or earlier, few birds were culled because of dyschondroplasia (399). However, dyschondroplastic lesions can be recognized on radiographs and with a hand-held lixiscope from 2 wk of age (454). Interestingly, dyschondroplasia within the proximal tibiotarsus appears to be bilateral, and the incidence and severity of the tibial dyschondroplasia is similar in both legs (134). Downgrading of carcasses and trimming of deformed legs at processing have been attributed to dyschondroplasia (48, 399).
30.7. Medial view of sagittal sections of two proximal tibiotarsal bones from broiler chickens with tibial dyschondroplasia. The abnormal cartilage is only present in the posterior part of the metaphysis (*right*); abnormal cartilage fills the whole metaphysis, and the proximal end of the bone is enlarged (*left*). (Craig Riddell)

If broiler chickens are kept to roaster weights, lesions due to dyschondroplasia may be much more severe. In such birds, fractures below the abnormal cartilage in the tibia may cause severe crippling (Fig. 30.8). Resolution of the abnormal cartilage may start as early as 48 days of age, but sequestra of abnormal cartilage separated from the growth plate and bowing of the tibia may persist to as late as 30 wk of age, even though the proximal growth plate of the tibiotarsus in a chicken closes at 16–17 wk of age.

In turkeys, dyschondroplasia is recognized as early as 5 weeks (363). It peaks between 12 and 14 weeks of age (192). The incidence rate of dyschondroplasia start dropping around 15 wk of age, until the age of closure of the proximal tibial physis at 22 to 24 weeks but 5% or more of the toms may still retain some abnormal cartilage (470). Whereas there is no correlation between the body weight of turkeys and dyschondroplasia in early ages, the severity of dyschondroplasia is directly correlated with body weight between 14 and 15 wk of age (375).

Microscopically, dyschondroplasia is characterized by persistence and accumulation of prehypertrophic cartilage. The separation of the prehypertrophic cartilage from the proliferating cartilage is not sharply demarcated and few vessels penetrate the abnormal cartilage from the metaphysis. Normal growth plates or those with small dyschondroplastic lesions have few or no apoptotic chondrocytes, while in severe lesions numerous apoptotic cells with shrunken nuclei and little cytoplasm are present (378), suggesting that apoptosis is secondary to the formation of the car-

tilaginous plug. Other studies have shown quite the opposite, that the dyschondroplasia lesions are associated with lack of apoptosis, which may be responsible for the retention of chondrocytes (326).

Ultrastructural and biochemical studies have demonstrated that the lesion begins in the prehypertrophic zone. The chondrocytes in the abnormal cartilage do not differentiate into fully hypertrophic chondrocytes (173, 362, 473), which are needed for cartilage vascularization, mineralization, and resorption. The abnormal chondrocyte mitochondria retain less calcium and phosphorus as compared to normal chondrocytes. Changes in extracellular matrix composition between the abnormal cartilage and normal hypertrophic cartilage that have been reported include lower levels of sulfur, potassium, calmodulin, alkaline phosphatase, collagen type X, prostaglandin precursors, proteoglycans, glycosaminoglycans, and transforming growth factor-ß (TGF-ß) and c-myc protein (133, 270, 338, 454, 473). The increased in nonreducible collagen cross-links observed in the matrix of abnormal cartilage in chickens (338) may be associated with the lack of release of collagen type X from the chondrocytes (473).

Pathogenesis and Etiology
The pathogenesis of dyschondroplasia is not well understood. Many hypotheses associated with defects of metaphyseal vasculature tried to explain the cause of dyschondroplasia. These include abnormal cartilage that cannot be invaded by metaphyseal vessels (363), occlusion of vascular canals from the epiphysis (101) and defective degradation of cartilage (256). It is now accepted that dyschondroplasia is a consequence of an inability of the prehypertrophic chondrocytes to undergo terminal differentiation. It is essential to recognize the mechanisms involved in the maturation of chondrocytes in order to prevent dyschondroplasia; unfortunately, these processes are not fully understood.

Some studies have shown that locally produced peptide growth factors play important autocrine and paracrine roles in development of the growth plate (261). A malfunction of one of these factors may be important in the development of tibial dyschondroplasia (454). TGF-ß has been found in the prehypertrophic and hypertrophic chondrocytes of the growth plate, and it regulates chondrocyte differentiation (457). TGF-ß expression was reduced in transitional chondrocytes in tibial dyschondroplasia, but its expression was increased where the lesion was being repaired (270). Fibroblast growth factor-ß, a potent angiogenic factor, is also reduced in tibial dyschondroplasia (487). Additionally insulin-like growth factor-I (IGF-I), basic fibroblast growth factor, and transforming growth factor-α, which are normally found in the more mature chondrocytes of the growth plate, are reduced in dyschondroplastic chondrocytes (457). Systemic as well as local growth factors may be important in the pathogenesis of tibial dyschondroplasia (456, 457). An altered paracrine function of growth plate "macrophages" may result in reduced cartilage degradation and tibial dyschondroplasia (68). Alkaline phosphatase and type X collagen, markers of chondrocyte differentiation, as well as c-myc protein an inducer of apoptosis, are reduced in the extracellular matrix of dyschondroplastic lesions (134, 473). On the other hand, the chondrocytes still retain the ability to express alkaline phosphatase and type X collagen (379, 473). This suggests that tibial dyschondroplasia is due to a metabolic dysfunction rather than to an alteration in the expression of genes.

Vitamin D_3 and its metabolites have been shown to reduce dyschondroplasia. A recent study (477) showed high concentration of vitamin D_3 (250 μg/kg) prevented tibial dyschondroplasia. Previous to this report, only addition of vitamin D metabolites, such as 1,25-dihydroxicholecalciferol, have been shown to be very effective in reducing the incidence of dyschondroplasia (134, 382). No correlation between the plasma level of 1,25-hydroxycholecalciferol and the incidence of tibial dyschondroplasia was found in one series of experiments, and it was suggested that the ability to utilize the vitamin D metabolite at the receptor level might affect the incidence of tibial dyschondroplasia (129). On the other hand, Parkinson *et al.* (348) found some broiler strains that have a higher predisposition to dyschondroplasia also have lower serum concentrations of 1,25-hydroxycholecalciferol. However the higher concentration also decreased body weight. The incidence of tibial dyschondroplasia was prevented when chicks received ultraviolet radiation even without vitamin D_3 supplementation (125).

The incidence and severity of tibial dyschondroplasia can be influenced by nutrition and genetic selection (134). Rapeseed meal, sorghum, and some types of soybean have been suggested to increase the occurrence of tibial dyschondroplasia (469). Some dietary supplements that are linked to increased incidence of dyschondroplasia include rations containing added cysteine or homocysteine (338), copper-deficient diets (260), rations contaminated with the fungus *Fusarium* sp. or its product fusarochromanone (59, 338), and rations containing dithiocarbamate fungicides (338, 377, 379). Also some antibiotics, such as zinc bacitracin and salinomycin, may increase the incidence of tibial dyschondroplasia (469).

Though in original reports calcium and phosphorus levels in the ration were considered to have no effect, it has been shown that the incidence and severity of tibial dyschondroplasia in broiler chickens can be increased by feeding high levels of phosphorus relative to the level of calcium (124, 127, 398, 400). Feeding turkeys similar levels of phosphorus and calcium did not result in a high incidence of tibial dyschondroplasia in turkey poults (405). Tibial dyschondroplasia in broiler chickens was not eliminated by feeding a ration containing 1.5% calcium and 0.5% available phosphorus (398).

It has been assumed that rapid growth is a major cause of tibial dyschondroplasia, because restricting feeding reduces the incidence of this disorder (400). The presence of the most severe lesions of dyschondroplasia in the proximal tibiotarsus may be due to the growth plate at that site having the most rapid growth. Daily fasting can also reduce incidence of tibial dyschondroplasia without causing growth depression (126). It has been suggested that diurnal rhythms may be important in reducing tibial dyschondroplasia (129). An interrupted- and increasing-light program had no effect on clinical and subclinical tibial dyschondroplasia in roaster chickens (394). An intermittent light program reduced the incidence of tibial dyschondroplasia in one line of broiler chickens, but not in another two lines (506). Although reducing the growth rate of experimental birds decreased the incidence of tibial dyschondroplasia, there was no direct correlation between growth of individual birds and the incidence of tibial dyschondroplasia (246, 388). Numerous investigators (386, 455, 505) have shown that the occurrence of tibial dyschondroplasia is susceptible to genetic selection. After several generations of selection Yalcin *et al.* (507) were able to reduce the incidence of tibial dyschondroplasia without affecting the body weight of the birds.

Osteoporosis

Osteoporosis in laying hens is defined as a decrease of normal mineralization of structural bone, resulting in increased fragility and susceptibility to fracture. It was first described in caged laying hens that had brittle bones and were unable to stand, but willing to eat and drink (70). The condition was then called "cage layer fatigue." Osteoporosis is still the most significant disease of the skeleton of laying hens kept in battery cages. Bone fragility is responsible of up to 30% of fractures of commercial flocks during their life, and the incidence may reach up to 90% during catching, transporting, and processing (162, 476).

Clinical Signs and Pathology
Osteoporosis normally consists of loss in bone quality which predisposes the birds to fractures in a range of bones of the body. Ischium, humerus, and keel bones show the highest incidence of fractures, followed by fractures of pubis, ulna, coracoid and femur (160). In the most severe cases, it can cause paralysis due to the collapse of the spinal bone (16). They often are alert, but later become depressed and die from dehydration. Osteoporosis is more severe between 25 and 50 wk of age (138).

On postmortem examination, fractures are normally found in leg and wing bones, and bones throughout the skeleton are easily broken. If the bird is paralyzed, fractures of the vertebra are rarely seen; however, the loss of structural bone may lead to exposure of the spinal cord leading to pressure on exposed nerves (476). Sterna are often deformed, and there is characteristic infolding deformation of the ribs at the junction of the sternal and vertebral components. The bone cortex is thin, but there are no changes in the external dimensions of the bone, because cortical bone resorption is restricted to the endosteal surface (11). Parathyroid glands are enlarged. Many birds have regressive ovaries and are dehydrated, while some dead birds have an egg in the oviduct and have died acutely.

On histology, the cortices of bones are thin, with enlarged absorption spaces. Medullary bone is reduced in amount, and largely consists of osteoid. The deformation of the ribs can be due to small fractures. Damage to the spinal cord is often associated with pressure on the nerves, which may cause paralysis.

Pathogenesis, Etiology, and Control
With the onset of sexual maturity there is a rise in estrogen that results in a switch from structural bone formation to accumulation of medullary bone (476). The resorption of structural bone starts at sexual maturity and continues during the production life so that osteoporosis is more severe at the end of lay. Additionally increased bone fragility is associated not only with loss of mineral, but also with modifications in the collagen structure (240, 440).

Type of housing has been shown to affect the incidence of osteoporosis. Confinement of laying hens in cages has been shown to reduce bone strength significantly (241, 323). Structural bone loss and bone strength are directly associated with the amount of exercise allowed. Numerous publications discuss the relationship between type of housing and bone strength (139, 265, 472, 475). Bones from laying hens kept in perchery systems are stronger than those from hens kept in enriched cages, litter or wire systems; while hens kept in conventional cages had the weakest bones. One experiment demonstrated that bones from egg layers became stronger after just 20 days of transferring the birds from cages to floor pens (320). Studies directed at defining and preventing bone breakage when hens are processed at the end of their production cycle revealed that a greater incidence of freshly broken bones in laying hens after handling at processing time has been described in hens from cages, compared with hens from other housing systems (162). The incidence of bone fractures is also influenced by the method of handling (161).

Nutritional methods of preventing osteoporosis have not been successful. However poor nutrition may exacerbate the problem. The formation of strong cortical bone and adequate medullary bone prior to egg production may be helpful in reducing osteoporosis. Increased calcium in the ration prior to egg production may be necessary, but it has been suggested that if increased calcium is fed for too long before egg production, the parathyroid gland may be suppressed. Feeding calcium in particulates, either as oystershell or limestone granules, may extend the period of calcium absorption during the night, which reduces the depletion of medullary bone and benefits the eggshell quality (137, 138); however it does not have much impact on the loss of structural

bone. Combination of limestone with fluoride and/or vitamin K_3 during the laying period had no greater benefits than limestone alone (137).

Treatment of pullets with alendronate, an inhibitor of bone re-sorption, just prior to the onset of lay decreased the loss of can-cellous bone (460). Unfortunately at the time of lay, alendronate prevented only the loss of medullary bone, but did not stop the loss of structural bone (500).

Selection pressure to maximize egg production might have contributed to the osteoporosis by producing strains of birds with poor bone quality. Bishop *et al.* (24) were able to reduce the in-cidence of bone fractures and increase bone strength after five generations in a commercial line of white leghorns. They found that cancellous and medullary bone volumes were poorly herita-ble parameters; but keel radiography density, humeral and tibial strengths, and index calculated from these 3 traits are promising predictors of bone characteristics and resistance to osteoporosis.

Valgus and Varus Deformation

Deformation of the long bones of the broiler chicken and turkey is a significant cause of economic loss due to culling and death of affected birds. Such deformation includes many different types of twisting or bending of the bones and has been described by terms such as *long bone distortion*, *twisted legs*, or *crooked legs*. The general topic of deformation of the long bones in do-mestic poultry was reviewed by Riddell (388, 391) and Thorp (453, 454). The most common type of long bone deformation in the broiler chicken is valgus or varus deformation (VVD) of the intertarsal joint (219, 373, 399). In the turkey, similar deforma-tion of the intertarsal joint is also common but is often associated with varus deformation of the femoral-tibial joint (387). In broiler chickens, the incidence of birds affected with varus defor-mation varies from 1 to 3% while valgus of the tarsal joint affects 30 to 40% of the birds (263). Male broilers have higher incidence of VVD than females (219).

Clinical Signs and Pathology
Valgus or "knock-kneed" results from the outward deviation of the tarsometatarsus when placed in line with the tibiotarsus (373). Varus deviation or "bow-legged" is the consequence of in-ward deviation of the tarsometatarsus when lined with the tibio-tarsus (373). The major deformity is in the distal tibiotarsus, with similar but less severe angulation in the proximal tarsometatarsus (Fig. 30.9 and 30.10). The valgus deviation is more common; but varus deviation may result in more restricted walking ability in poultry (67, 263). The defect may affect both legs but is often unilateral, with the right leg more commonly affected than the left leg (121, 399). Approximately 70% of affected birds are males (399). Most birds have either valgus or varus deformation, but the occasional bird will have valgus deformation of one leg and varus deformation of the other leg. These birds have been de-scribed as "windswept" (112). Abnormal rotation of the femur may also be present (121).

Leterrier and Nys (263) observed that valgus angulation ap-pears progressively between 2 to 7 wk of age and is often bilat-eral; on the other hand, varus deviation appears suddenly between

30.9.   Broiler chicken with unilateral valgus deformation of the in-tertarsal joint. (*Avian Diseases*)

30.10.   Tibiotarsal and tarsometatarsal bones from a broiler chicken with unilateral valgus deformation. (*Avian Diseases*)

5 and 15 days of age and most of the cases are unilateral. Other researchers found a similar appearance and progression of both defects with age (219, 389). As the severity of the valgus angula-tion increases, the gastrocnemius tendon may become displaced and the distal tibial condyles become flattened. In the varus de-

viation, the gastrocnemius tendon is always displaced medially (263). In some cases, the angulation progresses to displacement and separation of the tarsal bones from the shaft of the tibia. With severe angulation, birds are forced to walk on the posterior surface of the hock, which becomes bruised and swollen. In some instances, the distal shaft of the tibia will penetrate the skin.

Pathogenesis and Etiology

The pathogenesis of the deformation has not been defined. The last 40 years have seen an increase in growth rate as well as incidence of VVD. Slowing growth rate can reduce the incidence of VVD (188, 198, 389). However, reducing energy in the diet does not improve the quality of the cortical bone and reduced limb angulation might be due to lower body weight placing less stress on the skeleton (264). A higher incidence of VVD occurs in broiler chickens raised in cages compared with broiler chickens raised in floor pens (188, 380, 389). This may be explained by a lack of exercise in cages (188). Stronger cortical bone in chickens occurs with exercise (402). Different photoperiods will affect the incidence of VVD (63, 394). It is unknown whether this is due to a change in growth rate, amount of exercise or a hormonal factor. An increased incidence of angular limb deformities has been reported in turkeys subsequent to malabsorption syndrome at an early age (358).

Young normal broiler chickens have slight valgus deformation. This small inclination of the growth plate in a rapidly growing chicken may promote deviant growth (373, 396). In the rapidly growing modern broiler chicken, the vascular morphology of the growth plate is irregular, and this may predispose the chicken to VVD (452). Some workers (88, 205, 206) have noted a delay in cortical bone differentiation, which precedes the angulation. It has been suggested that valgus and varus deformities may each have a different etiologic pathogenesis (263) and that these deformities may be heritable (258). It is also considered that selection may influence the incidence of leg deviations. Le Bihan-Duval *et al.* (259) estimated that the susceptibility to valgus deformity was genetically independent of meat conformation, while varus deformation increased with body weight.

VVD should not be mistaken with leg deformities caused by several nutritional deficiencies, such as manganese deficiency. In manganese deficiency there is a generalized disorder of the growth plates or dyschondroplasia of the long bones (388). No evidence of the microscopic growth plate lesions has been recognized in VVD (373, 395). The possibility that submicroscopic lesions of the growth plate due to marginal nutritional deficiencies may result in VVD should not be ignored. An association between VVD and dyschondroplasia has been noted (363, 373, 389). Although dyschondroplasia may weaken bones and predispose to deformation, it may be secondary to the deformation (502). In a breeding study, it was observed that VVD was unrelated to dyschondroplasia (386).

Degenerative Joint Disease

Degenerative changes in joints have been recognized primarily in coxofemoral joints of mature male turkeys (103, 107) and mature meat-type chickens (107, 113), and in the spine of laying hens

30.11. Anterior and lateral views of distal femora from breeding turkeys with degenerative joint disease. Note the erosions, and thinning of the articular cartilage.

(508). They have also been reported in the femoral-tibial and intertarsal joints of turkeys (104, 118) and male broiler breeding fowls (113, 117). Duff (103) reviewed early reports of degenerative hip disease in poultry.

Clinical Signs and Pathology

Degeneration of the articular cartilage causes pain and lameness (123) by exposing the subchondral bone and impairing the ability of the cartilage to provide a smooth articulating surface to the joint (65). Turkeys with degenerative hip disease assume a stance with abducted pelvic limbs and constantly shift weight from one leg to another and are reluctant to move. In turkeys, the initial gross lesions are found in the articular surface of the antitrochanteric region of the acetabulum (103). As the degeneration progresses both the femoral and acetabular components of the coxofemoral joint become involved. Degenerative lesions are also found in the femoral-tibial and intertarsal joints (Fig. 30.11). Erosions, fissures and thinning are characteristic lesions of the articular cartilage. In addition flaps of cartilage and/or osteophytes that may break free to give fragments within the joint may form in the degenerative articular cartilage. The articular cartilage of birds with degenerative joint disease is more hydrated with a higher uronic acid content than those from normal joints (6). Periarticular fibrosis accompanies severe lesions (103).

Microscopic changes in the cartilage include loss of normal structure, areas of necrosis, fissures, and massive chondrocyte clusters (102). Surface fibrillation occurs in the articular cartilage (6). In some cases there is evidence of disturbed endochondral ossification. It was proposed that the lesion in such cases could be described as osteochondrosis dissecans (104). There is also mild hyperplasia and hypertrophy of the synovium (6).

Pathogenesis and Etiology

The pathogenesis of many of the joint lesions described above is not clear; however morphologic and biochemical changes of the articular cartilage are similar to mammals. Many may result from primary damage to the articular cartilage, while others may be sequelae to osteochondrosis (107, 113). Since heavy breeds, white-broad breasted turkeys and broiler chickens are more af-

fected by this disease, genetic factors may play a role in modifying cartilage development (6).

Spontaneous bone fractures

Bone fractures are one of the causes downgrading and trimming of poultry carcasses. Breakage of leg bones are economically more important. Fractures may occur spontaneously on the farm or during catching or transportation. In meat-type poultry, spontaneous fractures occur more frequently during the last part of the grow-out. In turkey breeders, complete fractures have been associated with preexisting stress or partial fractures in males (77). In laying hens, osteoporosis is the most common predisposing factor to bone fracture (see Osteoporosis section).

Clinical Signs and Pathology

Fractures of leg bones cause lameness in affected birds. Down birds may die if they do not reach feed or water or are killed by other birds in the flock. Femoral fractures were associated with increased mortality of up to 1% per week in flocks of heavy tom turkeys (77, 360). At necropsy birds had complete closed oblique fracture of the femur. In breeding turkeys the fracture line was associated with a site of callus formation (77). Lower ash, calcium and phosphorus were found in the bone cortex of broilers with fractures than those bones of birds from the same flock that did not have fractures (458). Similar findings have been reported in turkey breeder flocks (76).

Pathogenesis and Etiology

Poor bone quality increases the risk of bone breakage (78, 376). Growth rate is considered an important determinant of bone strength. One study (264) showed no improvement in mineral quality of the cortical bone when the growth rate was reduced; but this study did not investigate the effect on the organic components or the mechanical characteristics of the bone. Selection for increased body weight associated with increased breast muscle and no appreciable changes in the skeleton (67, 267) puts higher stress on the cortical bone increasing the probability of fractures. Heavy birds with large breast muscle are less active than light birds (190, 267); lack of exercise may be responsible for decrease of bone density (322). Growing male birds may be more susceptible to fractures than females, because males have a more porous cortex and less adapted to physical stress females (403). In turkeys, leg fractures occur more frequently in the femur of growing birds (267). There is indication that maturation, including mineralization rates, occurs slower in the femur than what is observed in the tibia (267). Bone strength is related also to the organic matrix composition, and especially to the collagen crosslinks of the cortex (374). Nutrition is also an important factor to bone strength. Imbalances in inorganic and/or organic nutrients may decrease the bone strength and increases the risk of fracture (376).

Handling of birds may create unnatural tensile and bending stresses on the bone, which may alter the cortex composition, predisposing the bones to complete fractures (77). To prevent and reduce incidence of fractures, care should be taken when catching birds. Chickens that are held by both legs have fewer incidences of broken bones than when they are held by one leg only (161).

30.12.   Broiler chicken with spondylolisthesis. (*Avian Diseases*)

Spondylolisthesis

Spondylolisthesis, also known as "Kinky Back," is the ventral dislocation of the anterior end of the articulating fourth thoracic vertebra with over-riding of the posterior end by the fifth causing spinal cord compression and posterior paralysis in broiler chickens. This rotation causes a kyphotic angulation of the floor of the spinal canal and spinal cord compression (Fig. 30.12). The deformation of the spinal column can be readily recognized by palpating the ventral surface of the spinal column during necropsy. Another form of spondylolisthesis is characterized by steplike defects between adjacent thoracic vertebrae producing stenosis of the vertebral canal (115). A diagnosis of spondylolisthesis is best confirmed by removing, decalcifying, and splitting the spinal column along a midline longitudinal plane to allow visualization of the spinal cord compression. A few birds affected with spondylolisthesis are found in most broiler flocks. In some flocks, the incidence of affected birds has reached 2%. The peak incidence occurs at 3–6 wk of age. Affected birds are alert, remain sitting on their hocks with their feet slightly raised off the ground (Fig. 30.13), and use their wings in an attempt to escape when approached. Severely affected birds often become laterally recumbent. Affected birds often die from dehydration if not culled. Wise (501) and Riddell (388) have written reviews on the condition.

Lordosis and subclinical spondylolisthesis are common in broiler chickens. The lordosis develops after hatching. It can be decreased by slowing the growth rate of the broiler chicken. The incidence of spondylolisthesis can be increased by genetic selection. It is postulated that spondylolisthesis is a development disorder influenced by conformation and growth rate.

Ligament Failure and Avulsion

Lesions of ligaments of the intertarsal joint were first described as a significant cause of lameness in meat-type poultry by Craig (72). Lesions have since been reported in the capital femoral ligament in young adult broiler chickens (108), in the posterior cruciate and other ligaments of the femoral-tibial joint in young

30.13. Midline longitudinal section through thoracic-lumbar region of the spinal column of a broiler chicken with spondylolisthesis, cervical end to right. Rotation of the body of vertebra T4, deformation of T5, and spinal cord compression. (*Avian Diseases*)

adult broiler chickens (105, 109, 110, 117) and turkeys (103, 118), in the intercondylar and collateral ligaments of the intertarsal joint of turkeys (118, 228) and broiler chickens (111, 117). Avulsion of the retinaculum on the distal tibia of turkeys has been reported recently (75).

Clinical Signs and Pathology

Lameness has been attributed to lesions in the capital femoral ligament. Lesions found include stretching, partial or total rupture, and avulsion—sometimes with a piece of cartilage or bone—from the femoral head insertion. Stretched ligaments sometimes contain hematomas or are infiltrated with fat. Microscopic lesions include fraying of collagen bundles, acellularity and hyalinization of the collagen in the tendon, along with necrosis, fissures, and hemorrhage in cartilage adjacent to the site of insertion (108). Lameness has also been associated with lesions in ligaments of the femoral-tibial joint. The posterior cruciate ligament has been the most commonly affected, but the cranial cruciate, collateral, and caudal meniscofemoral ligaments have also been affected. In the cruciate ligament, total or partial rupture near the tibial insertion or avulsion from the tibial insertion occurs. Microscopic lesions are similar to those described for affected femoral capital ligaments. In addition, multicellular clusters and mucoid degeneration in the tendons and disorganization of subchondral bone with cysts and granulation at the avulsion site are found (105). Some abnormalities of the menisci of the knee joint have been associated with ligament disruption (114). Lameness has also been associated with partial or total rupture of intercondylar ligament and with rupture or avulsion of collateral ligaments. Most microscopic changes in affected ligaments have been similar to those described for other affected ligaments (111, 228). In contrast to the previously de-

scribed clinical signs associated with avulsion of other ligaments, lameness was not observed in the affected birds due to avulsion of the retinaculum; however, there were increased condemnations of legs due to hematomas and muscle discoloration at slaughter (75).

Pathogenesis and Etiology

Ligament rupture is probably due to trauma. Microscopic lesions similar to these described in ruptured ligaments have been described in intact ligaments of broiler-type chickens, indicating that these changes precede the rupture (109). In individual male broiler breeding chickens, tendon or ligament failure is often found at more than one site, suggesting a predisposition to ligament and tendon failure in these birds (110). Ligament failure may in part be age related, as the incidence appears to increase with age (117). Ligament lesions were less severe in turkeys fed a restricted amount of feed when compared with turkeys fed *ad libitum* (118). Rupture of ligaments may be secondary to stress induced by limb angulation (111). In converse, it has been suggested that ligament rupture may result in limb angulation (228, 388).

Other Abnormalities of the Skeleton
Osteochondrosis

Osteochondrosis is a focal degenerative lesion of the growth plate, articular cartilage or bone, associated with ischemic and necrotic lesions of the growth plate, articular cartilage or bone. It is rare in poultry, and when it occurs, its causes are usually related to focal bacterial infection (459) or mechanical forces acting on rapidly growing cartilage (120, 291). A variety of microscopic degenerate lesions including eosinophilic streaks or scars, occlusion and thrombosis of vascular canals, and necrosis in the growth plate and epiphysis have been described in growing meat-type birds (291, 396). These lesions may be associated with dyschondroplasia, and in some cases, may cause dyschondroplasia (101). Osteochondrosis has primarily been described in cervical and thoracic vertebrae of broiler chickens (201, 274), and in the femoral head (99, 101, 120, 229, 396) and the antitrochanter (107) of broiler chickens and turkeys. Most birds with osteochondrosis do not have clinical sings (291, 396).

Rotated Tibia

Rotated tibia has been reported in turkeys, broilers, guinea fowl, and ratites (388, 399, 446). Rotated tibia is very common in ratites especially in ostriches and emus. Affected birds often have the affected leg extended laterally. Either or both legs may be affected. The defect is restricted to the shaft of the tibia, which is rotated externally often to 90 degrees or greater. There is no angulation of bones, and the hock joint is normal, with no displacement of the gastrocnemius tendon. In some extreme cases, the rotation reaches 180 degrees. In such cases, if both legs are extended ventrally, the two-foot pads face in opposite directions (Fig. 30.14). Rotation or torsion of the femur, tibiotarsus, and tarsometatarsus is normal during early development of the chicken. Femurs and tibiotarsi rotate externally, while the tarsometatarsi rotate medially when the axis of the distal articular surface is compared with that of the proximal articular surface (122).
30.14. Turkey with rotated tibia of left leg. Rotation is nearly 180 degrees and the footpads face in opposite directions. (Craig Riddell)

30.15. Two-day-old turkey poults with splayed legs.

Rotated tibia represents excessive and abnormal rotation during development. The exact etiology of tibial rotation is not known, but genetics, nutritional, and management factors may be involved (446). Early rickets has been suggested as a predisposing factor in guinea fowl (18). An increased incidence of rotated tibia has been reported in turkeys subsequent to malabsorption syndrome at an early age (358). Rotated tibia differs from VVD in that no angulation of bones is present, and that in broiler flocks, the peak incidence occurs at 3 wk of age, no sex predisposition is apparent, and the number of birds with either the right leg or left leg affected is approximately equal (399).

Crooked Toes
Crooked toes are a common finding in meat-type chickens and turkeys. The syndrome was first described by Norris *et al.* (324) and later reviewed by Riddell (386). An incidence of 4.8–7.7% was reported in broiler chickens in Europe (363), while incidences exceeding 50% were reported in broiler chickens in Australia (308). The deformity, unless very severe, has limited clinical significance. It may interfere with the reproductive performance of breeding cockerels (308). Most digits or a single digit may be bent laterally or medially. Rotation of the phalanges often is present.

The pathogenesis is not understood though it has been proposed that shortening of flexor tendons may cause the deformation. This defect also has been attributed to a hereditary defect (58). A negative correlation between the presence of twisted legs and slipped tendons and the presence of crooked toes has been

reported. The tension in flexor tendons is probably decreased when legs are twisted (365). An increased incidence of crooked toes has been associated with certain types of flooring, infrared brooding, pyridoxine deficiency, and some toxins (25, 384). The syndrome should be differentiated from curly toe paralysis due to riboflavin deficiency.

Spraddle Legs
Birds with this condition have one or both legs splayed laterally from the coxofemoral joint (Fig. 30.15). It is usually associated with high humidity during incubation or when newly hatched chicks are placed on slippery floors. The birds have their legs directed laterally and are unable to stand. Affected birds are culled, but this condition may not be manifested until birds are 2–3 weeks of age as the leg deformity becomes obvious.

Miscellaneous Abnormalities of the Spine
Several other spinal deformities occur sporadically at a low incidence in commercial poultry. These deformities include scoliosis and rumplessness and have been reviewed by Riddell (384).

Crooked Neck
Riddell (393) described a syndrome in turkeys characterized by crooked-neck or wryneck. The major lesions were osteodystrophy of the cervical vertebrae and airsacculitis due to *Mycoplasma meleagridis* (MM). After wryneck was associated with MM infection in the breeders, control measures such as dipping eggs and the implementation of the National Poultry Improvement Plan were put into practice. The condition is rarely seen today. The latest report on this condition involved a back yard turkey flock (52).

Embryonic Cartilage in Ratites
Normal embryonic cartilage can be seen in the long bones including the vertebrae of ratites (ostriches, emus and rheas) between ages 1 day and 8 wk (381, 421, 428). The cartilage which appears like a core and extends from the growth plates from ei-
30.16. Sagittal section of tibiotarsal bone from a young ostrich with embryonic cartilage.

ther end of the long bones in to the metaphysis and diaphysis in birds up to one week of age (Fig. 30.16). As the birds mature, the cores become smaller leaving islands of cartilage in the metaphysis or sometimes in the diaphysis. The femur becomes pneumatic between 6–8 wk of age whereas the tibiotarsus and tarsometatarsus will have normal marrow and trabecular bone (421, 428). Diagnosticians may confuse the cartilaginous cores in the ratites for tibial dyschondroplasia (TD), but it is not TD. TD is a pathologic lesion, whereas cartilaginous cores are normal embryonic remnants of the cartilage that gets resorbed completely by 6–8 wk of age. Microscopically, TD will appear as a sheet of cartilage without interruption by blood vessels, but the cartilage in ratites will have blood vessels scattered through out (421).

Diseases of Muscles and Tendons

Deep Pectoral Myopathy

Deep pectoral myopathy has also been called green muscle disease. Ischemia following exercise in heavily muscled meat-type turkeys and chickens causes the condition. Condemnation of affected muscles has resulted in economic loss in breeder turkeys. The condition was first described in Oregon in breeder turkey hens older than 10 mo of age, with up to 9% of some flocks being affected (97). Several strains of bronze, as well as large, medium, and small white turkeys were affected. Both sexes have the defect (179). The lesion has been recognized in turkeys elsewhere in North America (165) and in the United Kingdom (214). The lesion has also been described in meat-type breeding chickens (181, 213) and in 7-wk-old broiler chickens (383).

Clinical Signs and Pathology

The lesion does not affect the general health of birds and is generally only found at processing. The lesion can be unilateral or bilateral. Chronic lesions result in dimpling or flattening of the breast muscles. These lesions can be detected by palpation (178). Comprehensive descriptions of the pathology of the lesion in turkeys have been provided by Siller and Wight (436), and in broiler breeder chickens by Wight and Siller (497). Lesions in

both types of birds are similar. In early lesions, the whole deep pectoral muscle is swollen, pale, and edematous with necrosis in the middle third to three-fifths of the muscle. The overlying fascia is often opaque with edema between the deep and superficial muscles. In older lesions, the edema disappears and the necrotic muscle becomes more prominent and drier with greenish areas. In chronic lesions, the necrotic muscle has shrunk and is uniformly green, dry, and friable and enclosed by a fibrous capsule. It may shrink to a fibrous scar. The muscle posterior to the necrotic muscle becomes atrophied, pale, and sometimes fibrosed. The sternum adjacent to the necrotic muscle is roughened and irregular.

When examined microscopically, the fibers in the green necrotic muscle are swollen and uniformly eosinophilic with discoid necrosis. Nuclei are absent or faint. Blood vessels within the necrotic tissue often contain only nuclei of lysed red blood cells. Surrounding the necrotic tissue, there is an inflammatory reaction with heterophils, macrophages, and giant cells, and in chronic cases, a fibrous capsule. Viable, degenerate, and regenerating muscle fibers are often enveloped by the capsule. Brown pigment and cyst-like structures containing yellow material are also found within the capsule. In the muscle posterior to the necrotic tissue, fibers may be atrophied and replaced by fat, and in some instances, fibrosis is present. Vascular lesions consisting of thromboses, intimal proliferation, and aneurysm formation are found in and around the necrotic tissue. Ultrastructural studies on affected muscles have been conducted (214, 497).

Pathogenesis and Etiology

In a series of experiments Wight (498), Siller (435, 437), and Martindale (274) demonstrated that deep pectoral myopathy is the result of ischemia secondary to the swelling in a tight fascia of a vigorously exercised muscle. In prior studies, surgical occlusion of arteries to the pectoral muscles in both turkeys and chickens resulted in infarcts similar in appearance to the lesions of deep pectoral myopathy (337, 438). In subsequent studies, temporary occlusion of the subclavian artery combined with electrically induced contractions of the deep pectoral muscle induced necrosis of the muscle in both lightweight and broiler strains of chicken. Similar electrically induced contractions alone produced necrosis of the muscle in the broiler strains, but not in the lightweight chickens (498). Subsequently, it was demonstrated that the necrosis could be produced by voluntary wing movements (437). Surgical incision of the fascia around the deep pectoral muscle prior to exercise, however, would prevent development of the lesion (435). Angiography demonstrated a complete ischemia in the deep pectoral muscle associated with an increase in subfascial pressure following electrical stimulation of the muscle. After 24 hr, the ischemia only persisted in the middle of the muscle (274).

It is possible that the high incidence of deep pectoral myopathy in turkey breeder hens is, in part, the result of the extensive handling these birds receive during artificial insemination. Modification of handling procedures may reduce the incidence (495). Some evidence has been produced for a hereditary predisposition (178). This predisposition may be related to inadequate

vasculature in muscles of meat-type birds (498). No specific nutritional factors are known to influence the condition (165, 180), but food restriction may reduce the incidence (497).

Rupture of the Gastrocnemius Tendon

For many years, lameness due to rupture of the gastrocnemius tendon has been recognized commonly in meat-type chickens and rarely in turkeys. It can cause considerable economic loss in broiler breeder flocks and in broiler chickens raised to roaster weights. The early literature on the condition was reviewed by Peckham (354).

Clinical Signs and Pathology

Up to 20% of a flock may be affected. Most outbreaks have been in broiler breeder chickens older than 12 wk of age, but the condition has been recognized in broiler chickens as early as 7 wk of age. The rupture can be unilateral or bilateral. Onset of lameness is acute. Birds with bilateral rupture have a characteristic posture in which the bird sits on its hocks with its toes flexed (Fig. 30.17). In affected birds, a swelling can be palpated on the posterior surface of the leg just above the hock. With acute lesions, hemorrhage can be seen through the skin. With older lesions, there is green discoloration. With chronic lesions, no discoloration may be apparent, but a very firm mass of abnormal subcutaneous tissue can be palpated. Dissection of acute lesions reveals a blood-filled swelling under the skin on the posterior surface of the leg. Within the hematoma, the free end of the ruptured tendon can be found. The rupture generally occurs as an irregular transverse break just above the hock joint. In older and chronic lesions, the blood is partially or completely reabsorbed and fibrous tissue encloses the end of the ruptured tendon and surrounding tissue. Microscopic lesions are variable. In many acute lesions, there is hemorrhage only. In older lesions, there is fibrous tissue surrounding resolving hematomas and the ruptured tendon. Synovial hyperplasia and infiltration of heterophils and macrophages vary from very little to massive. The infiltration of inflammatory cells occurs within the tendon and in the synovial membranes and cavities, and may be associated with masses of heterophil debris and some bacterial colonies.

Pathogenesis and Etiology

Duff and Randall (119) reviewed the literature on the causes of rupture of the gastrocnemius tendon. They concluded that tenosynovitis, in particular that due to reoviruses, may be implicated in some cases. In other cases, the rupture appears to be spontaneous. In such cases, a frequent concurrent finding is rupture of other pelvic limb tendons or ligaments. In cases associated with tenosynovitis, there was a marked inflammatory response, while in spontaneous rupture there was a minimal inflammatory response.

   The tensile strength of the flexor digitus perforatus and perforans tendon to the third digit is less in meat-type chickens than in egg-type chickens. It has been suggested that this could predispose meat-type birds to tenosynovitis (464). This could also predispose to spontaneous rupture of tendons. Tissue of the gas-

trocnemius tendon in meat-type birds has a less organized appearance than that in egg-type birds (465). In addition, many meat-type birds have a hypovascular area in the gastrocnemius tendon just above the hock joint. This hypovascular area is associated with thickened chondrocyte plaques, chondrocyte death, and excessive lipid accumulation in the tendon. These changes may predispose to noninfectious tendon rupture (116). Little research has been conducted on the effect of nutrition on tendon strength. In one study, administration of glycine, vitamin C or E, or copper had no effect on tensile strength of tendons (466). In another study, restricted feeding had no effect on tensile strength of tendons, but the ratio of tensile strength to body weight was less in chickens fed *ad libitum* than in those fed a restricted amount of feed (396). A recently study demonstrated that prolonged sitting by the broilers does not predispose the tendons to ischemia and subsequent necrosis (82).

Diseases of the Circulatory System

Pulmonary Hypertension Syndrome in Broiler Chickens

Pulmonary hypertension syndrome (PHS), also known as ascites syndrome, occurs worldwide in growing broiler chickens and is a significant cause of mortality in many flocks. A low prevalence of the syndrome has been found in most broiler flocks at processing (390). The average incidence of ascites in broiler flocks is 4.7% (309). Interactions between the environmental and genetic factors play a significant role in developing this disease (93). PHS was first reported in flocks of broiler chickens reared at high altitudes in Bolivia (171). It has since been described worldwide in flocks reared at high (51, 79, 195, 269) and low altitudes (136, 234, 390, 449).

Clinical Signs and Pathology

Affected birds usually are smaller than normal and listless with ruffled feathers and pale shrunken comb. Severely affected birds

30.18. Broiler chicken with abdomen distended with fluid secondary to right ventricular heart failure. (Craig Riddell)

have abdominal distension (Fig. 30.18), may be reluctant to move, and are dyspneic and cyanotic (287). Some birds may die suddenly before ascites develops (222, 234). Accumulation of straw-colored ascitic fluid with or without fibrin clots explains the abdominal distension (171, 287, 499). Electrocardiogram of affected chickens shows an increase voltage of ventricular depolarization complex, consistent with dilation and hypertrophy of the right ventricle (325, 483). These changes in the echocardiogram are preceded by modifications in the left ventricle consistent with en-largement, progressive left failure and compensatory right ventricular hypertrophy in birds raised at low altitudes (328, 333).

Gross lesions include ascites, right-side cardiac enlargement, often left-side ventricular dilation, and variable liver changes. The cardiac enlargement includes dilation of the right atrium, sinus venosus, and vena cava as well as the right ventricle (Fig. 30.19) and hypertrophy of both the right ventricle and right muscular atrioventricular valve. The ratio of the weight of the right ventricle to the weight of the total ventricles is greatly increased in affected birds (195). Nodular thickening of the atrioventricular valves is characteristic of hearts from ascitic birds (171, 332). Endocardiosis is more common in the left atrioventricular valve than in the right (332). Hydropericardium may be present. The livers in affected birds vary from congested or mottled to shrunken with a grayish capsule and irregular surface. Lungs are congested and edematous (171, 287, 499). Blood from affected birds has increased packed-cell volume, hemoglobin, and red and white blood cell counts. Heterophils and monocytes are increased at the expense of lymphocytes (287). A condition with similar pathologic changes in heart and liver has been reported in meat-type ducklings (221)

Microscopic lesions have been described in the heart, liver, lung, and kidney (171, 287, 309, 499). The myocardial fibers are mildly disorganized, with occasional myocardial degeneration and calcification, edema and some proliferation of loose connective tissue between fibers, focal hemorrhages, and infiltrations of heterophils. The liver has hepatocytic necrosis, dilation of hepatic sinusoids and often fibrosis of the capsule. Foci of lymphocytes and heterophils in the liver are common. The lungs are often hyperemic with visible evidence of hemorrhage, edema, and hypertrophy of smooth muscle around the parabronchi, and collapse of the atria and air capillaries. Increased numbers of cartilaginous and osseous nodules have been found in the lungs of birds affected with ascites (130, 279, 309, 340). However, there was little correlation between the numbers of nodules in lungs and birds that developed PHS (340). The authors hypothesized that hypoxia alone has little influence on the development of pul-

monary nodules and that the nodules probably are secondary to poor ventilation, increased levels of ammonia and/or dust. Kidneys may have congested glomeruli with thickened basement membranes and scattered foci of lymphocytes (287).

Ultrastructural changes in PHS include myofibril disorganization, mitochondrial abnormalities and hyperplasia in the heart, thickening of alveolar and capillary walls in the lung, and thickened basement membranes and tubular degeneration in the kidney (282, 283, 288). Abnormal calcium deposits have been demonstrated in the mitochondria of cardiac myocytes of birds with PHS (285). Increased serum troponin T found in live birds with PHS was another indicator of myocardial damage associated with PHS (286). An additional ultrastructural observation in some birds with PHS was the presence of viral particles between muscle fibers in the heart (288). These virus particles were identified as retroviruses (350).

Pathogenesis and Etiology

Despite the intensive investigation of the syndrome for many years, the primary cause of ascites is unclear. Pulmonary hypertension causing right ventricular hypertrophy and failure has been considered the main cause of ascites (222). In recent years, it is becoming apparent that the pathogenesis of this syndrome is multifactorial with the interaction of genetic and environmental factors being the most likely causes (93, 231). Because there is a complex interrelationship between the cardiovascular, respiratory, circulatory and other systems in the body, some of the observed changes in ascites syndrome may represent secondary compensatory responses. It is also possible that multiple genetic factors involved in the development and regulation of these systems are key factors that play a role in this complex metabolic disease (369).

Wideman and French (480) showed that animals that survived an ascites challenge produce offspring with reduced ascites syndrome. Body weight has been shown to have a negative genetic correlation at cold temperatures (92, 346). On the other hand, this syndrome had a weak, but positive correlation to body weight when measured under normal conditions. Lubritz *et al.* (271) demonstrated correlations between clinical ascites and coronary arterial pressure index. Birds with a better feed efficiency appear to be slightly more susceptible to ascites (345). Since genetic factors play an important role in susceptibility of birds to ascites syndrome, it offers an opportunity for selection against this syndrome. Alternative selections systems that look into parameters other than just body weight should be considered to reduce PHS. Right ventricular to total ventricular weight of the heart and hematocrit value measured under normal and cold conditions may help to achieve high gain for body weight while keeping PHS level constant (344, 512). Although it is tempting to simply select-out this syndrome without further studies, it is important to understand the molecular mechanisms and genes underlying PHS since these might help improve our insight into the factors that play a role in cardiovascular functioning. Cisar *et al.* (61) found that the concentration of two mitochondrial matrix proteins involved in the aerobic metabolism were elevated in ascites-resistant line broilers with ascites.

Experimentally the two major factors that increase the incidence of PHS are hypoxia and increased metabolic rate (231). In the field the most important environmental factors causing the development of PHS in broilers are high altitudes and cold temperatures (344). Tissue hypoxia may occur at high altitudes, when the oxygen binding affinity with hemoglobin is decreased (79); PHS has been reproduced in hypobaric chambers (226, 341, 342, 503). Hypoxemia results in increased cardiac output, polycythemia, increased hemoglobin, and an increased hematocrit. These changes in the blood produce an increased blood viscosity and larger and more rigid red blood cells, which may have difficulty passing through the capillary bed of the lung, contributing to pulmonary hypertension (284, 300). It has been hypothesized that the modern broiler chicken is susceptible to PHS because its rapid growth causes a higher demand for oxygen (232). In addition, the modern broiler chicken may be more susceptible to hypoxemia because its small lung relative to body size (187, 230, 468), thicker blood-gas barrier (468), and larger and less deformable red blood cells (280, 300). There has been little evidence that reduced environmental oxygen causes PHS at low altitudes (235, 432). Hypoxic conditions induce tachycardia to increase blood oxygenation. While chickens with ascites raised at high altitudes have tachycardia, fast growing chickens with ascites in low altitudes are bradycardic (331), suggesting that different factors trigger PHS.

Several studies have demonstrated that low oxygen levels during incubation influences the occurrence of ascites later in life. Hypoxia during incubation caused lung congestion that was still present at 5 wk (289). Buys et al (50) observed that embryos exposed to high carbon dioxide concentrations during the third week of incubation had lower incidence of ascites during the growth period than those incubated under normal concentrations. On the same lines, Hassanzadeh et al (186) found that birds incubated at high altitude (low oxygen) showed less right ventricular hypertrophy and ascites mortality than those incubated at low altitude. In both studies, authors observed that chickens exposed to less oxygen during incubation hatched earlier than those exposed to normal amounts, and the embryos might have experienced hypoxia for a shorter period of time. They also had higher plasma triiodothyronine and thyroxine (50, 186). Furthermore, embryos incubated at high altitude had higher plasma corticosteroid and lactic acid levels (186) and reduced binding capacity of myocardial beta-adrenergic receptors (185), suggesting an adaptation of the heart to hypoxia.

Abnormal metabolic rate has a direct effect on the incidence of PHS. Low temperatures are also known to induce ascites (10, 344). Chickens susceptible to ascites are believed to be hypothyroid with a limited ability to produce T_4 hormone and a low capacity for oxygen consumption (412). Because of the low concentration of thyroid hormones in the plasma, chickens susceptible to PHS may be unable to meet the increased demand for oxygen at cold temperature (212), resulting in hypoxemia. The addition of 3,3-,5-triiodothyronine to the diet of broiler chickens increased the incidence of right ventricular hypertrophy and the cumulative mortality linked to ascites (94), possibly secondary to an increase in oxygen demand.

The incidence of PHS can be decreased by reducing growth rate (430). Apparently, broilers with restricted feed intakes do not exhibit the bradycardia observed in broilers fed ad libitum (331). The increased cardiac output in the feed-restricted animal may prevent the hypoxia. On the down side, feed restriction reduced breast muscle growth (1). The incidence of PHS is lower in broiler chickens fed mash diets when compared with broiler chickens fed pelleted diets (87, 431), without reducing body weight, weight gain, feed consumption or feed conversion rate (32). Feed restriction reduced the incidence of PHS in birds exposed to low temperature by reducing lipid peroxidation, promoting the activity of enzymatic antioxidant and inhibiting pulmonary vascular remodeling (347).

Accumulation of reactive oxygen may damage the cell membranes of different systems in the body. A direct correlation between low concentration of antioxidant in the lung and enlarged right ventricular weight has been found in broiler chickens (33). Lower levels of antioxidants also have been reported in the lung and liver of broiler chickens affected with PHS (131). This suggests a deficiency in the control of oxidative stress. Dietary supplementation with coenzyme Q_{10} reduced PHS in broilers (149), probably by reducing free radicals.

Several drugs have been used experimentally to reduce ascites. Supplemental L-arginine reduced the incidence of PHS mortality in experimental broilers. This was explained on the basis that L-arginine might be required as a substrate for the production of nitric oxide, a powerful endogenous pulmonary vasodilator (485). On the other hand, nitric oxide may induce pulmonary hypertension by releasing reactive oxygen that may destroy cellular membranes in the vascular and pulmonary system (7, 69). Pulmonary artery hypertension was prevented at low temperatures by blocking the endothelin-1 receptor with BQ123 (510). Angiotensin II may trigger right ventricular hypertrophy even in the absence of pulmonary hypertension (84).

During the development of ascites chickens develop systemic hypotension, which triggers retention of fluid and electrolytes (140). It is not surprising that furosemide, a diuretic that acts as a vasodilator, reduced PHS mortality in experimental broiler chickens, probably by reducing fluid and electrolyte retention, and pulmonary vascular resistance (481).

Systemic acid/base balance also influences the ventilation and perfusion through the lung. Intravenous infusions of 1.2 M HCl led to pulmonary vascular resistance and bradycardia, and could trigger pulmonary hypertension (484). Alternatively, the addition of 1% sodium bicarbonate to a broiler ration to cause alkalosis reduced the incidence of PHS in experimental birds in a hypobaric chamber (343).

Increased resistance to blood flow through the lung can cause pulmonary hypertension, and consequently right ventricular failure and ascites. Pulmonary hypertension in broiler chickens has been induced experimentally by clamping of a single pulmonary artery (482). Clamping of the arteries induces pulmonary hypertension more successfully than occluding the left extrapulmonary bronchus (486); probably because chickens have an effective gas exchange system, but poor blood perfusion through the lung. Inflammatory reaction causes thickening of the gas exchange barrier that may persist even after the causative agent is gone (130). Right ventricular hypertrophy and subsequent ascites are associated with lung damage induced by infectious agents such as *Aspergillus* (223), *Escherichia coli* or infectious bronchitis virus (461); however, pulmonary hypertensive response secondary to exposure to endotoxins or other micro-particles in the lung (56) is linked to genetic factors rather than the source or dosage. Hypervolemia also produces resistance to the blood flow through the lung. Sodium toxicosis resulting in ascites secondary to the increase of blood volume and decrease of erythrocyte deformability (299, 301) should not be mistaken with PHS.

Dilated Cardiomyopathy in Turkeys

Dilated cardiomyopathy (DCM) has commonly been called round heart disease and less commonly the cardiohepatic syndrome. It is desirable that the term *round heart disease* be discontinued, as it is used for a different disease that occurs in chickens (see below); additionally it only describes a gross change but does not indicate the pathology accurately. The early literature on the syndrome has been reviewed by Czarnecki (86) and the reader is referred to this review for more detail and specific citations.

Clinical Signs and Pathology

The highest rate of mortality due to spontaneous DCM occurs in young poults, commonly peaking at 2 wk of age and disappearing at 3 wk of age. The authors have occasionally seen spontaneous dilated cardiomyopathy in turkeys up to 10–12 wk of age. Mortality in flocks averages 0.5% to 3.0% (141), but it has been as high as 22%. Affected young turkeys may die suddenly or may have ruffled feathers, drooping wings, and labored breathing prior to death. On the electrocardiogram, affected turkeys have increased end-diastolic volume, and decrease ejection fraction and systolic blood pressure (148). On postmortem examination, affected young turkeys have greatly enlarged hearts due to dilation of both ventricles. Often, the right ventricle is more dilated. Hydropericardium and ascites may or may not be present. Lungs are generally congested and edematous. Livers may be slightly swollen with rounded edges. In older turkeys from affected flocks the most prominent lesion is enlargement of the heart and hypertrophy of the left ventricle.

Microscopic changes in abnormal hearts are nonspecific and include congestion, degeneration of myofibers, focal infiltration of lymphocytes, and in older turkeys, increased fibroelastic tissue under the endocardium of the left ventricle. Vacuolization of hepatic cells, focal necrosis, bile duct hyperplasia, and intracytoplasmic PAS-positive globules in hepatocytes have been described in the swollen livers.

Pathogenesis and Etiology

Domestic turkeys may be predisposed to the disease due to the abnormal structure of their troponin T (22, 23), an essential protein in the Ca^{2+} regulation of striated muscle during contraction. This discovery is significant as it helps to justify findings from previous research. Abnormal energy metabolism of the heart may cause alterations in the contractility of the heart observed on the electrocardiogram of turkeys with DCM (148). Turkeys with

DCM have a decrease in some enzymes involved in energy supply, such as creatinine kinase, lactate dehydrogenase, Ca^{2+} transport system, ß-receptor-stimulated adenylyl cyclase (148), diminished concentration of ATP (266), and reduced concentration of fatty acids, the main substrate for cardiac metabolism (257). However, what triggers the DCM is still unknown. A genetic influence was demonstrated by breeding trials. Birds with spontaneous cardiomyopathy were selected using electrocardiography, and by mating affected males to affected females, the incidence of the condition was increased in the progeny.

Furazolidone is toxic for turkey poults in concentrations as low as 300 ppm in the feed, and produces a syndrome that is similar to DCM. However, the concentration of polyunsaturated fatty acids in the heart from furazolidone-induced cardiac dilation is markedly increased, while the concentration of these fatty acids in the heart from DCM is markedly reduced (257).

Dilated cardiomyopathy in turkeys has been reproduced with similar environmental and management factors as PHS in chickens. Dilated cardiomyopathy has been related to hypoxic conditions in incubation (81). Clinical observations indicate that the incidence of DCM is increased at high altitude and with cold weather (141). Raising turkeys in a hypobaric chamber at an atmospheric pressure of 592 mm Hg (equivalent altitude 2054 m) resulted in a high incidence of DCM (233). Slowing the growth rate of young poults by dietary manipulation both in a hypobaric chamber at a reduced atmospheric pressure (233) and under commercial conditions (41) reduced the incidence of spontaneous cardiomyopathy. Turkey poults kept at a simulated high altitude on a fast-growth diet developed polycythemia (224), similar to chickens with right ventricular failure and ascites (79). A light program designed to reduce growth rate at an early age also reduced the incidence of spontaneous cardiomyopathy (64).

Sudden Death Syndrome in Broiler Chickens

Sudden death syndrome (SDS) describes a condition in which healthy broiler chickens die suddenly for no discernible cause. The syndrome has been described as sudden death syndrome, heart attack, and flip-over. The latter term has been used because birds dead from the syndrome are commonly found on their backs. The condition was first described as "edema of lungs" in England (189) and subsequently as "died in good condition" in Australia (208). Today, birds dead from SDS are found in most broiler flocks throughout the world. The incidence varies from 0.5 to 4.0% (42, 53, 194, 399, 444). A brief review on SDS was written by Riddell (392).

Clinical Signs and Pathology

Sudden death syndrome has been reported to occur from 1 to 8 wk of age, with the greatest losses occurring from 2 to 3 wk of age in most flocks (42, 399, 444). It occurs more commonly in males than females (330, 335). In a behavioral study, lack of consistent behavioral symptoms did not allow SDS identification prior to death (316). In some broiler flocks, the weekly incidence appears to increase throughout the growing period, suggesting an error in diagnosis or a different syndrome (399). It is possible that birds dying from PHS may have been misdiagnosed as SDS (392).

Affected chickens show no clinical signs or unusual behavior until less than a minute before death. Birds may squawk during a sudden attack characterized by loss of balance, convulsions, and violent flapping (316). Most birds die on their backs with one or both legs extended or raised, but some may die on their sterna or sides (397, 444). Comparison of blood from birds just after death from SDS with blood from killed healthy birds revealed no consistent differences in serum levels of sodium, potassium, chloride, calcium, phosphorus, magnesium, or glucose (397). On the other hand, serum activities of lactate dehydrogenase, glutamic oxaloacetic transaminase (203), and creatinine phosphokinase (368) were increased in SDS chickens compared to healthy chickens.

At necropsy, birds dying from SDS are well fleshed with a full gastrointestinal tract. Livers are enlarged, pale, and friable and, generally, the gallbladder is empty. Kidneys may be pale and the lungs are often congested and edematous (335, 444). The congestion and edema of the lungs may be a postmortem artifact, as it is not found in freshly dead birds (397). The ventricles of the heart are generally contracted and the thyroid, thymus, and spleen may be congested; there may be hemorrhages in the kidney (335).

Microscopic lesions reported are nonspecific. Degeneration and infiltration of lymphoid cells and heterophils have been described in the heart (335). However, the cellular infiltrations have been considered to be normal lymphoid foci and foci of ectopic hemopoiesis (397). Use of an allochrome stain and a hematoxylin-basic fuchsin-picric acid stain did not demonstrate any degenerative changes in hearts of birds dying from SDS (397). In contradiction to these previous studies of the heart in SDS, a more recent study described arteriosclerotic changes and myocardial necrosis mostly in the left ventricle of broiler chickens that had died suddenly without clinical signs (236). The birds studied were 34 to 64 days of age, older than when most SDS mortality occurs and than when birds were examined in one of the prior studies (397). There were also congestion, edema, and lymphoid cell infiltration in the lungs; hemorrhages in the kidneys; and mild bile duct hyperplasia and periportal lymphoid infiltration in the liver. In a study of organ weights, relative liver weights of broilers dead from SDS were significantly greater than the liver weights of control birds, but no significant differences were noted between SDS and control birds in relative weights of lungs, hearts, and intestines (39).

Pathogenesis and Etiology

The pathogenesis of SDS is not understood. Sudden death syndrome was associated with acute cardiac dysrhythmia, consistent with ventricular fibrillation (329). Birds that later died of SDS had a higher heart rate than the rest of the flock (333). Furthermore, a higher percentage of chickens that died with SDS had cardiac arrhythmias (330). It has been suggested that SDS is a metabolic disease and that genetic, nutritional, and environmental factors may affect the incidence (397). Lactic acid or acid-base balance does not appear involved in SDS (209). Sudden death syndrome has been described in most modern broiler-type chickens (42, 399), but the heritability is low (55).

Similar susceptibility to SDS was found between six strains of commercial broiler chickens, including Arbor Acres, Avian Farms, Cobb-500, Hubbard-Peterson, ISA and Ross (156). The incidence of SDS was higher in birds fed crumble-pelleted feed compared with those fed mash feed (366). The authors suggested that this difference in mortality might be associated with changes in the pelleted feed and not with increased growth rate. Incidence of SDS was not affected by growth rate under field conditions (399). Severe feed restriction eliminated SDS in a small experimental trial (40), but restriction of feed intake for 7 days early in the life of broiler chickens did not significantly reduce the incidence of SDS (401). A lighting program in which birds were exposed to a short photoperiod at an early age decreased early growth rate and also decreased the incidence of SDS (63, 394).

Several nutritional factors have been studied with regard to the incidence of SDS. In a field survey, a higher incidence of SDS was noted in flocks fed wheat-based rations compared with flocks fed corn-based rations. This difference was also noted in some experimental trials (26), but no differences were noted in other nutritional trials (199, 302). Protein type and concentration in the diet influence the incidence of SDS. Chickens fed meat meal protein had lower incidence of SDS than those fed soybean meal (26). Also, higher percentage of protein in the finisher diet reduced the incidence of SDS (302). Addition of vitamins did not affect the incidence of SDS (199, 302, 367, 445, 478). Lipid metabolism may affect cardiac sarcoplasmic reticular transport (60). Increased amounts of calcium, phosphorus, and magnesium (220) or potassium (199) in rations had no effect on the incidence of ADS. In contradiction to some of these previous studies, a more recent study indicates that increase in the dietary calcium and phosphorus boost the susceptibility to SDS. A calcium antagonist, verapamil, added to the diet had no effect on the incidence of SDS (158). It has been suggested that thiamine may influence the incidence of SDS (62).

Flock size has been proposed as a factor that might influence the incidence of SDS (399). High stocking density can increase the occurrence of SDS (204). An experimental study showed that light intensity did not affect the incidence of SDS (319), but a field trial suggested that intermittent light may decrease the incidence of SDS (336). Extended dark periods (more than 8 hours) also reduced SDS, but had negative effect on body weight (414). Decrease in SDS may be associated with lower heart rates during dark periods (27). Increased light intensity alternating from side to side within pens, when superimposed on a background of low light intensity, had no effect on the incidence of SDS (317, 318).

Aortic Rupture

Aortic rupture or dissecting aneurysm is characterized by sudden death in growing turkeys due to internal hemorrhage. The condition has been recognized throughout North America, in Europe, and in Israel. Mortality in the past has been reported to reach 50%, but losses in affected flocks at present usually only reach 1–2%. Aortic rupture also has been described in ostriches and emus (446).

Clinical Signs and Pathology

The condition occurs in turkeys between 7 and 24 wk of age, with a peak mortality between 12 and 16 wk of age. The incidence is primary in male turkeys. Affected birds die suddenly. Gross and microscopic lesions have been described by McSherry *et al.* (295) and Pritchard *et al.* (365). At necropsy, the head, skin, and musculature are anemic. Occasionally, blood will run out of the mouth, or the oral cavity will be bloodstained. Upon internal examination, large clots of blood will be found in the abdominal cavity and beneath the capsule of the kidney. Clotted blood may be present in the pericardial sac, lungs, and leg muscle. Aneurysm and rupture of other arteries, such as the coronary artery, have also been described (425). In the ruptured aorta, a longitudinal slit is present between the external iliac and ischiatic arteries (Fig. 30.20). In one study a linear or semi-linear tear was found in the aorta at the origin of the coeliac artery in majority of the turkeys (429). In this region, the aorta is dilated; the wall is thin and has lost its elasticity. The tunica intima and media may be thrown into deep folds and partially separated from the tunica adventitia. Fibers of the tunica media may show mild to severe degenerative changes and may be infiltrated with heterophils and macrophages. The media may be thickened due to an increase in ground substance and fibroblastic proliferation. Dissolution or disappearance of the elastic laminae of the media occurs at the site of rupture. Degenerative changes and areas of erosion and cellular infiltration may be present in the adventitia. A marked intimal thickening or a large fibrous intimal plaque often occurs in the region of rupture. Sudan II stains reveal lipid accumulations in the affected intima.

Pathogenesis and Etiology

Several reports have emphasized the possible role of intimal plaques in the pathogenesis of aortic rupture in turkeys. It has been suggested that these plaques and the absence of an intramural vasa vasorum around the abdominal aorta result in impaired nutrition to, and degeneration of, the media (313). High blood pressure in young male turkeys may also be a precipitating factor, but paradoxically, the administration of diethylstilbestrol decreased blood pressure and increased the incidence of aortic aneurysm (244, 245). Diets containing high levels of protein and fat may increase the incidence of aortic rupture (365). Low copper levels were found in the livers of turkeys from field outbreaks of aortic rupture (157) and coronary artery rupture (425). Like in turkeys, aortic rupture in ratites has been associated also with copper deficiency (467). Copper is important in collagen synthesis and it has been suggested that copper deficiency may play a role in aortic rupture. Because the incidence of aortic rupture occurs primarily in male turkeys and copper deficiency has not been consistently found in birds with aortic rupture, genetic diseases such as connective tissues disorders of the elastin and/or collagen should also be investigated. Beta-aminopropionitrile, a toxic product that occurs in the sweet pea (*Lathyrus odoratus*), will produce aortic rupture in the turkey but has not been incriminated in the field syndrome (354). Uncontrolled field studies suggest favorable results in treatment of ruptured aorta with reserpine. This has not been confirmed experimentally and such treatment may depress growth rate (354).

Sudden Death in Turkeys Associated with Perirenal Hemorrhage

Sudden death in turkeys associated with perirenal hemorrhage (SDPH) has been recognized as a significant cause of mortality in male turkeys between 8 and 14 wk of age in many areas of North America (143, 307, 504). It was first recognized in Israel in 1973 (312). Documented mortality due to SDPH varies from 0.8 to 1.80% (143, 504). Estimates of mortality as high as 6% have been made (307). The syndrome has also been described as hypertensive angiopathy (225, 247).

The dead turkeys are in good condition, with food in their crops and the remainder of the gastrointestinal tract. They have congested and edematous lungs, splenomegaly, congested livers and digestive tracts, and clotted blood surrounding a portion or the whole of the kidneys (142, 254, 307, 504). Perirenal hemorrhage is not a consistent lesion (504). The most significant gross lesion is probably cardiac hypertrophy affecting the left ventricle and intraventricular septum (142, 254). Microscopic lesions in-

clude congestion in various organs, with edema in the lungs and hemorrhages in the lungs and kidneys (142, 254). Arterial lesions including internal vacuolation and medial hyperplasia have been found in affected turkeys (142, 225), but have also been recognized in normal control turkeys (307). Hyperplasia of the epithelium and a decrease of colloid in the thyroid glands were noted in the only study in which these glands were examined (254).

It has been proposed that the cause of death in SDPH is acute congestive heart failure secondary to cardiac hypertrophy. The renal hemorrhage may result from severe passive congestion, which may be compounded in part by closure of the renal valve in the renal portal circulation (254). The thyroid hyperplasia may contribute to the hypertrophic cardiomyopathy (254). Hypertension is common in young male turkeys (244) and may explain the cardiac hypertrophy and vascular lesions. It has been postulated that poor exercise tolerance in the modern turkey may result in cardiac arrhythmias and SDPH (38). Male turkeys have greater relative left and total ventricular weights than those of females of

the same age. This might explain the greater susceptibility of male turkeys to SDPH (37). In the opinion of the authors, perirenal hemorrhage in turkeys may be related to aortic rupture. This is based on the observations that many birds that died during an episode of aortic rupture also had perirenal hemorrhages. Careful dissection of the posterior abdominal aorta and its branches in the vicinity of the kidneys revealed microscopic lesions in them. Occasionally small tears or ruptures could be seen grossly in the posterior abdominal aorta and its branches; renal, external iliac and ischiatic arteries.

Fast weight gain, continuous lighting programs, crowding, and hyperactivity have been suggested as factors that may influence the incidence of SDPH (307). Increased room temperature, toe clipping, step up/step down lighting, and dietary reserpine reduced the incidence of SDPH (144). Dietary aspirin had no effect on the incidence of SDPH (36, 144).

Miscellaneous Diseases of the Cardiovascular System

Atherosclerosis

Atherosclerosis is a common disorder of the aorta and other major arteries of the domestic poultry (167, 243) and occasionally pigeons (364). It is more common in males than in females (248). Atherosclerotic changes can be found in birds at any age, but older birds have more severe lesions (242).

The amount of lipid in the lesion is variable. In the most severe cases, thickening of the aorta can be seen grossly. In milder cases, atherosclerosis can be detected grossly with the aid of Sudan IV stain. Microscopically, there are extracellular and intracytoplasmic fatty vacuoles in the smooth muscle of the inner tunica media. The tunica intima is thickened with accumulation of diffuse fatty streaks. In addition, mucopolysaccharides that can be demonstrated with special stains, such as toluidine blue, are abundant in the intima. Abundant fibrous tissue forms a cap over the lesion. Numerous macrophages and occasional mineral deposits are also found in the atherosclerotic plaque.

Atherosclerotic plaques protrude into the aortic lumen, retarding blood flow, and increasing surface tension. It has been suggested that in turkeys these changes may predispose to aortic rupture; however, the relation of atherosclerosis to aortic rupture has not been determined. Hypertension has been associated in atherogenesis (30); but drugs, such as reserpine that lowers arterial blood pressure and the incidence of aorta rupture (354), do not affect the extent of atherosclerosis. Atherosclerosis has been reproduced in chickens with Marek's disease virus and has been used as a model to study human atherosclerosis (see Chapter 15, "Neoplastic Diseases").

Endocardiosis

Endocardiosis is the nodular thickening or fibrosis on the free edges of the atrioventricular valves. It is more commonly seen in the left atrioventricular valve than in the right. Only occasionally is it found in the ventricular endocardium under the atrioventricular valves. It is a common lesion in old birds and a frequent incidental finding during necropsy. In a recent study, endocardiosis was observed in commercial chickens as young as 7 days (332).

In the same study, the incidence of endocardiosis was 18% in normal birds, and up to 52% in birds with ascites. The cause of endocardiosis is not known. Severe endocardiosis may cause atrioventricular stenosis and predispose the bird to ventricular dilation (332). Endocardiosis of the right atrioventricular valve is common in chickens with ascites syndrome. Endocardial fibrosis in the left ventricle of chickens has also been described and has been observed by the authors (89).

Rupture of the Right Auricle

Mortality of 3.4% in a flock of 11,500, 10- to 14 day-old broiler chickens due to sudden death attributed to spontaneous rupture of the right auricle has been reported (35). Most of the birds necropsied had hemopericardium and the auricle rupture was present at the junction of the vena cava and the right auricle. The cause of this condition could not be determined.

Round Heart Disease in Chickens

Round heart disease is an acute cardiac failure due to myocardial degeneration in chickens commonly between 4 and 8 mo of age. It used to have a worldwide distribution but has not been reported in commercial poultry flocks for 25 yr. This condition has been reviewed by Riddell (393). Gross lesions consist in enlargement and yellow discoloration of the heart. The apex of the heart is blunt and may be dimpled. Both ventricles are hypertrophied. In some birds, there may be excess gelatinous fluid in the pericardial sac and in a few birds excess fluid is present in the abdominal cavity. Lungs are often edematous and the liver, kidneys, and spleen may be congested. Microscopically there is fatty change in the myocardium. Round heart disease in chickens may be due to a nutritional deficiency or marginal rations.

Diseases of the Respiratory System

Cartilaginous and Osseous Lung Nodules in Broiler Chickens

Cartilaginous and osseous nodules have been reported in the lungs of domestic birds for more than 50 yr, most commonly in the lungs of broiler chickens (227, 279, 407, 494). The nodules are microscopic in size, found in the parenchyma of the lung, and located some distance from large airways and blood vessels. No reaction is visible around hyaline cartilaginous nodules, but the other types of nodules may be surrounded by a thin layer of fibrous cells, heterophils, and macrophages. The nodules appear to change with age from hyaline to fibrous to mineralized cartilaginous types, and finally, to an osseous type (Fig. 30.21). They are more numerous in the left lung than in the right (281), and in males (494).

The cause and significance of these nodules are unknown. It is probable that the nodules may be derived from chondrocytes displaced from nearby bronchi during early development (494). Nodules might be the result of poor ventilation, increased levels of ammonia and/or dust (340). The number of nodules is greater in broiler chickens fed *ad libitum* than in broiler chickens fed a restricted amount of food (407). An increased incidence of nodules has been described in birds suffering from ascites and right heart failure (279, 281, 499).

Emphysema

Ridell (393) reviewed subcutaneous emphysema or "windpuff." This condition is caused by an injury or defect in the respiratory tract that permits accumulation of air beneath the skin. Subcutaneous emphysema is rarely observed today in commercial poultry, since caponization is rarely or not done at all. Puncturing the skin with a sharp instrument can alleviate this condition. In aquatic or flying birds, some of the pneumatic bones such as the humerus, coracoid, and sternum may fracture, allowing air to accumulate beneath the skin.

Diseases of the Digestive System

Pendulous Crop

Pendulous crop occurs at a low incidence in many chicken and turkey flocks. In severely affected birds, the crop is greatly distended and full of feed, particles of bedding, and fluid, which often has a foul smell (Fig. 30.22). The lining of the crop may be ulcerated. Birds continue to eat, but digestion is impaired and birds become emaciated and die. Carcasses of affected birds are generally condemned at processing. The possibility that diet may influence the incidence of pendulous crop is supported by the experimental production of pendulous crops with rations containing cerelose as a substitute for starch. It was suggested that increased liquid intake in hot weather may be responsible. Additionally hereditary predisposition has been proposed in turkeys. Neither of these factors appears to be important. For further discussion on the possible etiologies of pendulous crop review the 8th edition of this book (354).

Impaction

Impaction of the crop, proventriculus, or gizzard has occasionally been reported in poultry, waterfowl, and ratites. The condition is rare in chickens. Gizzard impaction can cause high mortality during the first 3 wk of life in turkey flocks. Proventricular and gizzard impaction are common in ostrich and other ratite chicks. Affected birds are emaciated, with empty intestinal tracts, but affected crops, proventriculi, and/or gizzards are full of a solid mass of interwoven fibrous material. This fibrous mass often extends into the first part of the duodenum, and in some birds, masses of fibrous material are found lower in the intestine. The impaction results from the birds eating litter or fibrous material that the crop, proventriculus, or gizzard is unable to handle. In ratites impaction due to foreign bodies such as rocks, metallic objects, pebbles, etc is common. A recent report of crop impaction due to feather eating has been associated with improper management (305). Prevention is aimed at discouraging the eating of litter or fibrous materials by young poults and ratite chicks.

Dilation of the Proventriculus in Chickens

In 4-wk-old chicks fed a purified diet, dilation of the proventriculus was first reported as proventricular hypertrophy by Newberne *et al.* (314). The abnormality is commonly observed as an incidental finding in broiler chickens. Occasionally, a high incidence in a broiler chicken flock may cause significant carcass contamination when enlarged proventriculi rupture at processing. The

30.22. White, broad breasted, meat turkey with pendulous crop.

enlarged proventriculi have greatly dilated thin walls and are full of feed. The gizzards in affected birds are poorly developed and there is no sharp demarcation between the gizzard and proventriculus (Fig. 30.23). The poor development of the gizzard is generally the result of a finely ground diet lacking in fiber, and the dilation of the proventriculus is secondary (385). This condition must be differentiated from transmissible proventriculitis in chickens the cause of which is not known and from Marek's disease. In Marek's disease, the proventriculus can be dilated occasionally due to infiltration of lymphocytes and plasma cells in the splanchnic nerves and in the subserosal nerves and ganglia of the proventriculus. Reticuloendothelial virus can cause similar lesions in chickens and turkeys.

Intussusception and Volvulus

These conditions are occasionally seen in ratites and sporadically in domestic fowl. Intussusception occurs most frequently in the intestine, but it has been reported also in the proventriculus (417). Volvulus occurs when there is torsion of the intestine around itself or the root of the mesentery. In young birds volvulus of the small intestine may be caused by twisting around the yolk sac (446). Intussusception and volvulus have been reported in chickens secondary to enteritis or abnormal peristalsis caused by nematode or coccidial infection (354); the authors have seen intestinal torsion associated with pedunculated neoplastic stalks. The clinical signs are anorexia and progressive weight loss, and death occurs over a few days. The affected and distal portion of the intestine are severely congested due to circulatory compromise and the intestinal epithelium becomes necrotic rapidly. If an early diagnosis is made, resection of the affected intestine can be performed in a valuable bird.

Cloacal Prolapse

Cloacal prolapse may involve the intestines, reproductive tract (oviduct or phallus), and ureter(s). The prolapsed tissue has a

30.23.   Gizzards and dilated proventriculi from broiler chickens fed only a commercial broiler starter (*left*) compared with those from broiler chickens fed a broiler starter containing oat hulls (*right*). The former gizzards are small and the proventriculis enlarged. (*Avian Diseases*)

smooth surface and is shiny and congested. Cloacal prolapse may be associated with diarrhea, impaction, or nutritional imbalances. It occurs commonly in young ostriches and it has been associated with *Cryptosporidium* sp. infection (19). In laying hens, cloacal prolapse may result from egg laying. In poultry, picking of the prolapsed tissue may result in cloacal rupture and evisceration.

Diseases of the Liver

Fatty Liver-Hemorrhagic Syndrome

Fatty liver-hemorrhagic syndrome (FLHS) occurs sporadically in commercial layers (442). It has been recognized in many countries of the world. The syndrome occurs primarily in birds kept in cages, but has also been recognized as a less significant problem in birds kept on litter. It is associated with birds fed high-energy diets, and most often seen during the summer.

Clinical Signs and Pathology

The first sign of the syndrome is an increase in mortality of the flock (49), with birds in full production being found dead with pale heads. Mortality usually does not reach 5%. There is often a sudden drop in egg production. Hens may be overweight, with large pale combs and wattles. Dead birds have large blood clots in the abdomen, arising from the liver and often partially enveloping the liver (Fig. 30.24). The liver is generally enlarged, pale, and friable; it may have smaller hematomas within the parenchyma. These hematomas may be recent and dark red, or older and green to brown. Similar hematomas may be seen in clinically healthy birds in the same flock if such are examined during or after an outbreak. Large amounts of fat are present in the abdominal cavity and around the viscera. Most of the birds have active ovaries and often with an egg in the oviduct.

Microscopic examination of the liver shows hepatocytes distended with fat vacuoles, hemorrhages of various sizes and or-

30.24.   Fatty liver-hemorrhagic syndrome. A large blood clot is molded over the left lobe of the liver. Note the excess abdominal fat.

ganizing hematomas, and often small irregular masses of uniform eosinophilic material, likely derivative of plasma protein (496). The fat content of livers generally exceeds 40% dry weight and may reach 70%. The content of phospholipids in the liver are decreased, while the oleic and palmitoleic acids are increased (207). These fatty acids probably are synthesized, since neither is normally found in the diet.

Biochemical evaluation of the plasma reflects cellular changes that occur in different organs. Birds from a FLHS-susceptible strain or commercial birds fed diets that induce FLHS had increased concentration of aspartate aminotransferase and other plasma enzymes (96, 511). This is not surprising since the selected enzymes are common indicators of hepatic disease. Laying birds normally have higher levels of estradiol, calcium, and phosphorus in the plasma than inactive birds. However, birds affected with FLHS have even higher concentrations of this hormone (169) and minerals (175) in the plasma than unaffected ones. No changes have been found in concentrations of progesterone (169), major plasma proteins or glucose.

Pathogenesis and Etiology
The pathogenesis and cause of the hemorrhage has not been defined. Factors involved in FLHS were discussed by Squires and Leeson (442) and Hansen and Walzem (172). Excessive energy in the diet induces FLHS regardless of the source. Excessive consumption of high-energy diets in birds whose exercise is restricted in cages is considered to result in a positive energy balance and excessive fat deposition. Excessive fat may disrupt architecture of the liver and result in weakening of the reticular framework and blood vessels in the liver. A pathogenic relationship between hepatic steatosis and hemorrhage has been suggested (352). Lysis of the reticulin framework of the liver has been reported in FLHS. A strong association of reticulolysis with severity of liver hemorrhage has been described in experimental birds. Rupture of intrahepatic portal veins associated with degenerative changes in the veins was described in the same birds (277). Focal necrosis of hepatocytes leading to vascular injury has been described as another mechanism to explain the hemorrhage (202, 509). It has been postulated that excessive lipid peroxidation of unsaturated fatty acids in the liver may overwhelm cell repair mechanisms and result in tissue damage (442).

Because energy balance is a factor in FLHS, many studies have investigated the influence of the diet composition on this syndrome. The incidence of this syndrome increases as the total energy in the diet increases, regardless of the source. However, when isocaloric diets were compared, a diet that provided the energy in fat rather than in carbohydrates reduced the occurrence of this syndrome (170). It was hypothesized that diets richer in fat might have reduced the hepatic metabolism by reducing *de novo* fatty acid synthesized in the liver. Furthermore, size of the liver, rather than lipid content in the liver or high-fat diets, was directly related to induction of FLHS (413). Some by-product ingredients such as dried brewer's grains, dried brewer's yeast and torula yeast, fishmeal, and fermentation by-products reduce the incidence and severity of FLHS (443). Although not indicated in the study, the reduction of FLHS could be due to the high selenium content of these nutrients. High levels of selenium, vitamin E, and other antioxidants reduce the peroxidation of lipids and may reduce the incidence of FLHS (442). Quail fed diets designed to induce hepatic steatosis and limit biologic oxidant defenses developed a syndrome similar to FLHS in chickens. Liver hemorrhage in these quail was reduced by adding vitamin E to the diet, but not by adding glutathione (441). In an attempt to test this postulate in chickens, the diet of a strain

of chickens susceptible to FLHS was supplemented with ascorbic acid, tocopherol or L-cysteine. None of these compounds, all of which have a role against oxidation, prevented FLHS (95).

In several reports, mortality in laying hens due to liver hemorrhage has been associated with the use of rapeseed meal in the diet (353). As this may occur without the development of fatty livers, it may be a separate syndrome (442). In addition, rapeseed meal has been shown experimentally to increase the extent and severity of liver hemorrhage, but in these experiments, liver hemorrhage also occurred in birds not fed rapeseed meal (277, 353). The possibility of toxins causing FLHS should not be ignored. Aflatoxin has been considered as a possible cause but produces different liver lesions.

The fat content in the liver normally rises with the initiation of egg production and is influenced by estrogen. Injection of immature chickens with estradiol has been shown to result in hepatic steatosis and hemorrhage (351). Similar injection of laying hens caused liver enlargement, death from liver hemorrhage, and neurologic disorders (443). The observation of greatly elevated plasma estrogen, calcium, and cholesterol in chickens from flocks with FLHS suggests that the syndrome may be due to a hormone imbalance (169, 177, 297). In one experiment, treatment with synthetic estrogens were more damaging at 34°C than at 21°C (3), which agrees well with the field observations that FLHS is more frequent during the hot weather. Additionally, birds exposed to high temperatures are more likely to be in a positive energy balance.

Hemorrhagic fatty liver syndrome in chickens must be differentiated from hemorrhage due to rupture of the liver associated with hepatitis E virus in chickens (see "Hepatitis E Infections" in Chapter 14). Livers are generally not fatty in ruptured livers of chickens associated with hepatitis E virus.

Hepatic Lipidosis of Turkeys

Hepatic lipidosis of turkeys is a disease of uncertain, but probable nutritional, etiology. It has been reported only in turkey breeder hens between 12 and 24 wk of age. The disease has also been referred to as acute hepatic necrosis. Sporadic cases of the disease have been seen in Canada and the United States for the past several years, but only two cases have apparently been described in the literature (147).

Clinical Signs and Pathology
The disease is characterized by an abrupt increase in mortality that may approach 5% during a 1- to 2-wk period. For a brief period prior to death, affected hens may become inactive and show dyspnea and cyanosis; most often, birds are just found dead. At necropsy, carcasses are in good condition with obvious fat deposits especially in the body cavity. The liver is enlarged and has a variable number of sharply contrasting pale yellow and dark red areas (Fig. 30.25). Other findings include petechial or ecchymotic hemorrhages in fat and on organs surfaces, pulmonary congestion and edema, and blood that fails to clot.

Microscopically, livers are characterized by multifocal coalescent central lobular hepatic necrosis and lipid vacuoles in the cytoplasm of hepatocytes around the portal areas. Necrosis and

30.25. Hepatic lipidosis in a 17-wk-old turkey hen. There is mottling and swelling of the liver. There are scattered, well-demarcated, large, pale foci on the liver. Bar = 1cm. (Richard P. Chin)

30.26. Photomicrograph of liver from a 17-wk-old turkey hen with hepatic lipidosis. Hepatocytes are vacuolated and with fatty degeneration. There is severe hemorrhaging and biliary hyperplasia. H & E, bar = 20 μm. (Richard P. Chin)

hemorrhage associated with vascular damage are also present. Large confluent areas of fatty degeneration represent pale areas seen grossly, while areas of necrosis and hemorrhage are responsible for dark red areas (147). Occasional nuclei of degenerating hepatocytes contain prominent eosinophilic nucleoli, which could be mistaken for viral inclusion bodies (Fig. 30.26).

Pathogenesis and Etiology
The cause of hepatic lipidosis is unknown, although nutritional, environmental, and management factors are considered to be involved. Affected flocks are typically on low-protein diets to control growth and development. These diets also may be low in lipotropic factors, especially methionine and cysteine, while still having high energy levels. These amino acids are required for production of apolipoproteins. High peroxide values also have been associated with the disease. High environmental temperatures and/or changes in lighting programs cause the birds to alter eating habits, leading to hepatic deposition of lipid and, eventually, to liver failure. Terminally, lipid peroxidation is considered to contribute to vascular damage, which results in lung edema and liver necrosis and hemorrhage (147).

Picornavirus-like particles suggestive of avian encephalomyelitis (AE) virus and low numbers of *Escherichia coli* have been identified in the affected livers (57). These are believed to be incidental because turkey breeder hens in this age range are typically vaccinated for AE using live viruses, and it would not be unusual to recover bacteria from livers of seriously sick or dead birds.

Administration of vitamin E to affected flocks (25 IU/hen) via water for 7 days reduced mortality (147). Hepatic lipidosis is prevented by having adequate methionine (0.2%) and methionine plus cysteine (0.4%) in the ration (311). Prevention of the disease
was achieved by supplementing the standard feed with 1 kg 60% choline, 1 kg methionine, and 20 g vitamin B$_{12}$ per ton (147). In some areas, apparent successful prevention of the disease has followed use of a protocol in which the initial AE vaccine is given via water followed by booster inoculation in the wing-web instead of giving two wing-web inoculations.

Diseases of the Urinary System

An excellent review of renal pathology of the fowl was written by Siller (434). This discussion covers only metabolic conditions of major importance commonly seen in commercial poultry. It does not cover descriptions of miscellaneous conditions such as congenital malformations and baby chick nephropathy. Urate deposition and urolithiasis together are responsible for significant losses in poultry. An increased substrate load on the kidney that leads to dysfunction of this organ with precipitation of insoluble products within the kidney itself or other organs can cause urate deposition or urolithiasis.

Urate Deposition ("Gout")

Uric acid is produced in the liver and is the end product of nitrogen metabolism in birds. Consequently, birds can develop urate deposits secondary to an abnormal accumulation of urates. Urate deposition should not be considered as a disease entity, but as a clinical sign of severe renal dysfunction that causes hyperuricemia. Clinicians and diagnosticians alike tend to use the historical terms "*visceral gout*" if the urates are deposited in the viscera and "*articular gout*" if the urates are deposited around the joints, which is incorrect. Gout is correctly used as a term in human medicine to describe an enzyme defect that produces an abnormal nitrogenous waste metabolism resulting in uric acid production. In birds, "gout" is a historical misnomer where as urate deposition or hyperuricemia are more correct terms, but for this chapter the historical terms "visceral gout" and "articular gout" have been listed.

Historically, "gout" occurs as two distinct syndromes, known as visceral urate deposition (or visceral gout) and articular urate deposition (or articular gout). These two syndromes are different from the point of etiology, morphology, and pathogenesis. The following narrative and table (Table 30.1) should help to distinguish between these two entities.

Visceral Urate Deposition ("Visceral Gout")

Visceral urate deposition is a common finding during necropsy of poultry. Visceral urate deposition is characterized by precipitation of urates in the kidneys and on serous surfaces of the heart, liver, mesenteries, air sacs, and/or peritoneum (Fig. 30.27). In severe cases, surfaces of muscles and synovial sheaths of tendons and joints may be involved, and precipitation may occur within the liver, spleen, and other organs. The deposits on serosal surfaces appear grossly as a white chalky coating, while those

Table 30.1.   Differences between visceral urate deposition and articular urate deposition in birds (modified from Shivaprasad (422)).

	Visceral urate deposition (Visceral gout)	**Articular urate deposition (Articular gout)**
Onset	It is usually an acute condition but can be chronic.	It is usually a chronic disease.
Frequency	It is very common.	It is rare or sporadic.
Age	1 day and above.	4–5 months and above. However, immature genetically susceptible chickens may be induced by high protein levels in the diet.
Sex	Both males and females are susceptible.	Mostly males.
Gross lesions		
Kidney	Kidneys are almost always involved, and they look grossly abnormal with deposition of white, chalky precipitates.	Kidneys are normal grossly. Kidneys may become abnormal with white urate deposits if the bird gets dehydrated.
Soft tissues	Visceral organs like liver, myocardium, spleen, or serosal surfaces like pleura, pericardium, air sacs, mesentery, etc. are commonly involved.	Soft tissues other than synovium are rarely involved; however, comb, wattles, and trachea have been observed to be involved.
Joints	Soft tissues around the joints may or may not be involved. Surfaces of muscles, synovial sheaths of tendons, and joints are involved in severe cases.	Soft tissues around the joints are always involved, especially feet. Other joints of the legs, wing, spine, and mandible are also commonly involved.
Microscopic lesions	Generally no inflammatory reaction in synovium or visceral surfaces. Kidney and viscera have inflammatory reaction around tophus.	Granulomatous inflammation in synovium and other tissues.
Pathogenesis	It is generally due to failure of urate excretion (renal failure).	It is probably due to a metabolic defect in the secretion of urates by the kidney tubules.
Causes	1. Dehydration 2. Nephrotoxicity: calcium, mycotoxins, (ochratoxins, oosporein, aflatoxins, etc.), certain antibiotics, heavy metals (lead), ethylene glycol, ethoxyquin, etc. 3. Infectious agents: nephrotropic IBV and avian nephritis virus (chickens), PMV-1 (pigeons), *Eimeria truncata* (geese). In psittacines: *Salmonella* sp., *Yersinia* sp., *Chlamydia psittaci*, microsporidia, cryptosporidia, *Aspergillus* sp., polyomavirus, etc. 4. Vitamin A deficiency. 5. Urolithiasis. 6. Neoplasia (lymphoma, primary renal tumors). 7. Immune mediated glomerulonephritis. 8. Anomalies. 9. Others?	a. Genetics b. High protein in the diet. c. Others?
30.27.   Visceral urate deposition over the heart and liver of an adult pigeon.

30.28.   Articular urate deposition ("articular gout") in a mature chicken causing enlargement and deformity of toes and feet. (M. C. Peckham)

within viscera may only be recognized microscopically. Much urate is lost when tissues are processed for histology, but evidence of its presence is often seen as blue or pink amorphous material under the microscope. Feathery crystals or basophilic spherical masses may be seen within tissues under the microscope in some cases. Fixing and processing tissues in 90% or absolute alcohol will preserve urates.

Visceral urate deposition is generally due to a failure of urinary excretion. This may be due to obstruction of ureters, renal damage, or dehydration. Dehydration due to water deprivation is a common cause of visceral urate deposition in domestic poultry. Outbreaks of visceral urate deposition in poultry have also been attributed to infectious causes, such as nephrotropic strains of infectious bronchitis virus (80) and renal cryptosporidiosis (462); and noninfectious factors, such as vitamin A deficiency, secondary to urolithiasis (434), treatment with sodium bicarbonate (90), mycotoxins, such as oosporein (355), and feeding growing birds layer rations that are high in calcium and protein (166). It is not clear whether the kidney necrosis seen in visceral urate deposition is primary or secondary to hyperuricemia and urate deposition. In a recent study, one of the first changes observed in birds treated with high concentration of sodium bicarbonate was metabolic alkalosis and hyperuricemia (306). The authors suggested that state of alkalosis induced the breakdown and turnover of nucleoprotein causing hyperuricemia, with the consequent precipitation and crystallization of urates. However, the mechanism for urate crystals precipitation to occur in certain sites is not known, yet.

Articular Urate Deposition ("Articular Gout")

Articular urate deposition, unlike the visceral type, is a sporadic problem of little economic importance in poultry. The clinical condition is characterized by leg shifting, lameness and inability to bend the toes. It is characterized by tophi, deposits of urates around joints, particularly those of the feet, hence confusion with bumble foot. The joints are enlarged and the feet appear deformed (Fig. 30.28). When these joints are opened, the periarticular tissue is white due to urate deposition, and white semi-fluid deposits of urates may be found within the joints. In chronic cases urate precipitates can also be observed in the comb, wattles, trachea, etc. Therapy is palliative only. Removal of the deposits is not recommended due to the difficulty and profuse bleeding. As it has been reproduced by feeding high-protein diets, it is tempting to infer that it results from excess production of uric acid. Studies in a line of chickens bred for high incidence of articular urate deposition, however, indicate that they may have a defect in tubular secretion of uric acid (9, 66).

Urolithiasis

Urolithiasis is primarily seen in laying flocks and has been associated with increased mortality and decreased egg production (273, 490). Urolithiasis is characterized by severe atrophy of one or both kidneys, distended ureters often containing uroliths, and varying degrees of renal and visceral urates deposits.

Clinical Signs and Pathology

Overall mortality in affected flocks may exceed 2% for several months, and in excess of 50% of this mortality may be due to urolithiasis (28, 273). Renal lesions have been recognized in clinically normal birds in flocks undergoing an outbreak, and 3.2–6.3% of hens in some affected flocks had renal lesions at processing (273). Laying chickens die suddenly and may be in good condition and in full lay (28) or they may have a reduced muscle mass, small pale combs, and white pasting on pericloacal

feathers (45). Atrophied kidneys and dilated ureters, often accompanied by diffuse visceral urate deposits, are found in affected birds (28, 45, 273) (Fig. 30.29). The kidney atrophy is often more severe in anterior lobes and is unilateral, but it may be bilateral. The surviving ipsilateral or contralateral lobes may be enlarged. The ureters arising from the atrophied lobes are dilated and full of clear mucus and often contain white irregular concretions or uroliths (45). These uroliths are composed of compact masses of microcrystalline to fine pleomorphic crystals of calcium sodium urate, with random substitution of magnesium and potassium for the calcium and sodium, respectively (327). Microscopic lesions in affected kidneys consist of dilation of ureter branches and tubules, tubular degeneration and loss of tubules, cellular casts, urate crystals, and varying degrees of fibrosis (28, 45). Urolithiasis has been primarily recognized as a disease of laying birds, but reports indicate that lesions and mortality may start during the rearing period (45, 71). In a sequential study of one outbreak, minor focal cortical tubular necrosis was found by microscopic study in grossly normal kidneys of 4-wk-old pullets. In 7-wk-old pullets, the kidneys were grossly swollen with tubular necrosis and casts, eosinophilic globules in glomeruli, and interstitial infiltration of heterophils and lymphocytes. Typical lesions of urolithiasis were found in 14-wk-old birds (45).

Pathogenesis and Etiology

Wideman *et al.* (491) conducted renal function studies on chickens during outbreaks of urolithiasis and concluded that the physiologic impact of the kidney damage was the result of reduced renal mass, rather than of inappropriate renal handling of minerals or electrolytes. A significant reduction in number of glomeruli has also been reported in birds affected by urolithiasis (321). The uroliths may cause sudden death by plugging ureters but probably occur secondary to kidney damage (273). The lesions described in outbreaks of urolithiasis are similar to those described in a long-term study of the pathogenesis of infection of chickens with infectious bronchitis virus (4). In many outbreaks of urolithiasis, it has been difficult to isolate infectious bronchitis virus from affected laying birds (28, 45, 273). This would not be unexpected, as recovery of infectious bronchitis virus was erratic in the long-term study mentioned above. Infectious bronchitis viruses, which have been shown to cause renal damage in experimental chickens, have been isolated in some outbreaks of urolithiasis (45, 71). In several outbreaks, potential problems in vaccination programs against infectious bronchitis have been identified (28, 71, 273).

Excess dietary calcium, in particular if combined with low available dietary phosphorus, fed to growing pullets has caused urolithiasis in experimental trials (151, 416, 479). Exposure of pullets to the Gray strain of infectious bronchitis virus subsequent to feeding a high-calcium laying ration increased the incidence of urolithiasis and gross kidney damage (152). A marked difference in susceptibility to urolithiasis caused by high-calcium diets has been described between two strains of leghorn chickens (262). The more susceptible strain produced more alkaline urine and had a higher proportion of juxtamedullary nephrons (491).

30.29. Urolithiasis in a chicken. Severe atrophy of the right kidney and anterior lobes of the left kidney. The right ureter is distended with white material. (Craig Riddell)

Formation of uroliths may be due to high levels of urinary calcium and decreased hydrogen ions in the urine (152). Dietary acidification with ammonium chloride, ammonium sulfate, or methionine has been shown to decrease the incidence of uroliths and gross kidney lesions in urolithiasis induced experimentally with high-calcium diets (150, 262, 487, 489, 488). The use of ammonium chloride was not considered a practical treatment for use in the field because it caused increased water consumption, urine flow, and manure moisture (150). The other compounds did not appear to have this disadvantage (262, 488). Ammonium sulfate was more effective than two forms of methionine in a single trial (262).

Water deprivation has been suggested as a cause of urolithiasis on the basis of field observations (218). The fact that some mycotoxins are nephrotoxic led to the suggestion that they should be considered as a potential cause of urolithiasis (273).

Diseases of the Eye

There are many conditions and diseases that affect the eye, which have been reviewed by Shivaprasad (423).

Ammonia Burn

Ammonia burn describes a keratoconjunctivitis in poultry caused by exposure to ammonia fumes resulting from unsanitary conditions. Ammonia in the poultry house results primarily from the nitrogenous compounds decomposition process occurring in the

litter and fecal matter. Clinical signs include photophobia, excess lacrimation, and respiratory congestion. Affected birds keep their eyelids closed and are reluctant to move. They may rub their head and eyelids against their wings. The cornea has a gray cloudy appearance and may be ulcerated. Edema and hyperemia may be present in the conjunctiva but often may not be very obvious. The condition is generally bilateral and affected birds do not eat and become emaciated. Microscopically, the lesions are characterized by necrosis of the epithelium of the cornea, ulceration, and infiltration of heterophils into the epithelium and substantia propria. The opacification of the cornea is a result of ulceration, cellular infiltration and edema of the cornea (423). Inflammation of the conjunctiva can be severe. Many birds recover if exposure to ammonia fumes is eliminated. Time of recovery depends on the severity of damage to the cornea and may take 1 month or longer if lesions are severe. Prevention of the condition is based on proper ventilation and litter management. The ammonia fumes are formed in wet litter.

Cataracts

The opacification of the lens is referred as cataracts. It is uncommon among most domestic poultry. The condition has been described in chickens, turkeys, and quail. It can be caused by viral diseases, such as avian encephalomyelitis; nutritional deficiencies, such as vitamin E; hereditary, and old age. Lens opacity is normally bilateral, resulting in blindness. Microscopically the lesion is characterized by degeneration of lens fibers, epithelial hyperplasia, formation of bladder cells and liquefaction in advance stages (423).

Developmental Anomalies

Several anomalies are described in young chicks and turkey poults. These include cyclopia, triple eyes, buphthalmia, anophthalmia, microphthalmia, optic nerve hypoplasia, cataracts, retinal dysplasia, corneal edema, and corneal ectasia (128, 145, 371, 419, 423). These defects can have genetic origin, but most are the result of suboptimal incubation conditions. Incubation temperature is one, if not the most, important factor for successful hatching.

Retinal Dysplasia

Abnormal development of the retina most probably inherited as autosomal recessive trait has been described both in layer and broiler commercial chickens (5, 423, 426). The disease is present in chicks when they are a few days old and becomes apparent when they are 5 or 7 days old. Clinically the chicks with retinal dysplasia are smaller than their counterparts, wander aimlessly and are unable to find feed and water. Ophthalmoscopic examination of the eyes in these chicks showed lack of papillary reflexes and normal posterior and anterior segments. The incidence of blindness was generally low, less than 1%, and postmortem examination did not reveal any gross lesions in the eyes. Microscopic examination of the eyes revealed degeneration of photoreceptors (rods and cones) in the earlier stages followed by rosette formation, disorganization of retinal layers, synechiae of the retina, reactive and proliferative   retinal pigmented epithelial

cells and inflammation of the choroid in later stages. If the birds survived for several weeks progressive changes such as retinal detachment, cataract formation, fibrosis, and metaplastic changes to cartilage were seen (423).

Partial retinal dysplasia and degeneration leading to blindness in 2 to 5% of chickens in a strain of chickens that was a cross between barred Plymouth Rock and Rhode Island red has been described (372). In this flock the clinical signs of blindness were first evident at 5 to 6 weeks of age and by 6 months most of the chicks did not respond to visual stimuli. Retinopathy characterized by loss of photoreceptors resulting in blindness in 0.2% of the chicks in a commercial layer breeder flock has also been described (85). This condition could be diagnosed in chicks as early as 3 weeks of age but it was more evident at 8 weeks of age.

Chorioretinitis and Buphthalmos in Turkeys

A turkey blindness syndrome due to chorioretinitis and buphthalmos has been described in meat (14) as well as breeder turkeys (408). The incidence of eye lesions in turkey breeder flocks ranged from 2 to 30%, and egg production was reduced between 4 and 40%. The affected poults could be recognized by their wandering movement, their tendency to peer at objects in a short-sighted manner, and occasionally by their holding their heads to one side. Blind poults grew normally and were able to locate feed and water. Eyeballs were enlarged by 5–7 wk of age and the corneas flattened. The palpebral fissures became oval. By 16–20 wk of age, many birds had cataracts. Ophthalmoscopic examination of affected eyes revealed pale areas in the retina. On section, severely affected eyes contained an abnormal fluid and some were hard to cut due to bone formation within the eye. Microscopic changes in affected eyes included choroid thickening, degeneration and detachment of the retina, and in severe cases, fibroplasia and islands of ossifying cartilage in the posterior chamber.

Pathogenesis and Etiology

Similar lesions to those just described have been induced in experimental turkeys by rearing them on continual artificial light (8, 14). Rearing experimental chickens under continuous light has caused enlargement of eyeballs, decreased corneal curvature, thinning of the retina and an accumulation of fluid in the vitreous body (255). Birds reared on low intensity, but diurnal, light also develop enlarged eyes, but in such eyes the corneas protrude rather than become flattened (183). Eye enlargement in chickens may also be induced by darkness (210).

Blepharoconjunctivitis

Blepharoconjunctivitis is characterized by inflammation of the eyelids, excess lacrimation, and in severe cases, destruction of the eyeball or inflammation of the eyelids and conjunctiva. This condition has been described in turkeys (20, 21, 334, 406). White frothy foam at the anterior canthus of the eye was followed by accumulation of caseous exudate and swelling of eyelids, which became encrusted and closed. Ulceration of the cornea may result in panophthalmitis and destruction of the eyeball. It has been associated with exposure to *Pasteurella multocida* via drinking

water (334). Previous damage of the eye might have predisposed to infection.

Eye-Notch Syndrome

Eye-notch syndrome refers to a widespread lesion in the eyelid of caged layers (423). The condition appears to start as a small scab or erosion on the lower lid, which develops into a fissure with a tag of flesh attached to one side. Microscopically, it is characterized as blepharoconjunctivitis. The significance and cause of the condition are unknown.

Ophthalmopathy

Cummings *et al.* (83) described this condition in 22-week-old broiler breeders. The condition affected 2 to 3% of the flock. Clinically, birds were partially blind and photophobic. Microscopically, there was retinal degeneration and detachment. Early cataract formation was also noticed. No cause was determined, but low-intensity light for only 6 hours a day might have been responsible.

Endophthalmitis

Chronic endophthalmitis of unknown etiology has been described in broiler chickens (493). Grossly it is characterized by opacity of the pupil, cataract formation, retinal thickening and detachment, and shrunken vitreous. Microscopically, there was granulation tissue throughout the eye and atrophy of optic nerves.

Diseases of the Reproductive System

Cystic Right Oviduct

In the female chicken embryo, two Müllerian ducts start to develop into oviducts. The left duct develops into a functional oviduct, while the right duct regresses. If this regression is not complete, partial development will result in a cystic right oviduct. Cystic right oviducts are common incidental findings in postmortem examination of chickens. They vary in size from small, 2-cm diameter, elongated cysts to large fluid-filled sacs up to 10 cm or more in diameter (Fig. 30.30). Small cysts are of little consequence, but large cysts compress the abdominal viscera. The large sacs can result in a bird with a pendulous abdomen and should be differentiated from ascites.

False Layer

The term *false layer* has been used to describe a bird that has the characteristics of a bird in production, visiting the nest regularly but not laying eggs (201). This bird has a normal-appearing ovary and oviduct, but the infundibulum fails to engulf the ovum after it has been ovulated. At necropsy, these birds show excessive amounts of orange-colored fat and have liquid yolk or coagulated yolk in the body cavity. This defect may result as a sequel to infectious bronchitis at an early age (43, 44).

Internal Layer

In some birds, soft-shelled eggs or fully formed eggs may be found in the peritoneal cavity. This indicates that the yolk pro-
30.30. Cystic right oviduct in a chicken. (M. C. Peckham)

gressed normally through the oviduct to a certain point and then reverse peristalsis discharged the egg into the body cavity. A bird with a large accumulation of eggs in the peritoneal cavity may assume a penguin-like posture.

Impacted Oviduct

Occasionally, an oviduct is occluded by masses of yolk, coagulated albumen, shell membranes, and in some instances, fully formed eggs. Large masses of yolk-like material may also be found in the oviduct, and upon transection, these masses have the appearance of concentric rings.

Egg-Bound

This term is used to describe a condition in which an egg is lodged in the cloaca but cannot be laid. It may result from inflammation of the oviduct, partial paralysis of the muscles of the oviduct, or production of an egg so large that it is physically impossible for it to be laid. Young pullets laying an unusually large egg are more prone to the problem. Prolapse of the oviduct, usually along with the cloaca, may be seen as a sequela of dystocia.

Phallus Prolapse

It is occasionally seen in anseriformes and ratites associated with infection or immunodepression. The exact cause of prolapse is unknown. In geese, phallus erosions and prolapse have been associated with *Neisseria* spp. infection (13). In ratites usually occurs at the end of the breeding season and after sudden weather changes (54, 193). One report associates *Cryptosporidium* spp. infection with cloacal and phallus prolapse in ostriches (357). Frostbite and bacterial infection may occur as a sequela of phallus prolapse.

Abnormal Eggs and Depressed Production

Poor egg quality and depressed egg production are common problems that cause great economic loss to the poultry industry. They can be due to a multitude of factors involving nutrition, management, environment, and disease.

Diseases of the Integumentary System

Contact Dermatitis

Erosive lesions affecting the skin on the plantar surface of the feet, the posterior surface of the hocks, thigh, or the breast overlying the sternum have been recognized in turkeys and in broiler chickens. Breast, thigh and hock conditions have been an important cause of downgrading of chicken and turkey carcasses (154, 293). Although the incidence in the footpads can be also high, these lesions do not contribute to downgrading of carcasses; but they may result in lameness and depression of body weight (275, 276) and it is becoming an important welfare issue (278). Depending on the site of lesion in the skin lesions have been called by different names. Lesions in the footpads are known as pododermatitis, while lesions on the breast are known as breast burn in chickens (159) and breast buttons in turkeys (154). Ulcers and erosions of the skin covering the thigh and hip of broiler chickens have been described as scabby hip (182, 359). A common feature of all of these skin lesions is that they appear to be due to contact irritation and are associated with poor litter conditions. In recent years, improvements in the litter management and the use of nipple drinkers in the poultry houses have contributed in reducing the incidence of this condition (296).

Clinical Signs and Pathology

Dermatitis on the foot and hock appear as dark black scabs filling ulcers on the plantar footpad, digits and caudal tibiotarsus-tarsometatarsus joint (159, 275). In turkeys, early changes of pododermatitis occur during the first wk of age and become more severe over a short period of time; by 6 wks of age the changes typical of pododermatitis are fully developed (290). Early changes include enlargement of foot scales, cracks, abrasions, and a superficial scab. These changes proceed to a deep ulcer. Histologic lesions include defective keratin in the *stratum intermedium,* particularly adjacent to the ulcer, and infiltration of heterophils in adjacent epidermis. The center of the lesion is occupied by a necrotic mass of cellular debris, which may enclose plant material and bacteria. The base of the mass is underlain by heterophils and often macrophages and a line of giant cells. Many birds also in addition to the foot lesions have similar ulcers filled with black scabs on the posterior of the hock and on the breast.

The breast lesions, in turkeys, were characterized by a granulomatous response with no giant cells noted but connective tissue proliferation occurred below the ulcers (154), probably related to the chronicity of the lesion. Scabby hip syndrome is characterized by ulcers and erosions covered by scabs on the skin of the thigh of broiler chicken associated with femoral head degeneration (359) and in chicken flocks kept in high density (182).

Pathogenesis and Etiology

Field outbreaks of contact dermatitis have been associated with poor litter conditions (159). An epidemiologic study by McIlroy *et al.* (293) found that lesions were more frequent with increased stocking density, increased age, particular feeds, in male birds, and in winter. A study has shown that the decrease in the prevalence of dermatitis in the 90s is associated with the better management of litter and improvements in house designs, particularly the use of nipple drinkers (296) even when stock density and age of slaughter are kept the same as in the 80s. Parameters that were associated to increased prevalence of dermatitis included male only flocks with inferior food conversion ratio and increased mortality rates. A recent study (278) demonstrated that other factors than high commercial stocking densities had more influence in the prevalence of pododermatitis in chickens; while it would probably be necessary to reduce stocking density drastically or to investigate new systems of floor drainage.

In experimental studies, the incidence of dermatitis has been increased by deliberate wetting of litter (174, 275, 276) and by using coarse bedding materials (191, 315). Cool temperatures prior to 12 wk increased the incidence of breast buttons; while, no association was found with the feathering condition (315). Marginal deficiencies of biotin have been suggested as possible cause of pododermatitis in experimental birds (176). In an experiment, the increase of almost ten-fold of biotin in the diet reduced pododermatitis in 19-wk-old turkeys (47). It has been suggested that biotin supplementation in turkey diets should be increased (361).

Breast blisters involving the formation of a subcutaneous cyst between the skin and the sternum (292) should be distinguished from the ulcerative lesions of contact dermatitis in the skin overlying the sternum. Both may be found in the same flock (276), but the breast blisters are more probably due to prolonged pressure from sitting (292) rather than contact irritation. Pressure up to 240mm Hg on the unfeathered breast of turkeys during 6 days for 6 hours daily did not cause any lesions (155).

Xanthomatosis

This condition is rarely seen in poultry today, but it was a significant flock problem circa 1960. It is characterized by an accumulation of semifluid yellowish material under the skin of chickens. Peckham (354) reviewed case reports and studies of the condition. White leghorn hens were primarily affected, and the incidence of affected birds in flocks reached 60%. Birds with lesions were bright, active, and in production. Wattles were often swollen. Swellings also occurred on the breast, abdomen, and feathered portions of the legs. The swellings often became nodular and pendulous. Initially, the lesions were soft and fluctuating and contained a honey-colored fluid. Later, they became firm with chalky white areas of cholesterol interspersed through the abnormal thickened subcutaneous tissue. Histopathologic changes included massive infiltration of foamy macrophages (Fig. 30.31), cholesterol clefts (Fig. 30.32), and giant cells. The cause is unknown, but because the xanthomatous tissue contained high levels of hydrocarbons it was postulated that a hydrocarbon in animal feed may have caused the condition.

Chapter 31

Mycotoxicoses

Frederic J. Hoerr

Introduction

A mycotoxicosis is a disease caused by a toxic metabolite of a fungus (mycotoxin). Mycotoxins drew attention in the early 1960s when aflatoxin produced by *Aspergillus* spp. was discovered to cause disease in poultry and fish. The disclosure of the carcinogenic properties of aflatoxins accentuated the significance. Diseases in humans and animals caused by moldy food, however, were recognized long before the discovery of aflatoxin. Ergotism, moldy corn poisoning of horses, stachybotryotoxicosis, alimentary toxic aleukia, various hemorrhagic syndromes, yellow rice poisoning, and other acute food poisonings are some of the historically significant mycotoxicoses of humans and animals.

The many naturally occurring mycotoxins now recognized (38, 541) vary by toxicity for poultry, target organs, and occurrence on feedstuffs. The mycotoxins associated with poultry health problems, and therefore the most studied, are the ergot alkaloids, aflatoxins, trichothecenes and other mycotoxins produced by *Fusarium*, ochratoxins, oosporein, citrinin, and fumonisins, but this list is not comprehensive. Although analytical surveys of grains used for poultry feed commonly detect low to moderate levels of mycotoxins, overt intoxication is relatively difficult to document. Despite this, subclinical mycotoxicosis is considered common. The impact of mycotoxins on poultry production may be measured indirectly by the improvements in poultry health that accompany mycotoxin control programs.

Ergotism

Etiology and Toxicology

Ergotism is characterized by vascular, neurologic, and endocrine disorders (reviewed 349). Ergotism descriptions date to the Roman Empire and to China of 5000 years ago, and epidemics killed many people in Europe during the Middle Ages.

Ergotism is caused by *Claviceps* spp., which attack cereal grains. Rye is especially affected, but also wheat and other leading cereal grains, with regional differences. *Claviceps purpurea* is frequently implicated because of its wide host range among cereals. The mycotoxins form in the sclerotium, a visible, hard, dark mass of mycelium that displaces grain tissue. In the normal cycle, the sclerotium falls to the ground, germinates, and produces spores that infect the flower of the new crop, and the cycle repeats. The sclerotium is channeled into the food chain during harvest.

Within the sclerotium are the ergot alkaloids that cause ergotism. Lysergic acid is the chemical building block of the 40 or more alkaloids produced by *Claviceps* spp. With individual variation, the alkaloids produce convulsive and sensory neurologic disorders, vasoconstriction and gangrene of extremities, and altered neuroendocrine control of the anterior pituitary gland (372). Some of the biological activities of the alkaloids are used pharmacologically.

Ergot is detected in wheat, barley, oats, rye, rice, and other cereals in cooler grain-rearing climates worldwide (reviewed 580). Sorghum ergot alkaloids produced by *Claviceps africana* spread globally from Africa in the 1990s (126). Tolerances for ergot in international trade vary, but grain can be declared "ergoty" with sclerotium concentrations as low as 0.1–0.33%. At concentrations that might be encountered naturally (0.33%), ergot has no significant interaction with the antinutritive factors in rye (362, 363). Weed seed contaminants of grain can also be a source of ergot (427). Pelleting feeds can increase the toxicity of ergot, perhaps through increased liberation of toxins.

Natural Disease

Ergotism in poultry reduced feed intake and growth, and caused necrosis of the beak, comb, and toes; and diarrhea. Leghorns developed coalescing vesicles and crusts on the comb and wattles, face, and eyelids (vesicular dermatitis, sod disease) (427). Combs and wattles became permanently atrophied and disfigured. Vesicles and ulcers developed on shanks of the legs and on the toes. In another episode, ergotism spared very young chickens, but those over 6 weeks of age failed to grow and had mortality of 25%. Laying hens had reductions in feed consumption and egg production, but there were no consistent lesions other than on the skin. Wet droppings in laying hens were associated from sorghum ergot produced by *Claviceps africana* (126).

Muscovy ducks fed wheat dockage contaminated with 1.17% ergot became listless and lethargic, stopped eating and drinking, and developed diarrhea (518). Younger ducklings experienced higher mortality than older ducks, with lesions confined to visceral congestion.

Experimental Disease

In chickens, wheat ergot caused reductions in appetite and growth, and mortality, but the effects were quite variable (466, 465, 467). Triticale ergot caused reduction of growth, poor feathering, nervousness, loss of coordination, inability to stand, and

mortality (53). Sorghum ergot impaired weight gain and conversion in broilers (31). Broilers are generally more sensitive to ergot than leghorns. The toxicity is mostly in the alkaloid fraction of the ergot extract, but the value of total alkaloid content is not highly predictive. Ergotamine tartrate, a common alkaloid, caused necrosis of toes in chicks, and cardiac enlargement likely due to increased cardiac workload from vasoconstriction and hypertension (581).

Metabolism and Residues

Ergotamine tartrate accumulated in only trace amounts in broiler tissues when fed at relatively high concentrations (800 mg/kg diet). About 5% of the alkaloid excreted unchanged, and 15–20% as a mixture of metabolites (581).

Fusarium Mycotoxins

The genus *Fusarium* produces many mycotoxins injurious to poultry, including caustic and radiomimetic injury; cardiac toxicity; and skeletal, digestive, and reproductive disorders. In the grain and feed production channels detectable *Fusarium* toxins include trichothecenes, fumonisins, zearalenone and moniliformin, alone or in combinations (481) or with aflatoxin or ochratoxin (7, 181).

Trichothecenes

Etiology and Toxicology

Trichothecene mycotoxins are produced by common soil and plant fungi found worldwide, including *Fusarium* and its perithecial stages, *Calonectria* and *Gibberella*; and the genera *Myrothecium*, *Stachybotrys*, *Cephalosporium*, *Trichoderma*, *Trichothecium*, *Cylindrocarpon*, *Veriticimonosporium*, and *Phomopsis* (reviewed 327, 359, 538). In one study, about 20% of isolates produced trichothecenes. *Fusarium* produces about one-half of the more than 100 trichothecenes (539), with greatest toxin production at high humidity and temperatures of 6–24°C.

Trichothecenes have a tetracyclic sesquiterpene nucleus with a characteristic epoxide ring. Poultry are usually exposed to nonmacrocyclic trichothecenes, which includes type A trichothecenes (T-2 toxin, neosolanial, DAS, and others) and type B (nivalenol, DON, fusarenone-X, and others) (reviewed 327). Toxicity resides in the epoxide ring, which is stable during prolonged storage or normal cooking temperatures (33, 359, 538). In general, trichothecenes damage structural lipids and inhibit the synthesis of protein and DNA (96, 349, 538). Many are caustic irritants, a feature used in detection bioassays.

T-2 toxin, diacetoxyscirpenol (DAS), deoxynivalenol (DON, vomitoxin), and nivalenol occur in feedstuffs worldwide, including corn, wheat, barley, oats, rice, rye, sorghum, safflower seed, mixed feed, and brewer's grains (327, 580). Deoxynivalenol is the most prevalent and can occur naturally with zearalenone, aflatoxin, and other mycotoxins (203, 213, 547). Grains contaminated with DON may be diverted to poultry feeds because DON has low toxicity for poultry compared to swine, which experience feed refusal and emesis.

Natural Disease

Both historical and recent accounts of trichothecene mycotoxicosis reflect caustic and radiomimetic effects expressed as feed refusal, extensive necrosis of oral mucosa and skin in contact with the mold toxins, acute digestive tract disease, and altered bone marrow and immune system function. Recovery generally occurs when an unadulterated diet is provided.

In the premodern era, avian fusariotoxicosis occurred in the former Soviet Union during periods when alimentary toxic aleukia was endemic in humans at certain times during the first half of the twentieth century. *Fusarium poae* and *F. sporotrichioides* isolated from grain and green vegetation feedstuffs were the likely sources of toxins. Chickens with fusariotoxicosis (probable trichothecene mycotoxicosis) had reduced growth, severe depression, and bloody diarrhea (reviewed 313). At necropsy, lesions were necrosis of oral mucosa, reddening of the gastrointestinal mucosa, mottling of the liver, gallbladder distention, atrophy of the spleen, and visceral hemorrhages. Presumed trichothecene mycotoxicosis caused by *Stachybotrys* spp. occurred in poultry during the 1940s as necrosis of oral and crop mucosa, digestive and neurologic disturbances, blood dyscrasias, and hemorrhagic disease (reviewed 237).

More recently in broilers, T-2 toxin produced by *Fusarium tricinctum*-contaminated feed and litter reduced growth and caused skin lesions on the feet and legs, and ulceration and crusting of the oral mucosa (568). Another report found digestive and nervous signs, reduced growth, rickets, abnormal feathering, pigmentation defects, and hemorrhages. T-2 toxin, neosolaniol, verrucarol, fusarenon-X, and crotocol were detected at 1–4 mg/kg in feed produced from crib-stored corn (456).

In hens, feed contaminated with T-2 toxin and HT-2 toxin rapidly decreased egg production beginning the day after feed delivery (485). Depression, recumbency, feed refusal, and cyanosis of the comb and wattles developed, and at necropsy, the ovary and oviduct were atrophied. Feed contaminated with T-2 toxin (3 mg/kg) caused decreases in feed consumption and egg production, and thin-shelled eggs (223). Thick yellow crusts formed over ulcers on the oral mucosa, and feathers were uneven and poorly formed. Oral and feather lesions lacked uniformity within and among cages. At necropsy, hens with oral lesions also had yellow-tan, friable livers, swollen kidneys, urate deposits in the ureters, focal ulceration and inflammation of crop mucosa, and a thickened, rough lining in the gizzard.

Grain sorghum contaminated with DON (0.3 mg/kg) and zearalenone (1.1 mg/kg) was associated with decreased egg production. Oral ulcers occurred in conjunction with squamous metaplasia of salivary and mucous glands (56). Oral crusts and ulcers in commercial layers, taken as presumptive evidence of trichothecene exposure, were associated with decreases in egg weight and shell weight (207). Older hens were more sensitive and the prevalence was influenced by genetic strain.

Deoxynivalenol (190 mg/kg) was the only trichothecene detected in feed associated with egg production losses, oral ulcerations, and gray to black discoloration of the tongue (201). Production returned and oral lesions improved with the addition of an organic aluminosilicate adsorbent to the feed. Deoxyni-
31.1. Fusariotoxicosis. Trichothecene mycotoxins cause chemical irritation of the upper digestive tract mucosa. A. Crusts at the beak commissure of a broiler chicken fed diacetoxyscirpenol for 8 days. B. Beak and palate ulceration and crusting in a broiler chicken following 14 days of consumption of diacetoxyscirpenol (4 mg/kg diet).

valenol did not cause oral lesions, and its presence in the feed was considered an indicator of undetected caustic trichothecenes.

Mortality in Brahma poultry was associated with oral lesions, hemorrhages, and necrosis and depletion in lymphopoietic organs (291). T-2 toxin (0.70 mg/kg) and DAS (0.50 mg/kg) contaminated the feed.

In geese and ducks, barley contaminated with T-2 toxin (25 mg/kg) caused reduced activity, feed refusal, increased water consumption, and death (204, 443). At necropsy, necrosis and pseudomembranes occurred in the esophagus, proventriculus, and gizzard. Histopathology revealed degeneration of intestinal epithelium and acute tubular injury in the kidney. Wild geese dying of fowl cholera were presumed stressed or immunosuppressed by feeding on corn contaminated with DON (< 5.0 mg/kg) and zearalenone (< 25 mg/kg) (236).

In turkey poults, feed refusal and high mortality was associated with feed contaminated with DON (0.81 mg/kg) and salinomycin (2.2 mg/kg) (338). In a feeding trial, much higher concentrations of DON and salinomycin were required to affect feed consumption and cause mortality, leading to the conclusion that undetectable toxins were involved in the incident.

Suspected fusariotoxicosis in sandhill cranes (*Grus canadensis*) was linked to trichothecene-producing *Fusarium* isolated from peanuts used as a food source in the wild (464). Loss of motor control of the neck, wings, and legs accompanied recurring annual episodes of high mortality. At necropsy, edema occurred around the head and neck, but the digestive ulcers usually attributed to trichothecenes were lacking. Principal lesions were hemorrhages, granulomatous myositis, thrombosis, and vascular degeneration.

Experimental Disease
Experimental trichothecene mycotoxicosis in poultry has required several approaches to reproduce fully the disease spectrum observed naturally: purified toxin administered either in solution or in the diet, and toxigenic fungal cultures (reviewed 274). Collectively, these toxins cause feed refusal, impaired growth and reproductive capability; and whole-body pathology including caustic injury to skin and alimentary mucosa; radiomimetic injury to bone marrow, lymphoid tissues, gastrointestinal tract, and feathers; hepatosis; and thyroid alterations.

Neurotoxicity of T-2 toxin and other trichothecenes is inconsistently reported as abnormal wing positioning, seizures, and loss of righting response (242, 571); brain neurotransmitters are affected (95, 517).

Pathology. Many trichothecenes caused erosive and exudative injury to the oral mucosa of poultry fed toxin-appended diets (91, 112, 568, 569). Focal, yellow oral plaques progress to yellow-gray, raised accumulations of exudate with underlying ulcers located near major salivary duct openings on the palate, tongue, and floor of the mouth. Thick crusts accumulate along the interior margin of the beak (Fig. 31.1A,B). Oral histopathology showed mucosal necrosis and ulceration; superficial crusts of exudate, bacterial colonies, and feed components; and submucosal granulation tissue and inflammatory cells.

The histopathology of acute oral intoxication by purified T-2 toxin or DAS was characterized by rapid necrosis and depletion of lymphoid and hematopoietic tissues and then relatively rapid recovery (241). The liver had foci of hepatocyte necrosis and hemorrhage, necrosis and inflammation of the gallbladder mu-

31.2. Feathers from a chicken fed T-2 toxin for 24 days (right) are narrow because of radiomimetic injury to the developing barbs; control (left).

cosa, and then mild proliferation of bile ductules. Necrosis of intestinal epithelium was followed by transient shortening of villi. Necrosis also occurs in the mucosa of the proventriculus and gizzard and in feather epithelium.

Quail were relatively resistant to T-2 toxin (LD50 14.7 mg/kg), but lethal intoxication was associated with necrosis and depletion of lymphoid tissue, and necrosis and fatty degeneration in the liver (209).

Extended exposure to T-2 toxin and DAS and other scirpenol toxins caused reductions in body weight and skin pigmentation, anemia, and malformed feathers (Fig. 31.2) (244, 243, 416, 572,

575). Lymphoid organs atrophied; the bone marrow became pale red or yellow; and the liver yellows (Fig. 31.3). Histopathology revealed cellular depletion of lymphoid and hematopoietic tissues and in the liver, vacuolar change in hepatocytes and mild proliferation of bile ducts. In the thyroid gland, the follicles became small and had pale colloid.

Deoxynivalenol (DON) is relatively nontoxic to poultry. Feeding DON to broilers produced no clinical signs. Intestinal mucosa development was delayed, with decreased intestinal weight and shortened, narrow villi (22, 23). Feeding DON and zearalenone to ducks caused atrophy of the bursa of Fabricius (124)

Trichothecene-producing cultures of *Fusarium* and *Stachybotrys* caused clinical signs and lesions similar to those of the purified toxins (242, 273, 480). Trichothecenes in fungal cultures, a model closer to natural intoxication, appeared more toxic than purified compounds. This is suggestive that even at a low concentration, certain trichothecenes are significant if detected in feedstuffs.

Mallard and Muscovy ducks were particularly sensitive to trichothecenes and develop extensive lesions in the oral cavity and gastric organs, as well as atrophy of the lymphoid organs (228, 376, 487).

Acute lethal DON intoxication in broiler chickens caused reduced spontaneous activity, dyspnea, diarrhea, visceral urate deposition (visceral gout), and hemorrhages in the subcutis and viscera (225). Broiler and leghorn chicks, leghorn hens, and turkey poults tolerated DON at levels likely to be encountered under natural exposure (39, 40, 220, 265, 286, 299). Oral plaques and gizzard erosions developed but only at concentrations much higher than other trichothecenes and greater than those causing feed refusal and emesis in swine (334, 365).
31.3. Experimental trichothecene mycotoxicosis in broiler chickens. A. Hemorrhage in the liver occurring 20 hours after consumption of feed mixed with a culture of *Fusarium sporotrichiella* that produced T-2 toxin and neosolaniol (242). B. Daily oral doses of T-2 toxin caused yellow discoloration of the liver (bottom row) compared with control (top row). The radiomimetic effects are evidenced by atrophy of the spleen, thymus, and bursa of Fabricius and yellow discoloration of the bone marrow (243).

Chronic nivalenol intoxication of leghorn hens reduced feed intake but not egg production. At necropsy after 55 days, lower doses caused pale fragile liver, and higher doses caused lesions in the gizzard, hemorrhages in the duodenum, and swelling of the cloaca and oviduct (182).

Clinical Pathology. In broilers, T-2 toxin and DAS generally caused anemia associated with marked hematopoietic depletion in the bone marrow (242, 243, 412). In laying hens, T-2 toxin caused leukopenia and DON caused mild anemia and leukopenia (299, 573).

Broilers fed growth-inhibitory levels of T-2 toxin impaired blood coagulation (134, 136). Serum biochemical tests in chickens and quail reflected lesions in the liver, intestine, muscle, and kidney, which recovered to normal within 10 days (89, 90, 209, 420; 575).

T-2 toxin reduced plasma vitamin E concentrations in broilers (105), likely through impaired lipid metabolism in the intestine.

Reproduction and Egg Production. Trichothecenes effect egg production and reproduction. T-2 toxin, DAS, and monoacetoxyscirpenol reduce feed intake, body weight, and egg production in leghorns, broiler breeders, and turkey hens (10, 11, 54, 90, 460, 575). T-2 toxin and DAS had synergistic effects on egg production (129). Decreases in egg production were abrupt, and intoxication impaired hatchability. During recovery, hens overconsumed feed (575). Short-term DAS intoxication, however, had little effect on broiler breeder egg production (55). Deoxynivalenol was essentially nontoxic to hens at concentrations likely to be encountered naturally (39, 220, 221, 286, 301, 334, 367). Mild changes in dietary intake were due to palatability or olfactory responses, and there were minor changes in egg components and embryonic mortality.

Immunosuppression. T-2 toxin fed to broilers decreased the splenic lymphocyte stimulation index, and hemagglutination inhibition titers to Newcastle virus (282). Despite the profound effects of many trichothecenes on lymphoid organs and bone marrow (522), measurable immunosuppression is not well documented in chickens or turkeys (50, 457, 494). This may result from using purified toxin-appended diets rather than feeding fungal cultures or oral dosing, which allow greater expression of toxicity by trichothecenes (242).

Ducklings fed T-2 toxin had lymphocyte depletion in the bursa of Fabricius, thymus, and spleen, and reductions in the lymphocyte mitogenic responses (266, 448). T-2 tetraol was cytotoxic to chicken macrophages *in vitro* (288).

Pharmacological Interactions
T-2 toxin reduced the anticoccidial activity of lasalocid (544).

Metabolism and Residues
Liver chiefly metabolized and excreted T-2 toxin in chickens (93). After a single exposure, only T-2 toxin was detected in liver, but T-2 toxin, HT-2 toxin, neosolaniol, T-2 tetraol, and others appeared in feces (196, 579), and most excreted from the body

within 48 hours (463). Relatively small amounts of T-2 toxin excreted into the egg (92), detectable in yolk and albumen.

Deoxynivalenol fed to broilers at field levels was undetectable in skeletal muscle (159). The concentration in hen plasma reached only 1% of an oral dose, and was rapidly eliminated in feces (437). Deoxynivalenol transmitted to eggs at trace to undetectable concentrations (543, 519). Nivalenol fed to hens occurred unchanged and in trace amounts in bile, and excreted to feces with a related metabolite (182).

Moniliformin
Etiology and Toxicology
Moniliformin, produced by *Fusarium verticillioides* (formerly *F. moniliforme*) and other *Fusarium* spp. (447), is cardiotoxic and nephrotoxic in poultry. *F. verticillioides* causes ear rot, kernel rot, and stalk rot of unharvested corn and occurs in stored high-moisture shelled corn and on oats, soybeans, sorghum, barley, wheat, and corn that are visually sound. Although moniliformin is quite toxic to poultry, diets made with purified moniliformin are less toxic than toxigenic fungal cultures. *F. verticillioides* also produces fumonisins, zearalenone, fusariocin A, and other toxic fractions (71).

Natural Disease
Verification of *F. verticillioides* (*F. moniliforme*) mycotoxicosis is relatively lacking, although industry reports indicate that it is a problem for poultry. Corn contaminated with *F. verticillioides* reduced rate of lay and delayed peaks in production in broiler breeders and leghorns (113). Intermittent overconsumption and underconsumption of feed occurred with diarrhea, dark fecal droppings with undigested feed, fecal-stained eggshells, and blood smears on eggshells. Contaminated corn was high in moisture, low in protein, and high in crushing strength, which caused large particle sizes in the feed leading to maldigestion.

Experimental Disease
Moniliformin toxicity is similar in the chicken, turkey, quail and duck and causes cardiac toxicity, ascites, and nephrosis. Intoxication by purified moniliformin caused reductions of feed intake and weight gain, slowing of the heart rate, dyspnea and cyanosis. In combination with fumonisin, moniliformin caused sudden death that resembled spiking mortality of broilers, with decreased blood glucose (270, 271, 453). Moniliformin is more toxic than fumonisin and the interactive effects were additive (324). Hens tolerated moniliformin at concentrations toxic to younger birds (311).

Lesions at necropsy were enlargement of the heart, ascites, and digestive and cutaneous hemorrhages and edema (41, 106, 166, 226, 374, 548, 583). The heart developed various degeneration progressing to necrosis of the cardiac muscle (44, 45, 226, 369), which was partially alleviated by selenium. Kidney had nephrosis with mineralized casts. Liver developed vacuolation, swelling, and focal necrosis of hepatocytes; bile duct proliferation and fibrosis occurred with chronic intoxication.

Antibody to Newcastle disease vaccination was decreased, as were serum immunoglobulins and macrophage activity when in combination with fumonisin (329, 330, 446).
31.4. Diarrhea (A) and catarrhal enteritis (B) in broiler chickens fed cultures of *Fusarium moniliforme* that produced fumonisin B1.

Fumonisins

Etiology and Toxicology

F. verticillioides (*F. moniliforme*) also produces the fumonisins, which are the cause of equine leukoencephalomalacia (moldy corn poisoning) (343) and porcine pulmonary edema syndrome (109). Several fumonisins are produced (B1, B2, B3), but fumonisin B1 is the most common. Other species of *Fusarium* also produce fumonisins (167, 233). The toxicity of fumonisin B1 relates to disrupted sphingolipid synthesis (555).

Natural Disease

Fumonisin and aflatoxin contamination of feed for laying hens caused black adhesive diarrhea, reductions in feed intake, egg production, and body weight, lameness, and increased mortality (436). The diarrhea was reproduced in chicks and in laying hens with the suspect feed and with diets spiked with fumonisin.

Experimental Disease

Fumonisin B1 caused diarrhea, catarrhal enteritis (Fig. 31.4A, B), and impaired weight gain and feed conversion in turkey poults, broiler chicks, and ducklings (42, 59, 63, 167, 232, 307, 308, 309, 322, 556). Poults are more sensitive than chicks, but poultry are quite resistant to fumonisins in comparison to horses and swine. Although concentrations toxic to poultry are much higher than those likely to occur in grain (306), *F. moniliforme* produces other toxins that could influence the safety of these feedstuffs for poultry (557).

Lesions of experimental toxicity were consistent enlargement of the liver and variable enlargement of the kidney, pancreas, and proventriculus and gizzard; atrophy of lymphoid organs; and rickets. Histologically, the liver had multifocal necrosis of hepatocytes, hyperplasia of hepatocytes and bile ductules, and hypertrophy of Kupffer cells (43,44, 125). The intestine had villous atrophy and goblet cell hyperplasia. Rickets developed with growth plates widened in both the zones of proliferating and hypertrophied cartilage. Fumonisin B1 in combination with moniliformin caused lesions reflective of both toxins, including ascites, and enlargement of the heart, liver, kidney, and lung (272). Immune system changes included lymphoid depletion from the thymus, decreased mitogenic responses, decreased bacterial clearance, and toxicity to macrophages and lymphocytes (86, 140, 285, 329, 330, 445). Hemostasis and serum proteins were mildly affected (168).

Increased sphinganine:sphingosine ratios occurred in the liver with fumonisin B1 toxicity in chickens and ducks (42, 232). This parameter is a potential indicator of fumonisin B1 toxicity in humans, and ducks have become a model for studying this marker of exposure (527). Fumonisin B1 is metabolized by the liver and excreted in feces(125).

Hens tolerated relatively high concentrations of fumonisin B1 with only transient adverse effects during the laying cycle (311).

Quail fed fumonisin B1 as diets appended with cultures of *F. verticillioides* had intoxication of variable severity including mortality (21, 74, 127, 387). Reductions in growth rate and egg

production, and increased susceptibility to *Salmonella* infection occurred with chronic hepatotoxicity with bile duct proliferation.

Fusarochromanone

Etiology and Toxicology

Fusarium spp. also produce fusarochromanone, which causes tibial dyschondroplasia (TD) in chickens. Long bone deformities in broiler chicken have been induced by cultures of *F. moniliforme* and *F. roseum*, *F. equiseti* as well as *Aspergillus niger* and *A. flavus* (100, 342). *F. roseum* isolated from overwintered barley in Alaska caused tibial dyschondroplasia when fed to broilers (551). Defective chondroclasis was a possible pathogenic mechanism. Of six components identified, one of the fluorescent components, TDP-1 (fusarochromanone), induced a 100% incidence of TD when fed to broilers (325, 326).

Experimental Disease

Chicks fed fusarochromanone as cultures of *Fusarium* developed dyschondroplasia in the tibial growth plate in 4 days (229). Although the action of fusarochromanone at the cellular and biochemical level is unknown, increased dietary copper and zinc had a partial sparing effect (565). The hypertrophic cartilage had a lower density of chondroclasts (319), and the chondrocytes from the cartilage core have degenerative changes that were likely secondary to the increased distance from their vascular supply (230). Fusarochromanone was much less toxic than T-2 toxin to chondrocytes *in vitro* (564). *Fusarium* strains that produced fusarochromanone were also immunosuppressive (565, 566).

Zearalenone

Etiology and Toxicology

Grains infected with the fungus *Gibberella zeae* (*Fusarium graminearum*, *F. roseum* Graminearum) are a source of zearalenone, a mycotoxin with estrogenic activity. Of seven chemical forms, only zearalenone and zearalenol occur naturally. Although zearalenone is the most prevalent and most studied in poultry, zearalenol is more active estrogenically (360). Zearalenone occurs in corn, sorghum (114), wheat, barley, oats, milo, rye, and other grains (reviewed 489, 580). Toxicity occurs chiefly in swine as reproductive failure. Chickens tolerate zearalenone better than turkeys or swine and provide an outlet for grains unfit for swine (6, 170). Zearalenone is relatively nontoxic for chickens, but it has potential adverse effects and may be an indicator of other potentially toxins present.

Natural Disease

Zearalenone (0.5–5.0 mg/kg) was detrimental to broiler breeders that experienced a reduction in egg production; however, fertility, hatchability, or broiler performance remained normal (49). The hens had lowered serum progesterone, ascites, and cystic inflammation of the oviduct.

Experimental Disease

Studies of zearalenone mycotoxicosis in broiler and leghorn chickens, turkeys, quail, and geese indicate relative resistance compared to swine. Turkeys are the most sensitive, with repro-

ductive tract and sex hormone-sensitive tissues targeted. Japanese quail are resistant (28).

In leghorn chicks, bursa of Fabricius weight increased (94, 504,) possibly related to hormone-induced cloacal swelling in birds. Cysts developed on the peritoneal surface and within the oviduct. Broilers were highly tolerant of zearalenone, with lesions limited to decreased comb and testes weight (9), oviduct enlargement (94), and leukopenia. Male turkey poults displayed precocious strutting behavior and developed caruncles, dewlaps, and soft tissue swelling of the vent (8).

In leghorn hens, egg specific gravity, eggshell thickness, and interior egg quality were reduced (504). Serum calcium decreased and phosphorus increased (94). Feed contaminated with zearalenone and DON reduced feed intake and egg production (122). Other studies showed leghorns highly tolerant of zearalenone and of corn contaminated with *F. roseum* (6, 94, 345). A water-soluble component of *F. roseum* cultures containing neither zearalenone nor trichothecenes caused reduced hatchability (325). In geese, fertility was reduced and spermatogenesis was inhibited (409, 410, 411). Turkey eggs had reduced hatchability, but neither zearalenone nor trichothecenes were the responsible toxins (10).

Metabolism and Residues

Zearalenone was distributed chiefly to liver and gallbladder (361) and excreted in feces as zearalenone and zearalenol (394). Egg residues occurred only in yolk (119) or were not detected (122, 519).

Other Fusarium Toxins

Strains of *F. moniliforme* (now *F. verticillioides*) that produced fusaric acid (101) and fusarocin C (344) were immunosuppressive in chickens. Fusaric acid, although a mild toxin, was synergistic with fumonisin B1 in toxicity in a chick embryo assay (29).

Chicks fed *F. moniliforme* developed signs of thiamin deficiency and responded to thiamin therapy (174). Dietary thiamin concentrations were low, possibly due to the thiamin destruction or utilization by the mold in the feed. Fumonisin B1 contaminated feed associated with paralysis in quail, but clinical signs could not be reproduced in feeding trials (208). Aurofusarin produced by *F. graminearum* deteriorated egg quality (350).

Aflatoxins

Etiology and Toxicology

Aflatoxins are highly toxic and carcinogenic mycotoxins produced by *Aspergillus flavus*, *A. parasiticus*, and *Penicillium puberulum* (reviewed 157). Poultry feeds and ingredients are vulnerable to fungal growth and aflatoxin formation. Aflatoxins are relatively stable in normal food and feed products but are sensitive to oxidizing agents such as hypochlorite (commercial bleach).

The aflatoxins have two fused dihydrofuran rings with various moieties, and members are designated by their blue (B) or green (G) color reaction to fluorescent light and their chromatographic Rf values. Aflatoxin B1 is the most toxic, and hepatotoxicity is the primary effect in nearly all animals. Chronic aflatoxicosis
31.5. Lethal aflatoxicosis in turkeys caused liver discoloration from dark red (left), due to congestion and necrosis, to yellow (right), owing to fat accumulation in hepatocytes. Aflatoxin B1 (200 ppb) was detected in the feed.

results in neoplasia in many species, usually in the liver, but gallbladder, pancreas, urinary tract, and bone may be involved (reviewed 408). Although several aflatoxin metabolites are carcinogenic, aflatoxin B1 is most potent. It binds to nuclear and mitochondrial DNA and is a model hepatocarcinogen for mechanisms of tumor initiation in the liver (reviewed 250). It may also be active in promotion through oncogene activation, hormone alteration, and dietary interaction.

Aflatoxin-producing fungi and aflatoxin-contaminated animal feedstuffs are recognized worldwide (115, 245, 287, 383, 484, 489, 580), usually with adverse implications for poultry production (275, 276, 337, 368).

Natural Disease

Previous editions provide detailed descriptions of the first cases of aflatoxicosis (247, 422). Early accounts of aflatoxicosis in literature are now recognized to have significant contributions from cyclopiazonic acid and possibly sterigmatocystin and other toxins (52).

Lethal aflatoxicosis in ducklings occurred as inappetance, reduced growth (20), abnormal vocalizations, feather picking, purple discoloration of legs and feet, and lameness. Ataxia, convulsions, and opisthotonus preceded death. At necropsy, liver and kidneys were enlarged and pale. Chronic cases had hydropericardium and ascites, shrunken firm nodular liver, bile-distended

gallbladder, and hemorrhages. Microscopic lesions in the liver were fatty change in hepatocytes, proliferation of bile ductules, and extensive fibrosis, accompanied by vascular and degenerative lesions in pancreas and kidney.

Turkeys developed inappetance, reduced spontaneous activity, unsteady gait, recumbency, anemia, and death (491, 552). At necropsy, the body condition was generally good, but there was generalized congestion and edema. The liver and kidney were congested, enlarged, and firm; the gallbladder was full; and the duodenum had mucoid content. Lethal aflatoxicosis caused either dark red or yellow discoloration of the liver due to congestion or fat accumulation, respectively (Fig. 31.5). Microscopic lesions in livers were swollen hepatocytes with homogenous to vacuolated cytoplasm, karyomegaly, and focal necrosis of centrilobular hepatocytes. Chronic cases had hepatocyte regeneration, proliferation of bile ductules, and reticuloendothelial cell hyperplasia and degenerative lesions in the heart, kidney, and intestine.

Aflatoxicosis in chickens closely resembled that in ducks and turkeys (19, 20). The occurrence of skeletal myopathy (184) may have reflected an interaction of selenium and aflatoxicosis (see "Experimental Disease").

Aflatoxicosis occurs in poultry worldwide (4, 60, 98, 116, 214, 234, 281, 286, 314, 391, 435, 452, 451, 490, 498). The direct and indirect effects of aflatoxicosis include increased mortality from

heat stress (broiler breeders) (116); loss of egg production (leg-horns) (66); anemia, hemorrhages, liver condemnations (314), paralysis, lameness (391), and impaired performance of broilers (276, 454); nervous signs (4), and mortality (ducks) (66); impaired ambulation and paralysis (quail) (561); impaired immunization (turkeys) (231); and increased susceptibility to infectious disease in many species (66, 435). Cases of concurrent aspergillosis and aflatoxicosis confirmed that *Aspergillus* spp. threaten poultry production in the feed, litter, and environment (451, 490).

Experimental Disease

Aflatoxicosis impairs all important production parameters including weight gain, feed intake, feed conversion efficiency, pigmentation, processing yield, egg production, and male and female reproductive performance. Some influences are direct effects of intoxication, and others are indirect, such as from reduced feed intake.

Susceptibility of poultry to aflatoxins varies among species, breeds, and genetic lines. In general, ducklings, turkeys, and pheasants are susceptible; and chickens, bobwhite and Japanese quail, chukar partridge, and guinea fowl are relatively resistant (17, 210, 213, 264, 332, 473). Wide variation exists among breeds, with age and sex also being important (65, 110, 559).

Pathology

The pathology of experimental aflatoxicosis is similar to the naturally occurring disease. Acute intoxication in ducks caused pale, yellow-green discoloration, and atrophy of the liver, with the left lobe being more affected (380). Microscopic lesions chiefly involved hepatocytes as cytoplasmic vacuolation (fatty change) and massive necrosis, often accompanied by hemorrhage. Proliferation of bile ductules developed by the second day and progressed rapidly. Subacute lethal intoxication of ducks, especially those fed cultures of *A. flavus*, caused extensive necrosis and loss of hepatocytes and severe proliferation of bile ductules. In nonlethal aflatoxicosis, the liver had fatty change in hepatocytes, karyomegaly, numerous mitotic figures, and proliferation of bile ductules (246). Membranous glomerular lesions and interstitial fibrosis occurred in the kidneys of ducks and goslings (373). Figures 31.6A–C and 31.7A–C illustrate the histologic changes in liver and kidney.

Aflatoxicosis in chickens caused yellow, ocher discoloration of the liver, with multifocal hemorrhage and a reticulated pattern on the capsular surface. In time, the livers developed white foci as hepatic lipid content increased. Histologic lesions occurred as fatty vacuolation of hepatocyte cytoplasm; karyomegaly and prominent nucleoli in hepatocytes; proliferation of bile ducts; and fibrosis. Basophilic, vacuolated, regenerative hepatocytes, and inflammation by heterophils and mononuclear cells occurred in the portal zones (77, 246). Turkeys developed bile duct proliferation and nodular regeneration of densely eosinophilic hepatocytes that compressed adjacent parenchyma (246, 381). Vacuolar change and fibrosis were mild, even in turkeys that died following prolonged toxin ingestion. For these studies in chickens, no aflatoxin-related lesions were reported in either the kidney or major lymphoid tissues (373).

Clinical Pathology

Aflatoxin caused anemia characterized by reductions in the packed cell volume, erythrocyte count, hemoglobin concentration, and mean corpuscular volume (261, 317, 364). Iron absorption and retention initially decreased but then normalized (316). Young birds were more susceptible to anemia (317). Total leukocytes were increased, but with concurrent lymphopenia (317, 531).

Aflatoxin decreased total serum protein, lipoprotein, carotenoid pigment, cholesterol, triglycerides, uric acid, calcium, phosphorus, iron, copper, zinc, and lactate dehydrogenase (139, 171, 261, 532, 540). Serum sorbital dehydrogenase, glutamic dehydrogenase, and potassium were increased (117, 444). Ducklings were similar(379). In selected lines of Japanese quail, the degree of reduction in total protein and albumin and the degree of increase in ß-glucuronidase correlated with resistance to aflatoxin (426). Blood clotting time and ratio of aspartate aminotransferase to alanine aminotransferase were indicators of resistance in ducks (402).

Bruising is a problem during transport and slaughter of poultry. Aflatoxin promoted bruising by increased capillary fragility and reduced shear strength of skeletal muscle (401). It also impaired coagulation in chickens and turkeys by interfering with several coagulation components, notably prothrombin (138, 135, 530, 562). Aflatoxin altered coagulation more than either ochratoxin A or T-2 toxin, but the effects of ochratoxin A lasted longer (135, 260).

Nutrition and Digestion

Skin pigmentation is desirable for broilers in some markets. Aflatoxin impaired pigmentation in broilers by inhibiting intestinal absorption of carotenoid pigments and causing sequestration in the liver (476, 477, 534, 533, 535). The severity of aflatoxicosis was enhanced by a diet low in fat (216, 459), protein (401, 460), and riboflavin or vitamin D3 (215, 217), and by a diet high in tannic acid (121). Aflatoxin influenced calcium and phosphorus metabolism by altering the metabolism of vitamin D and parathyroid hormone (198); however, conclusions regarding the need for supplemental vitamin D3 in aflatoxicosis are equivocal (47, 58). In broilers, a deficiency of pancreatic amylase and lipase resulted in steatorrhea (399, 400), but laying hens were resistant. These variables make it difficult to establish minimum- or no-effect concentrations for aflatoxin in poultry feeds.

Reproduction and Egg Production

Mature Leghorn males experienced lowered semen volume, testis weight, and spermatocrits, and testosterone values, caused indirectly by reduced feed intake during aflatoxicosis (482, 483). Microscopic examination of sperm revealed abnormal spermatozoa and histologically, a cessation spermatogenesis in seminiferous tubules (396). Plasma testosterone concentration and responsiveness were lowered in maturing leghorn males (103). Broiler breeder males had reduced body weight and mild anemia but semen was unaffected (57, 570).

Loss of hatchability due to embryonic death was the most sensitive indicator of aflatoxicosis in broiler breeders and leghorns (111, 249), and was more sensitive than egg production (293).
31.6. Aflatoxicosis in ducks fed toxic peanut meal. A. Early liver lesion showing degenerative changes in parenchyma and bile duct hyperplasia. B. Nodular hyperplasia of liver parenchyma and bile duct hyperplasia are present. C. Kidney. Proximal tubules are dilated; epithelium is undergoing necrosis; and some nuclei have enlarged bizarre forms with prominent nucleoli (arrow).
31.6. Aflatoxicosis caused by purified aflatoxin B1. A. Duck, liver. Coarse vacuolar change (fatty degeneration) is most severe in centrilobular hepatocytes. B. Broiler chicken, liver. Coarse vacuolar change is most severe in periportal hepatocytes, with periportal heterophilic infiltration. C. Turkey, liver. Focus of hyperplasic, regenerative hepatocytes (left) compressing hepatocytes with vacuolar degeneration (right).

Egg production was spared despite mild hepatotoxicity, although once declined may require several weeks to return (169, 185, 267). Aflatoxin impaired egg production by reducing synthesis and transport of yolk precursors in the liver, with egg size and yolk parameters decreased (254). In Japanese quail, aflatoxin hepatotoxcity impaired of feed conversion, delayed maturation, and reduced egg production and egg quality (137, 405, 474, 393, 404).

Immunosuppression
Spontaneous aflatoxicosis is strongly associated with increased susceptibility to infectious disease (156, 430, 452). Experimental definition of immunosuppression is less conclusive and reflects the complexity of defining mechanisms of natural toxins. Experimental approaches include purified toxin alone or in combinations, crude cultures or culture extracts of a cloned fungal species, and naturally contaminated feeds or grains. Potential interactions of mycotoxins and dietary nutrients possibly influence the results and definition of an effect at a given concentration.

In chickens, aflatoxin increased susceptibility to, or severity of, cecal coccidiosis, Marek's disease (155), salmonellosis (497, 574), inclusion body hepatitis (471, 492), and infectious bursal disease virus (85, 501). Vaccination failures were linked to aflatoxicosis in chickens (14, 36, 442), and impaired response to vaccination responses was demonstrated for Newcastle disease, infectious bronchitis, infectious bursal disease, and fowl cholera

(25, 26, 67, 178). Turkeys experienced vaccination failure to fowl cholera and increased susceptibility to coccidiosis (428, 563).

Aflatoxin-induced immunosuppression accompanied atrophy of the bursa of Fabricius, thymus, and spleen (85, 429), regardless of the immune response genetics (536, 537). Aflatoxin was toxic for B lymphocytes in the late-stage embryo, and immune dysfunction was identified in progeny of broiler breeders exposed to aflatoxin (434, 445). In ducks, lesions in the lymphatic system accompanied abnormalities in circulating lymphocytes (495), lymphocyte depletion from the thymus, and reduced mitogenic responses of B and T lymphocytes (266). Clearance functions of blood phagocytes and the reticuloendothelial system were impaired (80, 79, 81, 357, 364), and serum complement activity was reduced in chickens (508). Cell-mediated immune responses decreased in both turkeys and chickens (192, 191, 190). Despite the previous explanations of aflatoxin-induced immunosuppression, other data show no measurable effect on immune response at aflatoxin concentrations higher than commonly encountered in feedstuffs (154, 190, 192, 191, 246).

Pharmacological Interactions
Aflatoxicosis can influence drug effectiveness by altering the drug plasma half-life. Ceftiofur serum concentration was lowered (12). Chlortetracycline plasma concentrations were lowered due to decreased drug binding to plasma protein (358). Conclusions

differed on aflatoxicosis being spared or worsened by the addition of chlortetracycline to feed (318, 499).

Metabolism and Residues

Poultry reared on diets contaminated with aflatoxin constitute a minimal aflatoxin threat to the human food chain. Aflatoxins distributed to edible tissues in low concentrations and cleared rapidly after nontoxic diets were provided. In broilers, metabolites of aflatoxins B1 and B2 concentrated in gizzard, liver, and kidney (87) but cleared in 4 days. Aflatoxin B1 metabolized into conjugated aflatoxins B2a and M1 in the liver (97), and further reduced to aflatoxicol (418, 419). Aflatoxin B1 was excreted in the bile, urine, and feces as 6 major metabolites (222). In turkeys, aflatoxin B1, M1, and aflatoxicol concentrated in liver, kidney, gizzard, and feces and rapidly cleared (205, 458). Selenium supplementation increased the percentage of conjugated aflatoxin and partially protected turkeys (70, 206).

The half-life of aflatoxin B1 in laying hens is about 67 hours (473), and the feed:egg transmission is about 5000:1 (392). Most aflatoxin excreted through the bile and intestine, but aflatoxin B1 and aflatoxicol were detected in ova and eggs for 7 days or longer (268, 528). Aflatoxin B1 accumulated in reproductive organs with transfer to eggs (both yolk and albumen) and hatched progeny (yolk sac and liver) in chickens, turkeys, and ducks (503, 582).

Ochratoxins

Etiology and Toxicology

Ochratoxins are among the most toxic mycotoxins to poultry. *Penicillium viridicatum* and *Aspergillus ochraceus* produce nephrotoxic ochratoxins on grains and feedstuffs throughout North America, Europe, and Asia (reviewed 152). Ochratoxins are isocoumarin compounds linked to L-b-phenylalanine and are designated A, B, C, and D, and their methyl and ethyl esters. Ochratoxin A (OA) is the most common and most toxic, and is relatively stable. Some ochratoxin-producing fungi produce other mycotoxins toxic to poultry, including citrinin. Ochratoxin is the major determinant in porcine endemic nephropathy, a chronic wasting disease that caused failure to thrive in bacon pigs in Denmark and Ireland (reviewed 296).

Ochratoxin A occurs in North America, Europe, and Asia in corn (489, 488), most small grains and in animal feeds (76, 224, 281, 529, 580). Ochratoxin A contaminated moldy grain in game bird feeders (386) and ingredients for chicken feed, including sorghum, peanuts, sunflower, rice bran, and millet (524), some co-contaminated with aflatoxin.

Ochratoxin A readily forms in poultry feed under conditions of high temperature and high moisture (27). Ochratoxin A was the predominant toxin in spontaneous disease, with ochratoxins B and C detected only with high concentrations of OA (219).

Natural Disease

Ochratoxin in pelleted feed colonized with *A. ochraceus* and *Penicillium* spp. caused mortality and failure to gain weight in broilers (5). At necropsy, lesions were pale discoloration of liver and kidney, and enteritis. Contaminated corn or corn gluten meal caused ochratoxicosis in broilers (219). Renal disease affected growth, feed conversion, and pigmentation, and chickens developed airsacculitis. Ochratoxin and aflatoxin were linked to fragile intestines that tore and contaminated carcasses with intestinal content at processing (540).

Slaughter inspection identified poultry with enlarged pale kidneys (164). Kidney had OA residues, atrophy and degeneration of proximal and distal tubules and interstitial fibrosis. Ochratoxin A residues were similarly linked to pale enlarged broiler kidneys at processing, but factors in addition to the mycotoxin were contributory (509).

Ochratoxin contaminated corn caused feed refusal and mortality due to nephrotoxicity and airsacculitis in turkeys (219). Histopathology confirmed nephrosis as renal edema and necrosis of proximal tubular epithelium.

Two episodes of ochratoxicosis in hens caused by contaminated corn occurred as nephropathy and reductions in egg production and shell quality (407). Chronic renal disease and diarrhea caused yellow stains on the eggshells, resulting in decreased market value. Experimental feeding of OA caused a diarrhea with high urate content and the eggshells had yellow stains.

Ochratoxin A occurred in moldy bread and flour (398), which are components of bakery by-product, a feed ingredient. Moldy bread contaminated with ochratoxins A and B caused enteritis in chickens (549). A hepatopathy in geese and broilers was associated with ochratoxin contamination of corn. Geese had hepatopathy, gout, and mild nephropathy, and broilers had severe hepatopathy. An additional unidentified toxin was likely involved, and ochratoxin was considered an indicator toxin (486).

Experimental Disease

Experimental OA mycotoxicosis causes primarily renal disease but also influences hepatic, immunologic, and hematopoietic functions and has significant interactions with other toxins and nutrients.

Pathology

Acute lethal OA mycotoxicosis in chickens caused pallor of the liver, pancreas, and kidney; swelling of the kidney; white urate deposits in the ureter; and visceral urate deposition (145, 179, 251, 253, 421). The main histologic lesion was acute tubular nephrosis with focal necrosis of tubular epithelium, proteinaceous and urate casts, and heterophilic inflammation. Some chicks developed cytoplasmic vacuolation and focal necrosis of hepatocytes, followed by fibrosis. Suppressed hematopoiesis occurred in the bone marrow, and lymphocyte depletion occurred in the spleen and bursa of Fabricius.

Subacute OA mycotoxicosis increased weight of liver and kidney and decreased weight of lymphoid organs in turkeys, ducklings, and chickens. Ringneck pheasants and Japanese quail were the most sensitive game birds (468, 469, 470). Lesions were pallor of the kidney and catarrhal content in the intestine (149).

The histologic lesions among these species were tubular dilatation and cast formation in the kidney (73, 149, 253, 341). Hyperplasia of tubular epithelium and interstitial inflammation accounted for the kidney enlargement. Thickening of glomerular

basement membranes was dose related. The liver had vacuolar change in hepatocytes, which was associated with increases in glycogen content of liver and skeletal muscle in chickens (149, 257, 554). In ducks, the hepatocyte vacuolation was due to lipid accumulation (73), and in Japanese quail, it occurred with bile duct proliferation (143). Ochratoxin was toxic to mitochondria in the proximal renal tubules and in hepatocytes (61, 73, 150, 523). Severe lymphocytic depletion occurred throughout the immune system. Ochratoxin caused intestinal fragility associated with decreases in collagen (553) and heterophilic inflammation in the intestinal lamina propria and muscular layers (150).

Broilers fed OA developed soft bones with an increased diameter of the tibia relative to body weight and decreased breaking strength (150, 255). The bone histopathology showed osteopenia with disturbed endochondral and intramembranous bone formation (147). Osteoid formation was defective, and osteoporosis developed. Changes in the diaphyseal cortices accounted for the reduced breaking strength.

Chronic ochratoxicosis in hens caused reduced renal function that correlated with mild histologic lesions of ongoing necrosis and regeneration of tubular epithelium (295, 428).

Clinical Pathology
Ochratoxin A caused microcytic anemia involving iron metabolism (30, 256) and leukopenia (24, 82, 84). Coagulation disorders and decreased clotting factors occurred at OA concentrations too low to affect growth (145, 438, 134). Serum biochemical changes reflected damage to the kidney and liver (84, 262, 297, 475), as well as skeletal muscle, pancreas, and bone (163); and renal function was reduced (253, 295, 515).

Nutrition and Digestion
Experimental ochratoxicosis confirmed field observations of feed refusal by turkeys and leghorn hens but not broilers (68, 69, 441). Ochratoxin A impaired utilization of dietary carotenoids for carcass pigmentation (252, 475). The toxicity of OA was enhanced by vanadium and tannic acid (297, 300, 298). Combined exposure to OA and aflatoxin caused a synergistic reduction of growth and feed performance of broilers (546).

Reproduction and Egg Production
Ochratoxicosis in leghorn pullets delayed and blocked sexual maturity (99). The reluctance of hens to eat feed contaminated with ochratoxin caused reductions in body weight, egg production, and egg weight (438, 441). Ochratoxin reduced egg size, interior quality, and shell specific gravity at concentrations too low to influence the number of eggs produced (525). Japanese quail breeders experienced reductions of fertility and hatchability due to early embryonic death (439). In chickens, hatchability was reduced by embryonic mortality due to embryonic gout, and progeny had reduced growth (99, 384). Ochratoxin A was teratogenic for chicken embryos (193).

Immunosuppression
The immune system is a primary target of OA, seen as generalized atrophy and lymphocytic depletion of all lymphoid organs (72, 149, 292, 433). Ochratoxin A impaired cell-mediated immunity in broilers and turkeys (151, 493) and humoral immunity in broilers (148, 162). Other indicators of OA immunosuppression were impaired phagocytic activity of chicken heterophils and macrophages (83, 433); impaired vaccination responses (160); and increased severity of concurrent coccidiosis (259), salmonellosis (221, 211), and colibacillosis (312). The converse also applies, in that the renal lesions were more severe in broilers with coccidiosis (511).

Metabolism and Residues
Dietary OA distributed chiefly to the kidney with lesser concentrations to liver and muscle (180) Ochratoxin A was rapidly eliminated from chickens with a half-life of about 4 hours. Liver and kidney are the tissues of choice to monitor for residues (48, 356), and residues occurred in the absence of renal lesions (295). Residues persisted for 4 days or less when toxic diets were replaced (200, 440). Ochratoxin A distributed to egg yolk and albumin (175), which accounted for reductions in hatchability. Concentrations of OA in eggs had low correlation to dose, and several studies detected no OA in eggs (295, 438). In Japanese quail, OA was distributed to liver, kidney, proventriculus, and ovary and excreted in bile and in urine (176).

Citrinin

Etiology and Toxicology
Penicillium (102) and *Aspergillus* (reviewed 455) produce citrinin, a natural contaminant of corn, rice, and other cereal grains. *Penicillium citrinum* occurs mainly in Canada and northern Europe (reviewed 580), suggesting toxigenic *Penicillium* may have a competitive advantage in cooler climates. First purified as a yellow crystalline compound from *P. citrinum* in 1931, recognition of antibacterial and antibiotic properties preceded the discovery of nephrotoxicity. Citrinin was one of the causes of yellow rice mycotoxicosis in Japan and linked to porcine endemic nephropathy, which also involved ochratoxin. Citrinin is heat sensitive.

Natural Disease
Penicillium lanosum, which produced citrinin in culture, was isolated from broiler feed in a house in which the litter was wet and chickens were substantially smaller than expected at slaughter (37, 377). Fungal cultures fed to broiler chicks caused watery fecal droppings and reduced weight gain. At necropsy, kidneys were swollen, and the gizzard lining was discolored and fissured. Histopathologic changes in kidney were swelling and pyknosis of tubular epithelial cells. *P. lanosum* was also isolated from mycotic lesions in the gizzard lining.

Experimental Disease
Citrinin is nephrotoxic and causes diuresis in poultry (199, 212, 341). Removal of the toxin allows a return to normal renal function. Citrinin acts directly on the kidney to increase urine flow rates and free water clearance with increases in sodium, potassium, and inorganic phosphate excretion (197, 239).
31.8. Experimental acute lethal citrinin mycotoxicosis in a chicken. The kidneys are swollen (352).

31.9. Kidney from a chicken fed oosporein for 3 days. The renal cortex has necrosis of proximal tubules (62).

Pathology

A single dose of citrinin was nephrotoxic to chickens, turkey poults, and Peking ducklings, with turkeys being the most sensitive. Watery fecal droppings and increased water consumption accompanied swollen kidneys and histologic lesions of epithelial degeneration and necrosis in the proximal and distal tubules (352, 353) (Fig. 31.8). The liver had variable necrosis of hepatocytes, hemorrhage, and proliferation of bile ductules. Lymphocyte necrosis and depletion occurred in major lymphoid tissues, most prominent in ducklings (354, 351). Subacute to chronic toxicity in ducklings reduced weight gain and dose-related nephropathy with degeneration, necrosis, mineralization, and regeneration of tubular epithelial cells in cortical and medullary regions, interstitial inflammation, and fibrosis. Ultrastructural lesions in leghorn chicks showed that citrinin targeted epithelium in the proximal tubules (61).

Laying hens fed citrinin-appended diets developed wet droppings, but egg production and body weight were not affected (13).

The histologic evidence of lymphocytic depletion is suggestive of potential immunosuppression; however, citrinin had no effect on humoral or cell-mediated immunity at nephrotoxic doses in broilers (75).

Clinical Pathology

Penicillium citrinum-contaminated corn containing citrinin caused anemia and leukopenia in leghorn chicks (462). Hyperkalemia, metabolic acidosis, reduced blood pH, and base excess occurred during intoxication (351).

Metabolism and Residues

Citrinin fed to broilers was detectable only in the blood and liver (378). Citrinin fed to laying hens for 6 weeks distributed to skeletal muscle, egg yolk, and egg white (1).

Oosporein

Etiology and Toxicology

Oosporein is a red, toxic, dibenzoquinone metabolite of *Chaetomium* spp. and in poultry it causes high mortality from gout (107, 424). Oosporein originally was extracted from *Oospora colorans* (reviewed 578). *Chaetomium* spp. isolated from numerous feeds and grains, including peanuts, rice, and corn, are highly toxic in both plant and animal bioassays.

Natural Disease

Oosporein mycotoxicosis in both North and South America occurred as nephrotoxicity, gout, and mortality (578).

Experimental Disease

Pathology

Experimental oosporein mycotoxicosis in young chickens and turkeys caused visceral and periarticular urate deposition (gout) related to impaired renal function and elevated plasma uric acid (339, 340, 423, 424). Chickens fed oosporein for 3 days had necrosis of the proximal tubules in the renal cortex (62) (Fig. 31.9). Chickens were more sensitive to oosporein than turkeys. Water consumption increased and fecal droppings became fluid. Corn cultures of *Chaetomium*-producing oosporein were more

toxic to chickens than the purified organic acid of oosporein. Sodium and potassium salts of oosporein were more toxic than the organic acid, and their existence in cultures and naturally contaminated grains explained apparent enhanced toxicity (340).

Acute lethal doses of oosporein in chickens and turkeys caused dehydration, swollen pale kidneys, and extensive visceral gout (424, 425, 576). The liver was mottled and had focal necrosis, and the gallbladder was distended with bile. The proventriculus had an enlarged circumference; the mucosa was covered with exudate; and necrosis occurred at the isthmus. The gizzard lining and intestinal contents were discolored green.

Visceral gout is less pronounced or absent in subacute intoxication, but periarticular gout (white uric acid deposits in the joints) is apparent. Histologic lesions in the kidney occurred as proximal tubular nephrosis with periodic acid Schiff-positive granules in the macula densa (60). Interstitial granulomas around urate deposits in the kidney were common. Chicks that survived had renal lesions of interstitial fibrosis, hyperplasia of proximal tubular epithelium, and dilation of centrilobular distal tubules. Glomeruli were atrophic in fibrotic areas and enlarged in normal areas.

Oosporein reduced both feed consumption and egg production at doses capable of inducing nephrotoxicity and gout (576).

Clinical Pathology

Oosporein intoxication of broiler chickens had no hematological effect. Plasma uric acid concentrations were elevated in chickens and turkeys, and serum chemistry changes were generally reflective of renal toxicity (424, 425, 576).

Other Mycotoxins

Cyclopiazonic Acid

Cyclopiazonic acid (CPA) is a metabolite of *Aspergillus flavus*, the predominant producer of aflatoxin in feeds and grains. Some features of turkey "X" disease in the United Kingdom in 1959, notably enteritis and opisthotonus, were not fully accountable to aflatoxin and are explained by the presence of CPA, which was identified in stored samples from the original episodes (52, 108). Ten of 45 strains of *A. flavus* isolated from feed produced both CPA and aflatoxin in culture (347). The toxin is also produced by *Penicillium* spp. and is a contaminant of meats, outer portions of cheeses, peanuts, corn, and millet (315, 320).

In chickens, CPA affected weight gain and feed conversion, and caused mortality (141). It had additive toxicity with aflatoxin and T-2 toxin (305, 496). Lesions occurred in the proventriculus, gizzard, liver, and spleen. The proventriculus lumen was dilated, and the mucosa thickened by hyperplasia and ulceration (188). Mucosal necrosis occurred in the gizzard. Liver and spleen contained numerous yellow foci of necrosis and inflammation. Lymphocyte depletion from the thymus and spleen involved apoptosis (282, 545).

The reproductive tract of male broiler breeders was impaired (514).

Cyclopiazonic acid residues occurred in chicken muscles at 14% of an oral dose, 48 hours after dosing (385), and in eggs, with higher concentrations in albumen (142).

Sterigmatocystin

Sterigmatocystin, a biogenic precursor to aflatoxin B1, is hepatotoxic and hepatocarcinogenic. It occurs less commonly than aflatoxin and is associated with visibly moldy products (432). Sterigmatocystin is produced on small grains, coffee beans, and cheese by *Aspergillus versicolor* and other *Aspergillus* spp., *Chaetomium* spp., and other cereal fungi, with detection in North America, Europe, and Japan (reviewed 580). Sterigmatocystin is less toxic than aflatoxin but produced in higher concentrations (479).

Sterigmatocystin mycotoxicosis occurred in laying hens fed commercial crumbled feed colonized with *A. glaucus* and containing sterigmatocystin (5). Feed intake and egg production decreased, and brown-shelled eggs were pale. At necropsy, the livers were pale, fatty, and contained hemorrhages.

Experimental sterigmatocystin mycotoxicosis in Leghorn chicks affected liver, pancreas, lymphoid organs, and kidney (505, 506). Histologically, the liver had congestion and hemorrhage, and necrosis of periacinar hepatocytes accompanied by heterophils. Pancreas had cytoplasmic vacuolation from zymogen-granule loading in exocrine cells. Lymphocyte necrosis and depletion occurred in lymphoid organs. Kidney had mild degeneration and necrosis of tubular epithelium. Serum chemistries reflected target organ injury, and there was leukopenia.

Sterigmatocystin caused reduced embryonic weight, malformations, and mortality in chicken embryos (479). In combination with a low dose of aflatoxin, adverse changes occurred in poultry meat and in hematological parameters (2).

Rubratoxins

Rubratoxins A and B are hepatotoxic mycotoxins produced by *P. rubrum* and *P. purpurogenum* and were recognized before aflatoxicosis was defined (reviewed 560). In 1958, an investigation of poultry hemorrhagic syndrome yielded these fungi from feed and litter of affected chickens (172). It is noteworthy that *A. flavus* and *P. citrinum*, producers of aflatoxins and citrinin, respectively, were also studied (173). Chicks fed cultures of *P. rubrum* and *P. purpurogenum* developed bloody diarrhea. At necropsy, hemorrhages occurred in muscles and viscera, and erosions and free blood were in the proventriculus and gizzard.

Purified rubratoxin (20% A, 80% B) however showed relatively low toxicity for chickens (567). Acute lethal intoxication produced congestion and hemorrhages. Dietary rubratoxin impaired growth and caused liver enlargement and atrophy of the bursa of Fabricius. Hemoglobin, serum protein, and serum cholesterol decreased and capillary fragility increased.

Penicillic Acid

Penicillic acid, discovered in 1913, is a metabolite of numerous species of *Penicillium* and *Aspergillus* (reviewed 258) and is potentially important to poultry because of high concentrations in corn and poultry feed. Penicillic acid has low toxicity for broilers, and purified toxin had minimal effect when fed solely at concentrations likely to occur naturally. Growth and feed conversion were affected however when fed with low doses of aflatoxin (2).

Tenuazonic Acid and Alternaria Toxins

Tenuazonic acid, a metabolite of *Alternaria* spp., has a spectrum of biological effects (reviewed 189). Investigations of poultry hemorrhagic syndrome revealed marked toxicity by an isolate of *Alternaria* (173). *Alternaria* spp. grow on corn and other commodities and also produce alternariol, alternariol methyl ether, and altertoxin (reviewed 580). Tenuazonic acid had moderate toxicity for broilers and Leghorns. Acute lethal intoxication induced hemorrhages in skeletal muscle, heart, and subcutis. Subacute intoxication also caused hemorrhages, and erosions occurred in the gizzard lining.

Tenuazonic acid-producing cultures of *Alternaria longipes* were highly toxic to chicks and caused hemorrhages in the proventriculus and erosion of the gizzard lining (144, 500).

Patulin

Patulin is a mycotoxin produced by several species of *Aspergillus*, *Penicillium*, and *Byssochlamys*. Patulin-producing *Penicillium* spp. were isolated from chick starter feed (102, 333). Patulin had relatively low toxicity for chicks but produced sequential lesions of watery crop content, acute ascites, and hemorrhage in the lumen of the proventriculus, gizzard, and intestine. Growth was suppressed when fed in combination with low doses of aflatoxin (2). Hens fed patulin produced misshapen eggs with reduced calcium content in the shell (1).

Other Mycotoxins and Toxigenic Fungi

Kojic acid was mildly toxic to liver and kidney, and caused anemia in broilers but only at concentrations higher than would be likely encountered in feed and there were no significant interactions with aflatoxin (194, 195). Tremorigens, slaframine, and other toxigenic fungi examined for toxicity in poultry, including *Diplodia maydis*, *Phomopsis leptostromiformis*, *Helminthosporium maydis* Race T, and uncharacterized metabolites of *Penicillium citrinum*, were reviewed in a previous edition (247).

Diagnosis

Diagnosis of a mycotoxicosis begins with the assessment of the clinical history and signs. The onset of a problem may coincide with the delivery of new feed. Contaminated equipment for transportation, milling, and feeding can be the source of intermittent or chronic toxin exposure. Clinical signs and lesions caused by mycotoxins are not pathognomonic. For example, oral lesions are cited as evidence of trichothecene mycotoxins (T2-toxin), but similar lesions are caused by high concentrations of fines (small particles) in the feed (118, 370), copper sulfate, quaternary ammonia disinfectants, candidiasis, and hypovitaminosis A.

A definitive diagnosis of mycotoxicosis involves identification and quantification of specific toxins. This is difficult in modern poultry production because of the rapid and high volume use of feed and ingredients. The rather limited analytic capability of diagnostic laboratories (403) and the biochemical complexity of finished feeds are additional factors. Analyses for aflatoxin and zearalenone are readily available, but analyses for ochratoxins, zearalenol, DON, T-2 toxin, DAS, ergot alkaloids, and citrinin are less so. Confirmation of other trichothecenes, cyclopiazonic acid, sterigmatocystin, rubratoxin, or less common mycotoxins, especially in feeds, is possible in relatively fewer laboratories.

Analytic techniques for mycotoxins include chromatography (thin-layer, gas, liquid), mass spectrometry, and monoclonal antibody-based technology that use enzyme-linked immunosorbent assay (ELISA) technology. ELISA test kits should be used for validated applications as interfering substances in ingredients and feeds may give inaccurate results. Some assays are standardized and validated for grain and certain other ingredients but not for finished feeds, which can be a variable substrate for extraction and analysis. The black light evaluation of grains for *A. flavus* growth is an acceptable presumptive test for aflatoxin but does not confirm actual toxin (51). Numerous bioassays are defined for mycotoxin screening tests, but positive test results are presumptive.

Laboratory personnel should be consulted before sending samples, as laboratories differ in the capabilities to conduct screening and confirmation tests for mycotoxins. Identification of mycotoxin residues in blood or tissues is possible but not routinely available (238). An ELISA test for confirmation of aflatoxin in liver showed high sensitivity and specificity and would complement diagnostic investigation (186).

If a mycotoxicosis is suspected, a complete diagnostic evaluation is desirable in addition to feed analysis. A flock rarely experiences a single disease stress and other diseases may be occurring in concert with mycotoxins to affect production adversely. A suspected mycotoxicosis may not be confirmed by feed analysis; however, a complete laboratory evaluation can exclude other significant diseases (248). Birds that recently died and those obviously sick should be selected for submission.

Moldy feed appears unwholesome and indicates the potential for mycotoxin formation. It can be unpalatable and have reduced nutritive value, with vitamins, amino acids and the energy level of fats affected (68, 34, 35, 366, 461). *Aspergillus*, *Penicillium*, and *Fusarium* are mycotoxin-producing fungal genera that occur in most poultry feeds, so the potential is clearly evident (368).

Feed and ingredient samples should be properly collected and promptly submitted to a feed testing laboratory for analysis. Mycotoxin formation may not be uniform in a batch of feed or grain, and multiple samples from different sites, including areas with caked or moldy feed, increase the likelihood of confirming a mycotoxin formation zone (hot spot). Sampling is usually the largest source of variability associated with a mycotoxin test procedure (558). Samples should be collected all along the chain of ingredient storage, feed manufacture and transport, feed bins, and feeders within poultry houses. Fungal activity increased as feed moved from the feed mill to feeder pans (277) and was associated with an increase in fines and higher zinc concentrations.

Samples of 500 g (1 lb) should be collected and submitted in separate containers. Clean paper bags, properly labeled, are adequate. Sealed plastic or glass containers are appropriate only for short-term storage and transport because grain rapidly deteriorates in airtight containers. A written record of sample collection and the application of labels directly to specimen containers (not the lids) help to ensure sample integrity.

Rapid on-site screening tests for several mycotoxins (aflatoxin, T-2 toxin, DON, fumonisin, ochratoxin, and zearalenone) are available in monoclonal antibody-based detection kits. Grain can be screened for potential aflatoxin contamination by examination for green fluorescence under a black (ultraviolet) light to estimate the degree of *A. flavus* contamination. The presence of aflatoxin, however, must be confirmed by a chromatographic procedure (minicolumn technique) or other suitable method.

Treatment

Toxic feed should be removed and replaced with unadulterated feed. Poultry generally recover from most mycotoxicoses soon after an uncontaminated diet is available. Treatment of ongoing parasitic or bacterial diseases will alleviate additive or synergistic interactions. Substandard management practices are especially detrimental to poultry stressed by mycotoxins and should be corrected. Vitamins, trace minerals (especially selenium), protein, and lipid requirements are increased by some mycotoxins and can be compensated by feed formulation and water-based treatment. Increasing the crude protein, dietary energy, and vitamin supplementation can counteract the effects of aflatoxin (3, 46, 277). Dietary amendment with either sunflower or soybean oil alleviated some effects of aflatoxin (450). Vitamins E and C partially counteracted the toxicity of T-2 toxin and ochratoxin A in chicks (3, 240, 269).

Another strategy for treatment of mycotoxicoses in the presence of contaminated feeds involves specific nutrients that metabolize to form detoxicants (375, 431). Supplemental methionine and N-acetylcysteine counteracted aflatoxin likely through the enhancement of glutathione formation (128, 294, 542).

Prevention

Although overt intoxication by mycotoxins is relatively uncommon, contamination of feedstuffs by fungi capable of producing mycotoxins is quite common. Many mycotoxins described in this chapter have subclinical effects on hatchability, shell quality, immunosuppression, and processing parameters, at toxin concentrations too low to register as diagnostically significant. Preventing the insidious effects of mycotoxins by an integrated program to prevent mycotoxin formation and inhibit the effects of mycotoxins already formed can substantially benefit poultry health and production.

Feed Manufacturing and Management

Prevention of mycotoxicoses centers on using mycotoxin-free feedstuffs and feed manufacturing and management practices that prevent mold growth and mycotoxin formation. This ideally involves access to analytical capability to confirm the purchase of ingredients free of mycotoxins, or at least, the type and degree of contamination so that risk can be assessed and addressed. Proper storage of ingredients, and feed processing, shipping, and handling procedures are necessary to minimize mycotoxin formation. A quality control program can monitor success of these practices (521).

Manufacturing and maintaining feed of low moisture (11–12%), keeping the feed fresh, and maintaining clean feed handling equipment are key control points in preventing mold growth (382). Mycotoxins form in decayed, crusted, built-up feed in feeders, feed mills, and storage bins (218). Regular inspection of feed bins identifies flow problems like feed separation, central feed-down, and feed bridging (526), which enhance fungal activity and mycotoxin formation. Temperature extremes cause moisture condensation and migration in bins and create high-risk situations for mycotoxin formation (577). Bin inspection and cleaning between flocks to certify absence of feed residue are a practical control point. Tandem feed bins on farms allow cleaning between successive feed deliveries. Minimizing feed residence time on the farm is important, even under cool, dry conditions (202). Adequate ventilation of poultry housing to reduce relative humidity removes moisture available for fungal growth and toxin formation in feeders (276). Selection of feeder equipment that minimizes surface-area contact with feed diminishes mycotoxin formation (278).

Pelleting feed destroys some fungal spores (520) and generally decreases the fungal burden. Pelleting is made further effective by the addition of an antifungal agent.

Antifungal Agents

Antifungal agents added to feeds to prevent fungal growth have no affect on toxin already formed but may be effective with other feed management practices. Regulatory approval of these various compounds in feeds differs among countries. Organic acids are effective against *Fusarium*, *Aspergillus*, and *Penicillium*, in order of declining susceptibility (132, 235, 280). The effectiveness of organic acids may be influenced by ingredient particle size and buffering by certain ingredients (133, 131). Organic acids are generally corrosive and irritating to skin, but some have been modified to counteract this (417). Other agents showing efficacy in reducing fungal growth or mycotoxin formation include phosphates (tetrasodium pyrophosphate and alkaline sodium polyphosphate) (321), spice oils and extracts (146, 227, 502), and ammonium hydroxide (187). Gentian violet (88, 289) and thiabendazole (177) are effective but no longer approved for use in the United States for animal feeds. Copper sulfate is a poor mold inhibitor for poultry feeds (120). Other antifungal strategies include controlled storage atmospheres, irradiation, and fumigation (328).

Detoxification with Binding Agents

Detoxification using mycotoxin-binders holds promise for using contaminated feeds while preventing intoxication (reviewed 431). Inorganic mineral adsorbents or binders including various clays, soils, and zeolites can be part of an integrated approach (302, 335, 336, 388, 389, 390, 395). Zeolites are silica-containing compounds that are practical and economical feed additives that can reduce the effects of aflatoxin and cyclopiazonic acid (32, 153, 225, 323) but not T-2 toxin, DAS, or ochratoxin A (263, 303, 310, 472, 183). The adsorbent activity is shown by a number of zeolitic ores (225, 346, 395, 397) and bentonite clay (284, 355, 550). Further processing of silicate-type binders may

increase their efficacy for protection (304). Adsorbents can counteract mycotoxins but vary in efficacy and in the correlation of *in vitro* and *in vivo* testing (64)

Polyvinylpolypyrrolidone, a synthetic binder, diminished the toxicity of aflatoxin for chickens (78, 290).

Progress continues in the development and application of organic detoxification compounds. Esterified glucomannan, a cell wall derivative of yeast used in beer fermentation, *Saccharomyces cerevisiae*, was protective against aflatoxin and ochratoxin in broilers (449, 507, 283) and showed moderate binding activity for fumonisins, zearalenone, and T-2 toxin (128). Esterified glucomannan is generally protective against naturally contaminated feed containing multiple toxins (18, 449, 516). Some products are combinations of enzyme detoxicants and binders, and nutrient supplements (123, 130). Other organic natural compounds are under investigation and show some potential (449, 510, 512).

Other methods of prevention include ozone treatment of grain, which reduced aflatoxin contamination (348). Ammoniation was effective in decontaminating feeds and grains for aflatoxin (413), and composting contaminated corn with poultry litter was effective in detoxifying aflatoxin (279). Certain cultures of *Lactobaccillus* prevented aflatoxin absorption from the small intestine (161). Superactivated charcoal (fine particle size) had marginal or no binding activity for aflatoxin or T-2 toxin (158). Long-term efforts to prevent mycotoxin exposure involve developing grain-producing plants that resist fungal infection, reduce the toxic effects of the mycotoxins, and interrupt mycotoxin biosynthesis (104).

Public Health Significance

The history of mycotoxicoses contains many accounts of food poisonings, including ergotism, alimentary toxic aleukia and related syndromes caused by trichothecenes, and yellow rice poisoning (reviewed 38). Most grains used as feedstuffs for poultry and livestock are also ingredients for human food and carry the same risks for fungal growth and mycotoxin contamination. In addition, foods such as coffee, tea, spices, and dried fruits support fungal growth and toxin formation. Surveys of foodstuffs are ongoing worldwide and document toxin contamination at moderately high prevalence but usually at low concentrations. Coffee (331), wheat, cereal grains, and flours (165, 478), spices (406), and rice (415) are typical foods from which ochratoxin and trichothecenes and other fusarial toxins can be detected. Peanuts are closely monitored for aflatoxin and cyclopiazonic acid (371, 513).

Poultry products present low risk for human toxin exposure because mycotoxins have minimal distribution to skeletal muscle, the major form of poultry consumption. Mycotoxin distribution to liver, kidney, and eggs is of greater concern. Mycotoxins are rapidly metabolized and excreted in urine or feces. Residues in liver and kidney are generally transient and in low concentrations relative to the exposure dose. Chronic exposure to mycotoxins causes changes in color and size of liver and kidney, a visible indicator for rejection from the food chain at slaughter. In modern production, mycotoxin exposure of poultry is somewhat self-limiting because the adverse economic effects make prevention of exposure important.

In the United States, the Food and Drug Administration (FDA) has an action level of 20 parts per billion (ppb) for aflatoxin in foods (which would include poultry and eggs) and 0.5 ppb for aflatoxin M1 in milk (15). The FDA has a guidance level of 2 to 4 parts per million for fumonisins for corn products intended for food (16). Because of the global nature of food production and international movement of grains and food commodities, international standards and surveillance are important. Broadening the safety net to prevent mycotoxin exposure in the food chain requires international cooperation for safety, risk assessment, action levels, and advisories (414).

Chapter 32
Other Toxins and Poisons

Richard M. Fulton

Introduction

Paracelsus recognized more than 400 years ago that it is "the dose that makes the poison." Although that may be obvious with known toxic materials, it is also true for more benign products such as growth promotants and chemotherapeutic agents usually considered safe. Deliberate or inadvertent overdosages may cause illness, and a misplaced decimal in water or feed medication frequently results in toxicity. A general feature of modern complex poultry rations, feed mill equipment, and feed delivery to poultry farms is that any component included in a ration will at some time be mistakenly included at a higher than desired rate. This may occur through human or mechanical error. Furthermore, when toxicoses do occur, they are added to the pre-existing background of complicating infectious agents, vaccine administrations, and environmental exposures. This usually leads to multi-factoral mixed clinical presentations of toxic, infectious, environmental, and management diseases, rather than "pure" toxicoses. Additionally, some primary highly pathogenic infectious or environmental diseases of poultry will present such rapidly elevating mortalities that acute toxicoses are suspected incorrectly.

For example, sulfaquinoxaline poisoning occurs in meat-type chickens, even at recommended doses, because of high water intake in warm buildings, particularly in hot weather, or because of poor feed mixing. Disease may also be caused by toxic levels of some nutrients (e.g., excess dietary sodium causes significant losses in chickens and turkeys around the world). High levels of vitamins A and D are toxic. Some compounds have differential species or age toxicities, and others have increased toxicity in naive animals with no previous adaptative exposure. Ionophore anticoccidials commonly exhibit such differential adaptive resistance to toxicity. Furthermore, waterfowl are sensitive to some drugs at a dose safe for chickens and turkeys. The immune system seems to be affected by many toxic agents. In addition to disease caused by poisons, the problem of residues in eggs and meat must also be considered. For information on drugs approved in the United States, withdrawal times, and drug and chemical residues, see Booth (31), www.fda.gov/cvm/greenbook.html, www.compasnac.com, or the current Feed Additive Compendium. In rationalizing withdrawal times in egg-laying chickens, it must be remembered that compounds begin to be deposited in chicken egg yolk 10 days before that egg is laid.

Poisonous substances are widely distributed in nature. Mycotoxins, covered in the previous subchapter, are important to the poultry industry, but toxic agents are also produced by bacteria (botulinum toxin, methylmercury, toxic amines) or occur naturally (selenium, phytotoxins). Pesticides, herbicides, and other synthetic chemicals, metals such as lead, and industrial contaminants add to the list of toxic materials. Many chemicals and human drugs have been given to birds in feed and water to study their toxic effects. These experimental toxicities generally have not been included in this chapter, except as they may relate to potential naturally occurring or iatrogenic poisonings in poultry.

Poisons and toxins are not major causes of production loss or disease in poultry in most countries, although some, such as lead, pesticides, and botulism, are significant in wild birds. In 1985, Terzic and Curcic (318) reported, however, that 40% of 2065 poisoning cases seen at the Belgrade Veterinary Facility during a 17-year period were in poultry. In 2005, Sharpe and Livesey (288) reported that 1.4 % of 876 poisoning cases of food safety concern that were seen at the Veterinary Laboratories Agency in England and Wales were in poultry, most of which were lead poisoning in waterfowl. Poisoning occurs more frequently in free-range and backyard flocks and in village poultry where birds forage in neighboring gardens and fields or receive household waste and weeds cut from roadsides and fields. Some of these poisonings are malicious. Contaminated litter on the floor and in nest boxes is an added source of toxins in chickens not raised on wire. Because suspected toxicity cases are more likely to be submitted to a diagnostic laboratory than are other sick birds, statistics collected from that source may not be an accurate indication of the incidence of poisoning compared with other disease.

Toxicants covered in this chapter are presented by primary use. Levels of toxic substances that may cause depressed growth in broilers and turkeys or decreased egg production in layers are summarized in Table 32.1.

Antimicrobials, Anticoccidials, and Growth Promotants

Most reports of poisoning with chemotherapeutic agents involve inappropriate use or overdose of ionophore anticoccidials or growth promotants. Toxicity of a variety of chemotherapeutic agents in poultry and pigeons has been reviewed (266, 267).

Sulfonamides

Sulfonamides were used as the primary form of prevention and treatment for coccidiosis in poultry between the early 1940s and late 1950s. Sulfaquinoxaline and sulfamethazine were most

Table 32.1. Levels in feed (unless otherwise noted) of selected toxins documented to decrease growth rate in broilers and turkeys and reduce egg production in layers.

Toxin	Broilers	Turkeys	Layers
Antimicrobials and Growth Promotants			
Sulfadimethoxine (% in water)	NA[a]	NA	0.05
Sulfaquinoxaline (%)	NA	NA	0.10
Nicabazine (mg/kg)	NA	NA	70
Arsanilic acid (mg/kg)	1000	400	NA
Nitarsone (mg/kg)	300	600	NA
Roxarsone (mg/kg)	90	550	NA
Nutrients and Other Feed- and Water-Related Toxicants			
Aluminum (%)	0.30	0.30	0.15
Arsenic (inorganic pentoxide) (mg/kg)	40	40	40
Boron (mg/kg)	435	435	870
Boric acid (mg/kg)	2500	2500	5000
Cadmium (mg/kg)	400	400	8-60
Copper (mg/kg)	500-1000	500-1000	1000
Fluoride (mg/kg)	1300	1300	1300
Iodine (mg/kg)	500	500	300
Iron (mg/kg)	200-2000	200-2000	NA
Lead (acetate) (mg/kg)	630	630	630
Mercury (mg/kg)	50	50	5
Molybdenum (mg/kg)	200	200	200
Potassium (%)	0.90	0.90	NA
Selenium (mg/kg)	5	5	80
Sodium (%)	0.80	0.80	0.80
Sodium chloride (%)	2.0	2.0	2.0
Tungsten (mg/kg)	1000	1000	1000
Vanadium (mg/kg)	6	6	20-30
Zinc (mg/kg)	NA	NA	20,000
Other			
Ammonia (ppm)	**50**	**25**	**75**

widely used. The toxic level of sulfonamides is close to the therapeutic level in poultry, and even the therapeutic level has a detrimental effect on hemopoietic and immune systems. Previous low-level or continuous-preventive medication has a protective effect against subsequent higher doses (96).

Sulfonamides are difficult to mix evenly in feed, and they have low solubility in acidic water. These characteristics may cause some birds to receive a toxic dose even when appropriate treatment levels are added to bulk rations or water supplies. This is less likely at lower preventive levels. Both feed and water medication require accurate estimates of daily consumption if each chicken is to receive a therapeutic and nontoxic daily dose. Sulfa poisoning has occurred when no allowance was made for increased water and feed consumption of the modern broiler that eats to its physical capacity rather than to its metabolic need, or, more frequently, for the effect of increased water consumption at high environmental temperatures or in hot broiler houses. For broilers, previous authors of this chapter recommended one-half of the therapeutic dose, and at temperatures greater than 27°C (81°F), one-third of the therapeutic dose for water medication. Repeat treatment is

hazardous and should not be recommended without a postmortem examination of a subset of individuals to make sure that there is no evidence of sulfa toxicity. Even the newer so-called safe sulfas need to be used with care (61, 267). Under no circumstances should sulfas be given simultaneously in both the feed and water. Decreased solubility in acidic water may lead to delayed clearance of sulfas from water lines and result in detectable drug levels in meat and eggs beyond published withdrawal times.

Hemorrhagic syndrome, which occurred frequently when sulfas were in widespread use, is a manifestation of sulfa toxicity and occurs at and above therapeutic dose levels. In addition to blood dyscrasia, bone marrow depression, and thrombocytopenia, sulfonamides depress the lymphoid system and immune function in birds. Similar but more dramatic hematologic manifestations and diatheses are seen in domestic mammals given sulfa-containing poultry rations or water medications. Focal bacterial granulomas are often found in tissues and organs of chickens dying from sulfa poisoning. Epithelial necrosis and degeneration in the liver, kidney, and other organs may be caused by the direct effects of the drug, or hypoxia secondary to drug-induced

anemia. When determining withdrawal times in chickens whose eggs reach the human food chain, deposition in the yolk 10 days prior to the production of an egg must be considered (29).

Signs

Chickens and turkeys with sulfa toxicity are depressed, pale, and frequently underweight. In adults, there is a marked decrease in egg production and shell quality; brown eggs may be depigmented (68, 242). Secondary bacterial infections including septicemia and gangrenous dermatitis may follow sulfonamide toxicity (61).

Pathology

For descriptions of gross and microscopic pathology, see references 61, 68, and 97.

Hemorrhage in skin, muscles, and internal organs is the most consistent and extensive gross lesion of sulfonamide intoxication. Hemorrhage may be present in comb, eyelids, face, wattles, anterior chamber of the eye, and musculature of breast and thighs. Normal dark-red bone marrow in growing birds changes to pink in mild cases and yellow in severe cases. The entire length of the intestinal tract may be spotted with petechial and ecchymotic hemorrhages, and the cecal lumen may contain blood. Hemorrhage may be present in the proventriculus and beneath the ventriculus (gizzard) lining. There may be ulcers at the proventricular-gizzard junction. The liver is swollen, pale red, or icteric and may be studded with petechiae or foci of necrosis. The spleen is commonly enlarged, has hemorrhagic infarcts, and contains gray nodular areas. "Paintbrush" ecchymotic hemorrhages occur in the myocardium. Thymus and bursa of Fabricius are small.

Microscopically, areas of caseous necrosis surrounded by a mantle of giant cells occur in liver, spleen, lungs, and kidneys. Lymphocyte and heterophil infiltrates are present at the periphery of necrotic foci. Lymphoid hypoplasia around splenic sheaths, edema and fibroplasia of the capsule, and macrophages containing hemosiderin are common. Early changes in the liver are periportal mononuclear infiltration associated with bile duct hyperplasia. Hemosiderin deposits are present in necrotic areas, and thrombosis of portal vessels is present. An early change in kidneys is interstitial lymphocytic infiltrate, but this may be associated with concomitant infections. Degeneration and necrosis of tubular epithelium are associated with hyaline casts. Glomeruli are enlarged, and Bowman's capsule is dilated with hyaline material. Lungs are congested with interlobular and interstitial edema. Interstitial tissues contain mononuclear foci. There is degeneration and necrosis of lymphocytes and depletion of bursal follicles.

In femoral bone marrow, there is decreased intrasinusoidal erythropoiesis with thrombocytopenia and agranulocytosis, focal increase in extrasinusoidal lymphopoiesis, and, in some instances, myelopoiesis. There are also focal areas of hyalinization, necrosis, and fibroplasia. Hemosiderin deposits and extrasinusoidal edema are present.

Nitrofurans

Nitrofuran use is no longer permitted in some countries. Prominent signs of nitrofurazone (NFZ) toxicity in chicks include depression, incoordination, ruffled feathers, and growth retardation (242). Poor growth may be partially related to feed aversion, because feed consumption drops as the level of NFZ increases. Ducklings on toxic levels of NFZ die suddenly without clinical signs. Nervous signs and hyperexcitability have been described in acute toxicity in chicks and poults. Loud vocalization, opisthotonos, aimless running and flying, and convulsions may be seen. Acute nervous signs of NFZ toxicosis disappear within hours after supplying unmedicated feed and water. Chronic exposure to furazolidone also may reversibly delay sexual maturity in male broiler breeder chickens (10, 299).

Furazolidone (FZ) toxicity mainly affects the heart in turkeys, ducks, and chickens (58, 213). Marked individual and age susceptibility to FZ occurs. Some poults, chicks, and ducklings grow well without cardiac damage when fed 400–700 mg FZ/kg feed; whereas others fail to grow, develop ascites, and signs associated with heart failure. Frequency and severity of clinical signs are dose related. Recovery occurred in affected ducklings (334). There also is clinical evidence that FZ may cause nervous signs in chicks and poults and infertility in male breeders (266).

FZ causes dose-related biventricular cardiomyopathy with prominent dilation of ventricles and thinning of either the right or left ventricular wall. Secondary heart failure results in passive congestion with lung edema, or marked congestion of liver and other organs, and ascites depending on whether heart failure is mainly left- or right-sided. Right-sided heart failure with marked cardiac enlargement is usually more common up to 3 weeks of age (167).

In turkeys, FZ-induced cardiomyopathy cannot be distinguished from spontaneous turkey cardiomyopathy (STC). The cause of STC is not known, but clinically it is associated with rapid growth, low serum protein, and stressors such as low incubator oxygen, poor ventilation, and fumes from brooders, which might induce ischemic cardiomyopathy. The mechanism of how high doses of FZ cause dilatory cardiomyopathy is not known (127).

Most microscopic lesions result from heart failure. Cardiac lesions include edema, thinning of myocardial muscle fibers, and multifocal myocytolysis with increased connective tissue. Epicardial fibrosis and endocardial fibroelastosis may also occur. Ultrastructural changes include myofibrillar lysis, clumps of Z-band material, and increased glycogen in myocardial fibers. Changes in heart muscle enzyme levels accompany tissue alterations.

Aminoglycoside Antibiotics

After subcutaneous injection, gentamicin (an aminogylcoside) causes depression in turkey poults, edema and hemorrhages at the injection site, and large, pale, and nephrotic kidneys (25, 276). Aminoglycosides and various other antibiotics used for egg inoculation have caused embryo mortality. Streptomycin and dihydrostreptomycin sulfate injected intramuscularly for sinusitis in turkey poults causes respiratory distress, paresis, and mild convulsions (266, 267).

Ionophore Antibiotics

Ionophores (ion carriers) facilitate movement of some monovalent cations, such as sodium and potassium, and divalent cations

such as calcium and magnesium across cell membranes. They can have both anticoccidial and antibacterial activity, and the group is used extensively in poultry and ruminant feeds. Ionophores are coccidiocidal because of their ability to preferentially move ions, usually Na+, into various stages of the parasite.

Toxic levels of ionophores cause potassium to leave and calcium to enter cells, particularly myocytes, resulting in cell death. Signs of toxicity are related to high extracellular potassium and high intracellular (intramitochondrial) calcium. For more specific information on metabolism and toxicity of monensin, see references 31, 81, and 234. Ionophore toxicity varies with species and age; equidae are very susceptible, and adult poultry, particularly turkeys, are more susceptible than broilers (130, 151, 288). There is a synergistic effect with antibiotics in the same family of drugs (323) and increased toxicity with nonrelated antibiotics, other drugs (33, 39, 80, 185, 246, 252, 266), and low-protein rations (267). Dehydration because of diarrhea or periods of water and/or feed deprivation can precipitate toxic events (46, 124). Monensin, lasalocid, salinomycin, and narasin have been associated with toxicity in poultry, guinea fowl, quail, and other species (64, 124, 132, 204, 255, 283, 288, 336). Lethal toxicoses have been described in equidae, and other mammals accidentally exposed to ionophore-containing poultry rations. Poultry have an adaptative resistance to dietary ionophores, and an inverse age sensitivity, with adult naïve poultry being more susceptible than young previously exposed birds.

Signs

Signs vary from anorexia with depression, weakness, and reluctance to move to complete paralysis in which birds lie in sternal recumbency with neck and legs extended. Less severely affected birds may show posterior paralysis with legs extended. Dyspnea has occurred in affected adult turkeys (Fig. 32.1). Signs are associated with muscle damage. Death may follow respiratory failure or be secondary to dehydration. Mortality is variable but may exceed 70% (102). In some cases of suspected ionophore toxicity in turkeys, morbidity may be low with only a few poults paralyzed. The term *knockdown syndrome* has been used for this condition (46). Poults with botulism may show similar signs. Reduced egg production (336) and fertility with weak chicks also have occurred (247).

Pathology

Subchronic monensin toxicity (329) resulted in opaque fibrin plaques on the epicardium, hemorrhage in coronary fat, and decreased liver weight. In acutely affected turkeys, pallor and atrophy of mainly type I fibers of legs and back have been observed associated with monensin use (24, 250, 328). However, clinical signs and gross lesions are often absent in breeders ingesting high levels of monensin (102).

Microscopic changes in heart and skeletal muscle consist of scattered areas of hyalinization with muscle necrosis and myofiber degeneration and necrosis. Birds with respiratory signs often have lesions in tracheal muscles. Type I fibers appear to be selectively affected (132). Heterophils, macrophages, and occasionally lymphocytes may be present. Frequently, when exposed

32.1. Acute ionophore toxicity. Dyspnea and drooping wings are suggestive of heat stress. (Barnes)

to low doses or interaction with other drugs occurs, affected areas are very cellular with large numbers of satellite or sarcolemmal nuclei, indicating regeneration is occurring (Fig. 32.2). Ultrastructural changes have been described (323). Peripheral neuropathy characterized by edema, demyelination, and axonal degeneration accompanied by marked hypertrophy and hyperplasia of neurilemmal cells may be seen with lasalocid toxicity (124).

Differential Diagnosis

Because there is a marked individual, age, and species variation in susceptibility, and the toxic effect may be potentiated by other drugs, normal levels of ionophore should not be dismissed if clinical signs and histologic changes indicate ionophore toxicity. High serum or plasma levels of muscle enzymes may be useful in differentiating ionophore toxicity from botulism (223). Ionophore toxicity also must be distinguished from vitamin E/selenium deficiency and *Cassia (Senna)* ingestion, which may produce similar signs and lesions.

Other Anticoccidials

3,5-dinitro-*o*-toluamide (dinitrotolumide, dinitolmide, DNOT, Zoalene, Zoamix) can cause ataxia, torticollis, incoordination, and reduced growth (165, 242, 266). Nicarbazin (Nicarb) can make broiler chicks listless, dull, and ataxic; in older birds, there can be reduced egg production, shell depigmentation, yolk mottling, and reduced hatchability (18, 164, 191). Nicarbazin depresses growth rate at 150 mg/kg feed. Even when used at recommended levels, nicarbazin increases metabolic rate and heat production (20, 266, 342). This makes older broilers more susceptible to heat stress and pulmonary hypertension syndrome. Generally, there are no gross lesions, but there may be hepatic and renal epithelial degeneration (242, 267). Nitrophenide (Megasul) has caused nervous signs but with rapid recovery (242). Ducks, geese, and chukar partridges may have depressed growth and mortality from halofuginone (Stenorol) (21, 96), and reduced skin strength has been found in chickens (122, 208). Use of *t*-butylaminoethanol may result in reduced growth due to choline deficiency.
32.2. Muscle from a young turkey with knockdown. Minimal muscle necrosis and inflammation along with increased sarcolemmal or satellite cell nuclei indicate regeneration.

Antiprotozoals

Organic arsenicals and imidazoles such as dimetridazole (Nitrazol, Emtryl), used for histomoniasis, have caused growth depression, drops in egg production, nervous signs (ataxia, incoordination, tremors), convulsions, and death in geese, ducks, pigeons, and turkeys (266, 267, 270). Waterfowl may be poisoned by doses safe for other poultry. Quinacrine HCl (Atabrine), used for *Haemoproteus* infections in pigeons, was fatal at a dose of approximately 50 mg/kg.

Organic Arsenical and Imidazole Feed Additives

Phenylarsonic acids such as arsanilic acid (*p*-amino-benzene arsanilate) and sodium arsanate, roxarsone (3-nitro-4-hydroxyphenylarsonic acid), and nitarsone (4-nitrophenylarsonic acid, Histostat-50) are used to improve feed efficiency in livestock. *p*-Ureidobenzenearsonic acid (Carb-o-sep, Carbarsone) and dimetridazole (1,2-dimethyl-5-nitroimidazole, Nitrazol, Emtryl) are used for prevention and control of histomoniasis.

Toxicity occurs with accidental or deliberate overdose or in dehydrated animals or birds (234). Peripheral neuropathy causing lameness in turkeys developed after they were given twice the recommended level of 3-nitro-4-hydroxyphenylarsonic acid (349). Toxicity, with liver lesions suggestive of inorganic trivalent arsenite, occurred in broilers receiving 10 times the recommended dose of this same growth promotant. Lesions may have resulted from degradation and reduction of the organic product to the trivalent state, or, more likely, from biliary excretion of inorganic arsenic present as a contaminant (287). Cysteine exacerbates toxicity, perhaps by reducing the arsenical to the more toxic trivalent state.

Signs

Ataxia and incoordination usually are seen, but stunting and depression also may be prominent signs. Lameness may be evident in turkey poults.

Pathology

Gross changes may be absent, although affected birds are usually small with an empty digestive tract. Microscopically, peripheral nerves may show loss of myelin, fragmentation of axons, and proliferation of neurilemmal cells (267, 271). Ulcerative cholecystitis occurred in turkey poults (38).

Anthelmintics

All anthelmintics are probably toxic if a sufficient overdose is given, but generally birds are more resistant than mammals to anthelmintics.

Benzimidazoles

Cambendazole, mebendazole, and fenbendazole are well tolerated by birds (273).

Imidazothiazoles

Levamisole and tetramisole are not quite as safe as benzimidazoles. The lethal dose—50% (LD_{50}) of tetramisole for chickens—is 2.75 g/kg. Geese and captive birds are more susceptible (273) with a fatal dose for captive kiwis between 25 and 43 mg/kg (116); 300 mg/kg is toxic for geese and as little as 66 mg/kg of levamisole is toxic for some wild birds. Anthelmintic activity of *dl*-tetramisole resides in the *l*-isomer (levamisole), so the effective dose of levamisole is half that of tetramisole. This doubles the safety margin. Tetramisole is no longer available in most countries. Levamisole poisoning has occurred in geese being treated for *Amidostomum* infection (355). Levamisole was toxic for ducks parenterally at 40 and 80 mg/kg (129). Microscopic lesions in kiwis killed by levamisole were similar to those of mammals consisting of pulmonary congestion, edema, and bronchopneumonia and severe periacinar cytoplasmic vacuolation of hepatocytes (116).

Organophosphates

Organophosphorus compounds have caused poisoning in birds eating treated feed intended for horses (155, 201). The resin pellet form of dichlorvos (DDVP) is toxic because it is retained in

the gizzard. Colored breeds of chickens are more susceptible than white breeds to coumaphos, and naphthaphos has a narrow safety range for chickens, with 50 mg/kg being fatal (273).

Ivermectin

Ivermectin has a wide safety margin in birds. An oral or injectable dose of 0.1 mg/kg has been suggested (273). Ivermectin is effective against a wide range of parasites. Zeman (356) tried 1.8 mg/kg for *Dermanyssus gallinae.* This dose was more effective in chickens weighing more than 450 g. The toxic dose for chickens is 5.4 mg/kg, which causes 4-hour somnolence; 16.2 mg/kg, which causes 24-hour listlessness and ataxia; 48.6 mg/kg results in death 5 hours postinjection. Canaries given 20–60 mg/bird IM showed temporary immobility.

Other Anthelmintics

Phenothiazine is relatively nontoxic for birds, and hygromycin B is safe at 8 g/900 kg feed (273).

Nutrients and Other Feed- and Water-related Toxicants

Amino Acids

Interaction among some amino acids relate to growth, but only methionine is toxic to poultry. Methionine toxicity affects chickens and quail (174, 286) and has caused depressed growth and cervical paralysis in turkey poults (128). Mortality can occur at levels of 1.8% in feed. Methionine attenuates calcium-induced kidney damage (341). Ethinone (a methionine antagonist) toxicity in chicks can be relieved by methionine.

Antinutrients

A variety of feed stuffs and potential feed stuffs are poorly digestible, contain factors that inhibit digestion (protein inhibitors), depress growth, cause pasting of feces, or increase the incidence of skeletal disorders. Antinutritional factors in some of these products (e.g., soybean and some other beans) can be destroyed by heat. The nutritional value of some feedstuffs (e.g., wheat, barley, and rye) can be improved by enzymes (34, 114, 153, 163). Antinutrients that can be found in plants include proteases, tannins, saponins, antivitamins, lectins, b-glucans, pentosans, polysaccharides, concanavalin A, hemagglutinins, vicine, convicine, alkaloids, and sinapines. Feedstuffs known to contain antinutrient factors are alfalfa (166, 322), amaranth (4), jackbeans (77, 194, 231), fababeans (233, 277), lima beans (230), narbon beans (87), soybeans (166, 196), jojoba (13), lupins (35, 248, 275), peas (36), vetch (276), barley, rye, wheat (19, 34, 209), and sorghum (316).

Protein Supplements

Fish and Meat Meals

Gizzerosine, histamine, histidine, and other biogenic amines cause digestive disturbances, stunting, and osteoporosis (152, 313). Biogenic amines result from heating or bacterial spoilage of fish and animal byproducts. Toxic products get into poultry feed through fish or meat meal. Excess acid secretion in the proventriculus is stimulated by gizzerosine, causing gizzard ero-

sion and hemorrhage (148, 216, 273). Broiler chickens may die from hypovolemic shock. Black ingesta and blood may run from the mouth (*vomito negro*), and the contents of the digestive tract are often melanic. Other biogenic amines reduce broiler feed efficiency (177).

Minerals

For information on trace mineral deficiency and toxicity (tissue levels, signs, etc.), see references 259 and 260. Information on poultry in these references is included for the following minerals: aluminum, arsenic, cadmium, calcium, chloride, chromium, cobalt, copper, fluoride, iodine, iron, lead, magnesium, manganese, mercury, molybdenum, nickel, phosphorus, potassium, selenium, sodium, tungsten, vanadium, and zinc. More detailed information on macro and trace mineral deficiencies and excesses are reported in Chapter 29, "Nutritional Diseases."

Aluminum

Aluminum depressed growth rate in chicks, due to decreased feed intake, and decreased egg production in adults when 0.3% was added to the feed (30, 351). Aluminum also may interfere with phosphorus retention (85, 92, 157) and iron absorption resulting in anemia (131). Aluminum absorption after ingestion may be affected by the acidity of the ration (45).

Calcium

Excess absorbed calcium is excreted through kidneys; high levels cause ureter and kidney impaction, resulting in nephrosis. Very young birds are most susceptible. This condition may be produced in pullets by feed delivery mistakes where layer ration is accidentally fed to pullets. High mortality from hyperuricemia with visceral urate deposits may result from kidney damage because of high dietary calcium. Lung pathology with damage to parenchyma from calcium deposits may also occur in young chicks. It is possible that nephrosis and visceral urate deposits in young and dead-in-shell chicks may result from kidney obstruction by calcium. Excess unabsorbed calcium remaining in the intestine increases fecal water content of pullets and hens on high calcium rations. If the source of calcium is dicalcium phosphate, the alkaline solution formed in the upper digestive tract may result in epithelial necrosis (239, 242, 332), particularly if the mineral has been "top-dressed" on feed, and birds eat undiluted material.

Urolithiasis in pullet and layer flocks may be caused by high calcium and low phosphorus in pullet rations. The incidence may also be increased by infectious bronchitis virus infection (120).

Cobalt

Moderate levels (125 ppm) stimulate polycythemia and induce pulmonary hypertension. Higher levels (500 ppm) cause marked tibial dyschondroplasia, and necrosis and fibrosis in the pancreas, liver, and skeletal, smooth, and cardiac muscles. All levels reduce feed intake and growth (73).

Copper

Copper sulfate is added to water for treatment of enteritis or yeast infection or to clean algae or scum from water lines and drinkers.

Addition to feed is another method for treating enteritis and candidiasis. It also may be sprayed on litter to control *Aspergillus* or used as an antifungal preparation on wood. Birds occasionally are poisoned by eating copper sulfate crystals. Diets low in calcium may increase susceptibility to copper toxicity (189). Mortality in turkeys offered water containing copper sulfate may have resulted from dehydration caused by water refusal, rather than from copper poisoning. Toxicity signs are depression and weakness with convulsions and coma terminally (242) or anemia (140, 234, 271). Gross lesions include necrosis of proventriculus and gizzard epithelium with sloughing of koilin lining (117, 144).

Fluoride
Growth, production, and egg quality were reduced by 700 and 1000 mg sodium fluoride/kg feed (125). Leg deformity has also been described. Laying birds can tolerate ingesting 4.453 mg fluoride/day for up to 74 weeks (53).

Iodine
Reduced egg production and weight and increased embryonic mortality in the first week and at pipping occurred when 350 ppm of iodine was added to the ration of turkey breeder hens (51). With experimentally induced iodine toxicity in chickens, researchers found that clinical signs were poor growth and a bizarre syndrome of chicks falling over, lying motionless, getting up, and then repeating falling over (16).

Magnesium
Excess magnesium causes bone abnormalities by replacing calcium and affecting phosphorus utilization (190).

Phosphorus
Excess phosphorus affects growth plate development of bones and increases tibial dyschondroplasia and leg deformities. Phosphate may also be caustic to moist oral and epithelial surfaces. White phosphorus induces mortality and hematologic abnormalities after oral ingestion (306, 307).

Potassium
Potassium in the form of fertilizer or potassium permanganate is toxic. The latter causes epithelial necrosis of the digestive tract (242).

Sodium (Sodium Chloride, Sodium Bicarbonate)
Excess ionic sodium, usually from sodium chloride in feed or water, causes significant economic losses in poultry in many countries. Most toxicity results from consuming saline water; not water deprivation. Sodium in feed can be toxic for young chicks and poults with or without water deprivation. In some cases of toxicity at apparently low salt levels, analysis may have been for chloride, with salt level calculated from chloride level. When Na^1 toxicity is suspected, both feed and water should be analyzed for Na^1; not estimated from chloride content. There may be sources of Na^1 in feed or water other than sodium chloride. Levels of Na^1 in feed and water are additive. Sources of sodium may also be naturally occurring in soil or water (210).

Young birds are much more sensitive to Na^1 toxicity than are adults, probably because their kidneys are not yet fully developed (211). Water with Na^1 greater than 0.4% (4000 ppm) is quite toxic and will cause high mortality within a few days. Lower levels may be toxic as well, depending on the amount of Na^1 in feed. Levels of Na^1 greater than 0.12% (1200 ppm) are toxic for some chicks and poults and produce heart failure with edema and ascites. Feed with Na^1 greater than 0.85% is toxic for some chicks and poults. Much lower levels will cause heart failure and ascites even when water is available freely. Because steroids increase Na^1 and water retention (285), resulting in hypervolemia, hypertension, right ventricular failure, and ascites, stress may also contribute to Na^1 susceptibility. Birds have poor renal concentrating ability and difficulty reducing plasma osmolality by excretion of salt in excess of water. Some waterfowl have nasal salt glands, which allow them to excrete Na^1 if an excess is ingested.

Three forms of disease result from Na^1 toxicity in young birds. At high levels, birds develop acute, severe diarrhea and dehydration, lose weight, and die. There is often acute kidney damage, particularly with sodium bicarbonate (212), which may be ischemic because of increased red blood cell rigidity. Potassium may have a protective effect (301). At lower levels, loose droppings also occur, but birds gain weight, at least for 1–2 days, because of associated water retention. Depending on the Na^1 level, they may subsequently eat less and grow poorly, or continue to eat and grow well. Water retention, with hypervolemia and reduced red blood cell deformability (214), can lead to functional cardiac overload, causing marked right ventricular hypertrophy and dilation, valvular insufficiency, edema, and ascites in chicks (168, 169, 215). At intermediate levels of excess sodium, a variety of clinical signs and pathologic changes are seen, depending partly on how long birds survive with hypertension before heart failure occurs and how long they survive afterward. Many lesions described for Na^1 can be attributed to heart failure. The severity of ascites may be affected by other dietary, environmental, and water constituents (279, 297).

Signs. At low levels of excess Na^1, only watery droppings are seen until ascites occurs. At this stage, chicks and poults are dyspneic, depressed, and have a swollen abdomen. At high Na^1 levels, birds are obviously sick and depressed within a few hours, with thirst and diarrhea. They may have rough, dirty, wet feathers or down. Nervous signs may be present, and some birds may be prostrate. At intermediate levels, stunting of some birds may be prominent. Excess Na^1 may cause reduced egg production and increased mortality in adults (65).

Pathology. Chicks with ascites and edema frequently have excess fluid in lungs and hydropericardium. Young males may have cystic dilation of seminiferous tubules (271). There is cardiac hypertrophy, which in chickens is mainly right-sided. Poults have biventricular hypertrophy with dilatory cardiomyopathy. At levels of Na^1 causing dehydration, the following also may be seen: cyanosis, myocardial hemorrhage, nephrosis, and enteritis.

Microscopic lesions are frequently secondary to heart failure or dehydration. For a detailed description of histologic lesions,

see reference 217. Glomerulosclerosis (285, 301) may be ischemic in origin. Ultrastructural changes in heart muscle (232) include glycogen accumulation, myofibrillar disarray, Z-band streaming, and disruption of intercalated discs.

Sulfate

The toxic concentration of sulfate is affected by age of the birds, source (water or feed), other salts, etc., and is not clearly defined. Magnesium sulfate may be more toxic than sodium sulfate (325). Diarrhea, reduced growth, and depressed egg production can occur.

Selenium

Some plants accumulate selenium (347), and the addition of acceptable treatment levels of selenium to rations already containing high normal selenium levels may produce toxicosis. This often manifests itself as embryo deformities of the eye, head, or beak in the progeny from such breeder flocks (228). Decreased growth and feed intake resulted when there was 4–8 ppm selenium in drinking water (44), but the toxicity of selenium varies with the form present (149). Selenium can accumulate in the food chain of aquatic birds causing emaciation, hepatitis, and ascites (123).

Zinc

Toxic levels of zinc (>500 ppm) cause anorexia, depressed growth, reduced egg production, gizzard and pancreatic lesions, and hematologic abnormalities (66, 70, 175, 198, 202, 300, 343). Individual birds may be poisoned by ingesting metallic zinc, such as coins or other objects, or galvanized wire from caging in the case of pet birds (268) and in wild waterfowl via contaminated mining areas (300).

Metals and Metalloids

Arsenic

Inorganic, aliphatic, and trivalent organic arsenicals are used as pesticides, weed and brush killers, and defoliants. Toxic effects include diarrhea, nervous signs, and cyanosis. There is inflammation of the digestive tract including crop, proventriculus, and gizzard, hepatosis, and nephrosis (234, 287). Most reports of arsenic toxicity in birds are experimental, except those associated with grasshopper bait (242). For information on organic arsenicals, see "Antimicrobials, Anticoccidials, and Growth Promotants."

Cadmium

Toxic levels of cadmium found in industrial waste and sewage sludge cause decreased feed intake, decreased growth, induced kidney lesions, and reduced gonadal mass and function (154, 257, 259, 260, 340). Experimental cadmium toxicity in chicks, poults, and ducklings and free radical-induced lesions by cadmium, silver, and other minerals have been reported (25, 60, 324).

Chromium and Potassium Dichromate

Chromium from industrial waste or coated metal objects may cause depression, anorexia, and paralysis (154, 259, 260).

Lead

All species of birds are susceptible to lead poisoning. Lead is the only metallic poison causing significant disease in birds, and most toxicity occurs in wild species, especially waterfowl. Chickens are more resistant than waterfowl (259, 260). Birds as a group are at risk from metallic lead because the material is retained in the gizzard, ground down, and absorbed slowly. Experimental poisoning trials with chickens show an interaction with some nutrients (82, 167), production of immunotoxic effects with differential gender sensitivity (40), inhibition of avian bone healing (177), and immunosuppression (354).

Lead is widespread in the environment, and there are many possible sources for ingested lead when toxicity occurs. Wild water birds are at greatest risk from ingesting lead shot or contaminated sediments (150), which is the main hazard in North America (282) and elsewhere (139). Lead weights from fishing lines are the most important source in England. Pigeons may also ingest lead shot (69). Birds that eat carrion may be poisoned by lead shot ingested with tissues. Backyard and free-range poultry may pick up lead from paint chips, lead batteries, or other lead objects. Chicks have been poisoned by eating contaminated grit (242). Cage birds may be poisoned from the same environmental sources as children and dogs—mainly paint chips, leaded windows, toys, and lead objects (353).

Signs. Most lead poisoning in birds is chronic. Clinical disease usually is seen as wasting, ataxia, lameness or paralysis, and anemia. In acute cases, anorexia, weakness, prostration, and anemia may be prominent. Green diarrhea may result from anorexia, or it may be a direct effect of lead on digestive and nervous systems.

Hematology. Basophilic stippling and abnormal erythrocytes may occur in lead-poisoned birds but are not present in all affected birds (Fig. 32.3) (242). Finding anemia with mitosis of erythrocytes and large numbers of immature cells may be more significant.

Pathology. Most lesions probably result from anorexia and debility. Emaciation may be prominent, but many ducks and geese that die from lead poisoning are in good body condition. The carcass may be pale with watery blood. Erosion and ulceration of the gizzard lining can be extensive (Fig. 32.4). Impaction of proventriculus frequently is seen and is likely secondary to vagus nerve damage (Fig. 32.5).

Microscopically, the most diagnostic lesions are demyelination of peripheral nerves and focal areas of vascular damage in the cerebellum (156), and acid-fast, intranuclear inclusion bodies in the kidney (Fig. 32.6), liver, and spleen (199, 242, 271). Inclusions are composed of protein-bound lead and can be demonstrated by special staining or electron microscopy (Fig. 32.7) (227). Nephrosis with degeneration and necrosis of tubular epithelial cells containing brown pigment have been described. Hemosiderosis is prominent in the spleen and other organs. Scattered myocardial necrosis associated with hyaline or fibrinoid necrosis of blood vessels (172), arrested mitotic activity in proventricular epithelial cells, and degenerative changes in testes also may be found (206).
32.3. Duck with lead poisoning. A. Immature erythrocytes and two cells showing basophilic stippling. (Barnes) B. Basophilic stippling in an erythrocyte adjacent to an immature erythrocyte undergoing mitosis. (Barnes)
32.4. Gizzard from duck with lead poisoning. Severe erosion, ulceration, and bile staining of koilin lining. Note 2 lead pellets retrieved from the gizzard. (Barnes)

32.5. Lead poisoning, showing distended proventriculus (arrow); there were 15 leads shot in the gizzard.

1239
32.6.   Lead poisoning. Acid-fast intranuclear inclusion bodies (arrow) in kidney of mallard duck. ×480 (Locke)

32.7.   Proximal renal epithelium from a bird with lead poisoning. Nuclei contain irregular, variable electron-dense inclusion bodies typical of lead accumulation in kidney. Similar inclusions may be present in the liver. (Shivaprasad)

Diagnosis. The final diagnosis of lead poisoning is based on blood and tissue levels. In chickens, a blood lead level greater than 4 ppm, a liver lead level greater than 18 ppm wet weight, or a 20 ppm wet weight in kidney would be considered diagnostic (259, 260). Lead levels in bone can also be determined. Acid-fast inclusions in kidney epithelial cells suggest lead poisoning but may be found in birds that could have ingested lead but died from some other cause. Peripheral nerve lesions, in conjunction with fibrinoid necrosis of blood vessels, which may be found throughout the body not just in brain and heart, are useful in diagnosis, but similar changes are seen in methylmercury poisoning (271). In lead poisoning, however, lesions in the central nervous system are related only to vascular damage.

Mercury

Organic mercury, used previously as a seed protectant, is discussed later in this chapter along with fungicides. Most organic mercury in the environment today results from methylation by aquatic organisms and action of methogenic bacterial enzymes on elemental mercury from nature (decaying trees) or industry. Tons of mercury as bivalent inorganic mercury, elemental mercury, and phenyl mercury have been discharged into waterways around the world.

Methylmercury, a direct product of biotransformation, gets into small water organisms and enters the food chain when fish eat contaminated plants, insects, or animals (bioconcentration). Fish-eating birds, particularly ducks, may become poisoned from mercury in the food they eat (234). Mercury contamination of pheasants also has occurred. Experimental feeding of low levels of methylmercury resulted in decreased egg production, increased shell-less eggs, and reduced hatchability (234).
Residues in chickens given subclinical amounts of methylmercury were highest in liver, least in muscle, and intermediate in kidney. Eggs had 4 times as much mercury in albumin compared with yolk (234).

Inorganic mercury of medicinal or industrial waste origin may induce anorexia, enteritis, and nephrosis (234, 259, 260).

Tin

Tin from medicinal sources can cause depression, hunching up, and yellow diarrhea (295).

Uranium (Uranyl Nitrate)

Industrial uranium causes depression, anorexia, and nephrosis with severe lesions in collecting tubules, followed by hyperuricemia and visceral urate deposits in birds that survive (184).

Vanadium

Vanadium can contaminate phosphorus sources and cause reduced egg quality, growth, and hatchability (183, 259, 260). Also, there are many reports in the literature of experimental vanadium toxicity.

Vitamins

Vitamin A

Excess vitamin A reduces egg production (180) and growth rate and causes osteodystrophy and osteoporosis (315, 326).

Vitamin D₃ (Cholecalciferol)

Four percent mortality due to kidney failure occurred in chicks when feed was top-dressed with vitamin D_3 powder. Nephrosis with focal mineralization was present throughout the kidneys. Mineralization was also present in the walls of arteries, particularly arteries in the proventriculus. Excess vitamin D_3 has resulted in increased incidence of leg abnormalities in broilers (57). Experimentally induced toxicity indicated that 25-hydroxycholecalciferol was 100 times as toxic as cholecalciferol (265). A variety of lesions were seen, but renal damage was most significant (219). Poultry, pigeons, and wild birds may also be poisoned by rodenticides in which the toxic agent is 25-hydroxycholecalciferol.

Vitamin B₆ (Pyridoxine)

Pyridoxine is toxic for pigeons at levels safe for poultry (90–100 mg/bird, i.e., approximately 200 mg/kg body weight given by injection) (244).

Other

Ethoxyquin

Ethoxyquin (1,2-dihydro-6-ethoxy-2,2,4-trimethylquinolone) is a commonly used antioxidant that may be toxic at high levels (6500–12,500 mg/kg feed). Mortality is increased; affected birds have pale, swollen kidneys; dark-brown enlarged livers; and urates in joints. Proximal tubular necrosis in the kidney and accumulations of dark-brown pigment, interpreted to be ethoxyquin, in hepatocytes, bile ducts, and pulmonary blood capillaries are seen microscopically (195).

Lignosol

Calcium lignosulfonate, a pellet binder, may produce black, sticky cecal contents that adhere to the skin of processed broilers, causing increased condemnation from contamination. It has no effect on body weight or feed conversion (258).

Nitrate and Nitrite

Nitrate is converted to nitrite by bacteria in the digestive tract and is much less toxic than nitrite. High levels of nitrate cause diarrhea, dyspnea, and death. Lower levels affect growth and egg production. Blood hemoglobin is changed to methemoglobin. The effect is greater in young birds, as it is in young mammals, with fetal hemoglobin (74). Most reports of toxicity are experimental, although there are some reports of toxic nitrate levels in leaves and stems of plants (345).

Pen- and Litter-related Toxicants

Pen and litter-related toxicants include products accidentally or intentionally incorporated into litter or applied to the pen, that result in illness. Some are disinfectants and fumigants discussed later in this chapter. Except for boric acid, insecticides mixed into the litter (e.g., fire ant control products) or applied to walls, floor, or ceiling are covered later in this chapter. Copper sulfate, often used as a fungicide in litter, has been discussed with feed- and water-related toxicants above. Toxic

mixtures, such as copper-chrome-arsenic formulations, are used as preservatives in the timber industry (225). Occasionally, part of the building structure is toxic; geese have been poisoned from eating urea-formaldehyde foam insulation picked from the wall.

Boric and Orthoboric Acid

Boric acid is used in litter to control darkling beetles and may be consumed by broilers, which results in reduced growth and abnormal feathering (82, 274).

Iron

Ferrous sulfate heptahydrate added to litter to reduce ammonia formation was toxic to broilers (331). Affected chicks were depressed and lethargic. Those that died had severe gizzard ulceration and liver degeneration. The LD_{50} of ferrous sulfate is 7010 mg/kg body weight for a single dose. When added to the diet, 3% caused reduced growth and feed intake, and 1.5% had no effect (249).

Pentachlorophenol

Pentachlorophenol has been used as a pesticide in industry and agriculture, but its primary use is as a wood preservative. Logs may be treated before they leave the forest, or wood may be treated after cutting. Sawdust and shavings from treated wood frequently have been used as poultry litter; chickens can become contaminated from contact with these shavings. Because the product is used for many other purposes, pentachlorophenol may also contaminate broilers or table eggs in other ways.

Illness associated with pentachlorophenol has been caused by toxic impurities such as dioxins (see later discussion). Pure pentachlorophenol can reduce growth, cause kidney hypertrophy, and decrease humoral immune responses (256, 309). It has also been associated with musty taste in eggs and broiler meat. Chlorophenols in litter are metabolized by bacteria and fungi to chloroanisoles. Anisoles have a musty or earthy odor even at very low concentrations, and they are responsible for the taste in eggs and meat from chickens in contact with contaminated litter (112). Reduced hatchability has also been associated with pentachlorophenol contamination (115).

Sulfur

Elemental sulfur may be sprinkled on dirt floors and vaporized by adding water and heating the building before litter is put down. High mortality, ulcerative dermatitis mainly affecting moist areas of the body, irritation of respiratory mucous membranes, and conjunctivitis occurred in chicks placed in treated buildings (251). Lesions probably resulted from sulfur dioxide (from residual sulfur that had not vaporized) dissolving in moisture on the chick's body to form sulfurous acid (H_2SO_3).

Disinfectants and Fumigants

Fumigants are products producing toxic gases used to control rodents, insects, fungi, and bacteria. They can cause toxicity when

inhaled or ingested. Phenolic disinfectants can be toxic when inhaled or absorbed through skin.

Phenolic Compounds and Coal-Tar Derivatives

Phenol, cresol, creolin, carbolineum, and creosote products cause damage to vascular endothelium, epithelia of respiratory and digestive tracts, and parenchymal organs, such as liver and kidney (242). Thymus and bursa of Fabricius are small, but this may result from stunting rather than being a direct effect on the immune system. Hydropericardium is prominent, but ascites and subcutaneous edema are also frequently present if contact is severe. Mortality may be high. Diagnosis is based on a history of contact and by elimination of other causes of ascites and edema. Odor may also provide a useful clue. Cases of creolin toxicity still appear in the literature (193). Coal tar poisoning has been induced in ducks by feeding from clay pigeons (48).

Quaternary Ammonium (Cationic Detergents)

Use of sanitizers to clean poultry drinkers or treat water has resulted in reduced growth or production and, occasionally, severe lesions and death in young chicks (158). High levels of quaternary ammonia cause epithelial irritation of the mouth, pharynx, and upper respiratory tract, resulting in oral, ocular, and nasal discharges. Necrosis of epithelium leads to pseudomembranes in the mouth and epithelial thickening in the esophagus, crop, and proventriculus, with ulcers at the gizzard-proventricular junction (72, 242). Similar lesions have been reported in poults (205).

Chlorine

Low levels (37.5–150 mg/kg) may have a beneficial effect, but high levels (300–1200 mg/kg) result in reduced growth and increased mortality (63).

Formaldehyde

Formaldehyde gas and formalin (a 37% solution of the gas in water, which is then 100% formalin) have been widely used for many years as antibacterial and antiviral agents in the poultry industry. Photophobia and respiratory signs from contact with high levels of formaldehyde are seen occasionally in newly hatched or recently delivered baby chicks and poults. Prolonged exposure to high levels of formaldehyde, which dissolves in liquids on mucous membranes to produce formalin, in the hatcher impairs cilial function and causes tracheal epithelial degeneration and sloughing (281). Air quality during subsequent growout, however, has a greater effect on productivity than does early formaldehyde exposure (280). Epithelial necrosis of eyes, mouth, and trachea with pseudomembranous plaques in the mouth and trachea also may be found. Edematous swellings under the lower beak (118), subcutaneous edema (27) during the acute phase, and ascites or edema occurred later in exposed poults.

Other Fumigants

It must be assumed that most or all chemicals used as fumigants are toxic to poultry (234). A few reports of deliberate or accidental poisoning of poultry by other fumigants appear in the literature (294, 339).

Fungicides

Fungicides are used as seed dressings (protectants), wood preservatives, in paint and plastic, and on cereal crops, fruits, vegetables, and flowers. Previously, poisoning in poultry usually has resulted from the incorporation of treated seed into poultry feed.

Organic Mercurials

Mercurial fungicides, frequently ethyl or methyl mercuric chloride, that cause poisoning with central and peripheral nervous lesions in poultry, wild birds, animals, and humans consuming treated seed are no longer in use (142, 143, 271, 305). Signs of organic mercury poisoning may be nonspecific, or affected birds may show progressive paralysis or other neurologic signs. Specific gross lesions may be lacking, but microscopically, Wallerian degeneration of peripheral nerves and spinal cord, and neuronal damage in the brain may be present. Vasculitis may also be obvious in some vessels, particularly in the brain.

Thiram

Arasan (active ingredient thiram, a dithiocarbamate) has caused poisoning in poultry, producing lameness and leg deformity in chicks and poults and soft-shelled eggs in layers (126, 242). It is also teratogenic (236). Thiram increases the incidence and severity of tibial dyschondroplasia (89). The LD_{50} is 485–932 mg/kg body weight in pheasants and 2800 mg/kg body weight in mallard ducks (62).

Captan

Captan is an organic seed protectant. It is less toxic than Arasan. It depresses feed consumption, slows growth, and reduces egg production (242).

For descriptions of other organic synthetic fungicides, see reference 234; pentachlorophenol, a widely used wood preservative, and copper sulfate, a litter treatment, have been covered previously in this chapter.

Herbicides

Chlorates

Sodium and potassium chlorates used as herbicides and defoliants are moderately toxic for poultry. They act by converting hemoglobin to methemoglobin. The lethal dose for chickens is 5 g/kg (234).

Organic Synthetic Herbicides

Amitrate (3-amino 1,2,4-triazole) causes hypothyroidism and reduces weight gain in chickens (350). Phenoxyherbicides, such as 2,4-D, cause kidney enlargement. Some herbicides are toxic for embryos (84). See reference 234 for additional information.

Dipyridyl Herbicides (Diquat and Paraquat)

Paraquat toxicity results from free radical induced membrane damage caused by the inhibition of the glutathione peroxidase system. Selenium is protective. Experimental oral paraquat poisoning in turkeys produced diarrhea, listlessness, and anorexia

with terminal convulsions. Gastroenteritis was present at necropsy (274). Turkeys are more resistant than are mammals (140, 234), but exposure of mallard duck eggs produces cranial and pelvic deformities at hatch (278).

Insecticides

Insecticides may be referred to by either their common or registered name. The common name is not capitalized (e.g., carbaryl), but the trade name is (e.g., Sevin) (234). Organic insecticides (organophosphates, organochlorides, and carbamates) have been widely used, some on animals and birds as systemic larvicides and anthelmintics, as well as on buildings and pens. Wild birds have been poisoned by feeding on treated animals (32, 134). Many insecticides are quite toxic for animals as well as insects, arthropods, and helminths. Some more toxic products are used on crops, wood, trees, as soil insecticides, and as seed dressings. Extensive tables presenting general information on insecticides can be found in (234).

Organochloride Insecticides

The mode of action of organochloride (chlorinated hydrocarbon) insecticide toxicity is unknown. Generally, they act to diffusely stimulate or depress the nervous system. Organochloride insecticides often remain longer in the environment than other insecticides. Some more persistent ones have been taken off the market or have restricted use. Because they are fat soluble, organochlorides tend to build up in the food chain and be present in yolks of eggs. There is considerable literature available on insecticide toxicity in wild birds, with emphasis on organochlorides (218).

Signs. Nervous signs varying from excitement with vocalization to tremors, ataxia, and convulsions are prominent. Prostration and death may occur without other signs. Other signs include salivation, vomiting, diarrhea, and depression. Lameness and leg deformity may also occur. There may be decreased egg production, a drop in hatchability, embryo mortality, loss of pigment on pigmented eggs, a change in shell texture (chalky), and eggshell thinning. Administration of atropine to acutely affected birds will not alleviate or modify signs of toxicity.

Pathology. Specific lesions do not occur in organochloride toxicity. Nonspecific changes such as congestion and hemorrhage may be present. Excess cerebrospinal fluid may be noted when the brains of affected birds are examined.

Chlordane
Chicks develop ataxia and hyperexcitability; hens have reduced body weight, decreased egg production, atrophy and cyanosis of the comb and wattles, and hydropericardium (242).

DDT and DDE
Hens develop tremors, production drop, and weight loss, and there is eggshell thinning (242).

Dieldrin
Pigeons, gulls, and other birds may show nervous signs (9, 242).

Heptachlor
This may cause ataxia, salivation, prostration, and death (241, 330).

Lindane
Diarrhea, vomiting, anorexia, depression, convulsions, and sudden death have been associated with lindane poisoning (28, 242).

Mirex
This has caused embryo mortality (3).

Toxaphene
Lameness, thin shells, and osteomalacia may occur (238, 242).

Organophosphorus and Carbamate Insecticides

These products inhibit acetylcholinesterase, causing acetylcholine to accumulate, which results in the overstimulation of parasympathetic nerves and muscles (98). Atropine given to effect will often dramatically reverse clinical signs, but efficacy depends on the type of organophosphorus compound and the duration of the intoxication and amount of time lapsed between exposure and treatment. Repeated treatments may be necessary. Some organophosphates and carbamates have delayed neurotoxic effects (see the following discussion). Chickens and other birds are more susceptible than mammals to this type of toxicity.

Signs. Chicks and poults may die quickly, showing few signs except dyspnea and paralysis, or they may exhibit lacrimation, salivation, diarrhea, tremors, depression, dullness, lethargy, cyanosis, ataxia, incoordination, and convulsions prior to death. Because of respiratory signs and salivation in early stages, respiratory infection may be suspected initially.

Pathology. Few gross lesions occur. There may be congestion with dark blood, and hemorrhages may be present in heart muscle, on serosal surfaces, and on mucosa of intestines. No specific microscopic changes have been identified.

Diazinon
Diazinon is used to control fire ants and darkling beetles, but in birds, diazinon can cause incoordination, paralysis, respiratory signs, and death (147). It is also used to control pests in soil and grass, causing death in Canada geese (113, 308).

Dichlorvos (DDVP)
Dichlorvos induces staggering, frothing from the mouth, paralysis, and convulsions (91).

Dimethoate
Toxic effects include reduced growth and egg production (290, 291).

Famphur
Mortality in raptors has resulted from famphur toxicity (145).

Fenthion
Laying hens exposed experimentally had neurologic deficits followed by decreased egg production and reduced body weight (321).

Malathion

Malathion causes dullness, salivation, loose droppings, cyanosis, paralysis, and death; lesions include injected subcutaneous vessels and dark congested heart (37, 242). In geese, there may be flaccid paralysis.

Monocrotophos

Monocrotophos toxicity has been associated with salivation, mortality in quail, and weight loss and embryo abnormalities in chickens (296).

Parathion

Parathion induces lacrimation, salivation, dyspnea, tremors, and convulsions (242).

Carbamates

Various carbamates such as carbaryl, carbofuran, and others are toxic for pheasants, pigeons, turkey poults, chickens, and ducks (14, 91, 263). Signs include reduced growth, lameness, weakness, ataxia, and death. There may be tibial dyschondroplasia, retarded testicular development because of degeneration of seminiferous epithelium, nerve fiber degeneration, and congestion of organs and tissues.

Delayed Organophosphorus Neurotoxicity

Delayed neurotoxicity occurs several days to weeks after exposure, causing progressive degeneration of the peripheral nerves and spinal cord, which leads to weakness and paralysis. Acetylcholinesterase is not affected. Delayed neurotoxicity may result from ingestion or absorption of a variety of triaryl phosphates; chemicals found in phenylphosphorothioate insecticides such as leptophos, cyanofenphos, and their analogues; as well as a variety of industrial chemicals, including fire retardants and lubricants. Malathion and dimethoate may also cause delayed neurotoxicity. Mature chickens, pheasants, and mallard ducklings are highly susceptible (234). Chicks hatched after *in ovo* exposure also show clinical signs (99). There are many reports of delayed neurotoxicity in chickens from these products. Most describe experimentally induced lesions (1, 2, 86, 186, 200, 335). A previous author of this chapter had seen turkeys in Ontario, Canada, with typical clinical signs of ataxia and paralysis and histologic lesions of delayed organophosphorus neurotoxicity in spinal cord and peripheral nerves. Clinical cases occurred in Europe after chickens ate scraps of synthetic leather containing tri-orthocresyl-phosphate (TOCP) (242).

Signs. Ataxia, falling sideways, inability to rise, lack of leg reflexes, and prostration may be evident. Birds appear bright and eat and drink if given access to food and water for several days.

Pathology. There are no gross lesions. Degeneration of axons and myelin in peripheral nerves and long tracts of the spinal cord are diagnostic. Axons may be swollen, and spheroids may be present in axon spaces. Digestion chambers containing macrophages and debris may be present in subacute cases.

Other Insecticides

Pyrethrum and Synthetic Pyrethroids

These products are not very toxic to animals or birds, and there are no reports of illness (52).

Rotenone

Rotenone (derris powder) is prepared from roots of *Derris* spp. Mature chickens are relatively resistant (lethal dose 1000–3000 mg/kg); young birds are more susceptible (234). Fish are very susceptible to rotenone.

Nicotine

Nicotine sulfate (Black Leaf 40) has been used to paint chicken roosts to control insects and arthropods, particularly northern fowl mite. It has also been used for internal parasites. In low doses, nicotine stimulates the nervous system through an acetylcholine-like activity. At toxic levels, neural transmission is blocked causing death from respiratory paralysis (234).

Signs. Sudden death, occasionally preceded by depression and coma, is seen in affected birds.

Pathology. Because death is from respiratory failure, cyanosis and congestion may be marked. Hemorrhages may be present on the heart and in other tissues.

Rodenticides, Avicides, and Molluscacides

Rodenticides

Information on cholecalciferol and arsenic is presented in "Nutrients and Other Feed- and Water-related Toxicants."

Alpha-naphthyl Thiourea (ANTU)

ANTU causes depression, anorexia, weakness, prostration, and death. Lesions include pulmonary edema, hydropericardium, fatty change in liver, and myocardial degeneration.

Sodium Monofluoroacetate (Compound 1080)

Signs are reluctance to move, edema of wattles, dyspnea, cyanosis, and nervous signs. Lesions include dark, unclotted blood, pulmonary hemorrhage and edema, clotted blood in the trachea and air sacs, petechiation, enteritis, and hydropericardium (140, 234).

Strychnine

Toxic effects are tonic spasms, respiratory failure, reproductive failure, and increased mortality of progeny from exposed hens (234, 242, 243, 352).

Warfarin, Brodifacoum, and Diphacinone

These anticoagulant rodenticides are sold under a variety of trade names and may be combined with sulfaquinoxaline to interfere with vitamin K synthesis. They inhibit epoxide reductase, which converts vitamin K to its active form. Toxicity causes anemia with fluttering, gasping, and hemorrhages in eyes, mouth, and

other tissues (15, 140, 234, 292). Onset may be rapid, and death occurs within 72 hours of ingestion (221). With the long-acting anticoagulants, there is a cumulative effect, and if a small amount of anticoagulant is consumed repeatedly, there may be little or no product found in the digestive tract.

Phosphorus

Elemental yellow, red, and white phosphorus can induce depression, anorexia, diarrhea, ataxia, gastroenteritis, and death (234, 242, 306, 307).

Zinc Phosphide

Weakness, diarrhea, opisthotonos, and convulsions occur. There is enteritis, ascites, and hydropericardium (135, 292). In an accidental poisoning of broiler breeder chickens, birds were found dead following ingestion of zinc phosphide treated oats used as a rodent bait. No clinical signs were observed. Gross lesions consisted of hydropericardium and ascites. A petroleum-like odor, common feature with this poison, of crop contents was detected. Histologic lesions were those of congestion of many internal organs, along with severe pulmonary edema and congestion. (320) Wild birds may also succumb to this poison if they are allowed access to zinc phosphide treated grain (254).

For birds, the toxic doses of several rodenticides (a-chloralase, crimidine, pyriminil, phosphorus, a-chlorohydrim) are given in *Clinical and Diagnostic Veterinary Toxicology* (234).

Avicides

Avitrol (4-aminopyridine or 4-AP)

Avitrol causes disorientation and vocalization (distress calls). Affected pigeons may be molested by normal pigeons. Generalized congestion is present at necropsy, and the characteristic small pellets usually can be found in the ventriculus (111, 222).

2-chloro-4-acetotoluidine (CAT) and 3-chloro-P-toluidine (CPT)

No clinical signs have been described, but kidney necrosis (from CAT) and liver and kidney necrosis (from CPT) occur (119).

Molluscacides

Metaldehyde

Nervous signs were prominent in ducklings following ingestion of metaldehyde (11).

Toxic Gases

Ammonia

Ammonia levels should be less than 25 ppm, but in poorly ventilated litter-type houses, ammonia may exceed 100 ppm (171). High levels of ammonia (50–75 ppm) reduce food consumption and growth rate (67). Egg production is also reduced. Ammonia dissolves in the liquid on mucous membranes and eyes to produce ammonium hydroxide, an irritating alkali causing keratoconjunctivitis. If levels greater than 100 ppm persist, corneal ulceration and blindness can occur. The condition is painful, and photophobia and stunting are marked. At levels of 75–100 ppm,

changes in respiratory epithelium include loss of cilia (235) and increased numbers of mucus-secreting cells (8). Heart rate and breathing may be affected, and there may be hemorrhages in trachea and bronchi. For a review, see reference 47.

Carbon Monoxide

Carbon monoxide (CO) poisoning may occur in buildings where defective or unventilated gas-catalytic or open-flame brooders or furnaces are in use, or where poultry are exposed to internal combustion-engine exhaust fumes. Affected chicks or poults show drowsiness, labored breathing, and incoordination. Spasms and convulsions may occur prior to death. At postmortem, blood is bright red. Sublethal levels cause stunting (242, 310). In suspected cases, CO should be measured at several locations in the pen with the ventilation system shut off. Carboxyhemoglobin can be measured in the blood of affected birds. A previous author of this chapter found levels of 70 ppm CO in pens where a repeated high incidence of ascites due to pulmonary hypertension and right ventricular failure occurred. Toxic levels of CO for chickens are as follows: 600 ppm for 30 minutes causes distress; 2000–3600 ppm is lethal in 1.5–2 hours (234).

Aerial Endotoxin

Breakdown of bacteria in the litter and environment results in endotoxin in the air in broiler pens. Endotoxin from inhaled air can be found in the blood of people who work in broiler pens (79). The effect of inhaled endotoxin on poultry is not known.

Polytetrafluoroethylene

Fluorinated gases are released when this material, used as a nonstick coating (Teflon) on light bulbs, cookware, and ovens, is overheated. Pet birds that inhale the fumes die from lung edema and hemorrhage. Histologic examination reveals epithelial necrosis in tertiary (para)bronchi and vascular damage in blood capillaries (311, 337).

Other Toxic Gases

Levels of methane, carbon dioxide, hydrogen sulfide, methyl mercaptan, dimethyl sulfide, and dimethyl disulfide were found to be low in poultry and other livestock buildings in Finland (171), but toxic fumes from liquid manure pits in pig barns have killed humans and pigs in North America, and nitrogen dioxide formed in freshly filled silos has also killed humans and animals in Canada and the United States. Toxic gases associated with livestock production, including poultry, have been reviewed (234). The effect of sulfur dioxide in chickens has been described (100).

Household and Commercial Products

Alcohol

Ethyl alcohol may be used to dissolve experimental chemicals or drugs given to poultry in feed or water. Clinical signs of intoxication include ataxia and reduced feed consumption. Fatty change in the liver and heart lesions may occur (7, 59). Wild birds frequently are intoxicated from ingesting fermented fruit

(103). Pet birds may obtain alcohol inadvertently, or it may be given by the owner.

Antifreeze (Ethylene Glycol)

Ethylene glycol is toxic when ingested because it breaks down to oxalic acid, which combines with calcium to form calcium oxalate. Calcium oxalate crystals block renal tubules and cause tubular epithelial necrosis leading to hyperuricemia and urate nephrosis with visceral urate deposits. Diagnosis usually is based on finding typical crystals and tubular changes on microscopic examination of kidney (261, 271, 272, 312). Liver necrosis is found in pigeons. Other forms of toxicity may occur in other species (234). Coccidia oocysts treated with ethylene oxide were toxic to chicks and caused kidney lesions similar to ethylene glycol (338).

Carbon Tetrachloride

Carbon tetrachloride has been used previously as a household solvent and cleaner. It has also been used to treat tapeworms in chickens (273). It is toxic to animals and birds, interfering with fat metabolism and causing liver and kidney damage. Chickens are more resistant than rats, but low levels cause decreased growth.

Fertilizer

Lawn, garden, and farm fertilizers contain nitrogen, phosphorus, and potassium. The contents in that order usually are given by numbers representing each element as a percentage of the total. These elements have been discussed previously. Fertilizer may be attractive to birds because it is frequently in the form of small hard pellets. Some phosphate fertilizers contain very low levels of radioactive material.

Naphthalene

Mothballs frequently are recommended to keep pets and other animals away from gardens or out of attics. They have also been used in chicken nests for ectoparasite control. Mothballs are toxic and can cause poisoning in poultry and pet birds (181).

Urea

Urea is relatively nontoxic for birds. Because it is used in feed preparations for ruminants, the pellets occasionally are found in poultry feed.

Industry-Related Toxicants

Toxic Fat Syndrome, Chick Edema Disease, and Dioxin Toxicity

More than 30 years ago, the most toxic dioxin, 2,3,7,8-tetrachlorodibenzodioxin (TCDD), and other dioxins in the same polychlorinated dibenzodioxin group were found as contaminants in industrial fat (tallow from cattle hides) added to poultry feed. This material, which could be distilled from fat, was called "chick edema factor" until it was identified. It caused widespread disease in the broiler industry and in other poultry for several years. Occasional cases of dioxin toxicity (chick edema disease) occurred until about 1970. More recently, TCDD toxicity followed environmental contamination in Italy where adult fowl died with lesions of chick edema disease (253). Dioxin was probably the material causing lesions in toxicosis caused by paint containing chlorinated hydrocarbon (207).

Chickens are more susceptible than some mammals to the toxic effects of TCDD (234). In chickens, dioxin damages vascular endothelium causing vascular leakage and extensive movement of fluid into body cavities and subcutaneous tissue. The epithelium of some parenchymal organs is damaged, and there is degeneration of heart and skeletal muscle.

Because right ventricular hypertrophy and dilation have been described (6), and many lesions in dioxin toxicity are similar to right-sided heart failure from other causes, the possibility of dioxin contributing to right ventricular failure should be considered.

Depending on the level of TCDD in feed, variable numbers of broilers in a flock will show severe signs of stunting, respiratory distress, weakness, ataxia, and edema. Mortality occasionally can be very high. For a description and review of the syndrome, see reference 242.

TCDD may be present as a contaminant in herbicides. It and other dioxins are produced by incineration (234) and by industry (93). Contaminated poultry carcasses potentially could serve as a route for human exposure, because dioxins are retained in body fat after exposure.

Polybrominated Biphenyl (PBB) and Polychlorinated Biphenyl (PCB)

PBBs or PCBs accidentally may be added to feed, get into feed as contaminants (as in oil or grease from equipment), or be present in the environment from industrial contamination and deliberate dumping. Both PBBs and PCBs are toxic to birds. At low levels, they reduce production, reproduction, hatchability, offspring viability, and thyroid hormone levels (109). Hepatocyte damage and bursal depletion also occur with low-level PBB toxicity (65). Exposure of young embryos magnifies these effects (107). Residues may be found in eggs and meat from birds without clinical signs. PBBs are concentrated in eggs at 1.5 times the dietary level (93). At high levels, lesions of PCB toxicity are similar to dioxin toxicity. It is likely that in some cases, PCBs were contaminated with TCDD.

Crude Petroleum and Oils

Most information on toxicity of oil to birds deals with environmental contamination and the effect of oil spills on waterfowl. Ingested oil causes anorexia, weight loss, incoordination, tremors, and Heinz body anemia. Lesions include lipid pneumonia, enteritis, hepatosis with fatty infiltration, and nephrosis and degeneration of pancreas, spleen, and bursa (226). Immune responses are impaired. In herring gulls and puffins, lesions suggested a primary toxic hemolytic disease (191) with lymphoid depletion being secondary and stress related. Oil applied to chicken eggs caused embryo mortality and lesions in organs (55). Oils and oil products on the feathers and skin can be removed with detergents.

Biotoxins

Biotoxins are poisonous substances produced by living organisms including bacterial toxins such as botulinum toxin, which in birds is frequently associated with toxin-contaminated maggots, bacterial food poisoning, diseases such as necrotic and ulcerative enteritis, gangrenous dermatitis, and mycotoxins. Perhaps, even methylmercury produced by bacteria should be classed as a biotoxin. Insect and snake venoms (188) are also biotoxins. Most of these conditions are of little importance or are discussed in other parts of the text. Botulism is being seen with increasing frequency in housed turkeys and broilers. Birds are very susceptible to botulinum toxin and may show clinical signs following ingestion of very small amounts. The toxin apparently develops in dead birds left in the litter. Birds may pick up toxin from eating decaying tissue or contaminated fly larvae, darkling beetles or litter. An enzyme-linked immunosorbent assay (ELISA), which may be as sensitive as the mouse-inoculation test, has been developed to identify botulinum toxin (see also Chapter 22). Only algae poisoning and rose chafer toxicity are mentioned here.

Algae

Several species of blue-green algae produce a toxin that, when concentrated by rapid algal growth (bloom) in warm bodies of fresh water and a constant light wind blowing the toxic material to the side of the lake, may poison animals and birds consuming it. Toxicity varies directly with concentration (159). Affected chickens may show nervous signs and paralysis before death. Ducks and turkeys have also been poisoned (154). Cyanosis, congestion, and a dilated, distended heart may be seen at necropsy (242). The liver is swollen with necrosis of hepatocytes. Diagnosis is based on identifying toxin in the water (234).

Rose Chafers

Rose chafers (*Macrodactylus subspinosus*) are insects appearing in spring and early summer in eastern and central North America. Young chicks may be poisoned by 15–30 insects (242). Clinical signs include drowsiness, weakness, prostration, and convulsions (242).

Phytotoxins

All or parts of some plants are toxic, or if fed at low levels may only reduce growth rate. Antinutrients are discussed in the section "Nutrients and Other Feed- and Water-Related Toxicants." For additional information on plants that are toxic to poultry and pet birds, see references 12, 76, 78, 83, 108, 176, 298, 347.

Avocado (Persea americana)
Part of Plant
Fruit.

Signs and Lesions
Muscle degeneration, hydropericardium, and subcutaneous edema (41, 136).

Black Locust (Robinia pseudoacacia)
Part of Plant
Leaf.

Signs and Lesions
Depression and paralysis; hemorrhagic enteritis.

Bladder Pod (Sesbania [Glottidium] vesicaria)
Part of Plant
Seed.

Signs and Lesions
Diarrhea, cyanosis, prostration, necrotic enteritis, and gizzard ulceration (95).

Cacao (Theobroma cacao, Theobromine Toxicity)
Part of Plant
Bean waste.

Signs and Lesions
Acute cases, nervous signs followed by convulsions and death; cyanosis, cloacal prolapse, and mottled kidneys. Chronic cases, anorexia and diarrhea (242).

Cassava (Manihot spp. Cyanide, Polyphenols)
Part of Plant
Root (tuber).

Signs and Lesions
Sudden death. Depressed growth (94, 240).

Carolina Jessamine (Gelsemium sempervirens)
Part of Plant
All.

Signs and Lesions
Progressive muscle weakness, seizure activity and death. No lesions. (319)

Castor Bean (Ricinus communis)
Part of Plant
Bean.

Signs and Lesions
Progressive paralysis with prostration (like botulism); diarrhea, emaciation, swollen pale mottled liver, hemorrhagic catarrhal enteritis, petechiae, degeneration of lymphoid tissue and parenchymal cells of liver and kidney, bile duct proliferation (162, 229, 242).

Coffee Senna, Sickle Pod (Cassia occidentalis, C. obtusifolia, Senna occidentalis)
Part of Plant
Seed.

Signs and Lesions
Weakness, ataxia, paralysis, decreased egg production, diarrhea; toxic myopathy; pectoralis and semitendinous muscles pale; and edematous, muscle degeneration, and necrosis (105, 237, 242, 302, 327). There is also primary axonal damage producing a neuropathy that adds to the paresis (42, 137). Lymphoid populations in the spleen and bursa of Fabricius may also be decreased (303).

Corn Cockle (Agrostemma githago, Githagenin Toxicity)

Part of Plant
Seed.

Signs and Lesions
Depression, rough feathers, decreased respiratory and heart rate, diarrhea, depressed growth; hydropericardium; caseous necrosis of crop, pharyngeal mucosa, and mouth (146, 242).

Cotton Seed Meal (Gossypol Toxicity)

Signs and Lesions
Cyanosis, inappetence, emaciation, reduced egg production and quality; enteritis, degeneration of liver and kidney, and reduced growth (242).

Coyotillo (Karwinskia humboldtiana)

Part of Plant
Fruit and seed.

Signs and Lesions
Depressed growth, cyanosis, and paralysis.

Crotalaria spp. (Pyrrolizidine Alkaloids, Monocrotaline Toxicity)

Part of Plant
Seed, leaf, and stem.

Signs and Lesions
Dull, inactive, reduced feed consumption, stunting, bright yellow-green urates; subcutaneous edema, ascites, hydropericardium, lung edema, hepatitis, bile duct hyperplasia (5, 49, 75, 242, 346).

Daubentonia (Daubentonia longifolia, Sesbania drummondii, S. macrocarpa)

Part of Plant
Seed.

Signs and Lesions
Weakness, depression, stunting, diarrhea, emaciation; proventriculitis with ulceration and enteritis; liver and kidney degeneration (104, 106, 203, 289).

Death Camas (Zygadenus spp.)

Part of Plant
Leaf, stem, and root.

Signs and Lesions
Weakness, salivation, diarrhea, and prostration (202).

Eucalyptus cladocalyx (Cyanide or Prussic Acid)

Part of Plant
Leaf.

Signs and Lesions
Acute death without premonitory signs.

Hemlock (Conium maculatum, Conine Toxicity)

Part of Plant
Seed.

Signs and Lesions
Salivation, weakness, nervous signs, paralysis, diarrhea, reduced growth; hepatic congestion, enteritis (110).

Jimsonweed (Datura stramonium, D. ferox, Scopolamine, Hyoscyamine)

Part of Plant
Seed.

Signs and Lesions
Reduced growth (182).

Leucaena leucocephala (Mimosine Toxicity)

Part of Plant
Leaf containing mimosine.

Signs and Lesions
Depressed growth, osteopathy (141, 170).

Lily of the Valley (Convallaria majalis)

Milkweed (Asclepias spp. Asclepidin Toxicity)

Signs and Lesions
Weakness and incoordination, convulsions, prostration, leading to death or recovery (242).

Nightshade (Solanum nigrum, Belladonna Toxicity)

Part of Plant
Immature fruit.

Signs and Lesions
Dilated pupils, incoordination, prostration (133).

Nitrate (Numerous Plant Species)

See previous discussion on nitrates and nitrites.

Oak (Quercus spp., Tannin Toxicity)

Part of Plant
Leaf.

Signs and Lesions
There is severe diarrhea, anorexia, and increased water consumption; enteritis, swollen kidneys, and visceral gout; diffuse necrosis of proximal renal tubules (179).

Oleander (Nerium oleander, Glycosides)

Part of Plant
All parts.

Signs and Lesions
Depression, weakness, diarrhea; gastroenteritis, liver degeneration, death (242, 314).

Onions, green (Allium ascalonicum)

Part of Plant
All parts.

Signs and Lesions
Sudden mortality. Epicardial hemorrhage and palor, hydropericardium, and hepatosplenomegaly. Microscopic lesions of hemosiderin in heptocytes, Kupffer cells and renal tubules. Onions are known to produce a Heinz body anemia in animals but was not found in geese. (56)

Oxalate (Numerous Plant Species, Oxalic Acid)

Part of Plant
Leaf and stem.

Signs and Lesions
Oxalate nephrosis (345). See also the previous discussion on ethylene glycol.

Parsley, Ammi majus, Others (Photosensitization)

Part of Plant
All parts.

Signs and Lesions
Dermatitis (unfeathered areas); hepatitis (245, 293).

Pokeberry (Phytolacca americana)

Part of Plant
Fruit.

Signs and Lesions
Ataxia, leg deformity, ascites (17).

Potato (Solanum tuberosum, Solanine Toxicity)

Part of Plant
Green or spoiled tubers, peelings, and sprouts.

Signs and Lesions
Incoordination, prostration (teratogenic) (133, 317).

Ragwort (Senecio jacobea Pyrrolizidine Alkaloid)

Part of Plant
All parts.

Signs and Lesions
Focal hepatic necrosis and portal fibrosis (49).

Rapeseed Meal (Erucic Acid/Glucosinolate Toxicity; Antinutrients Sinapine, Tannin, Phytic Acid); Canola at Low Glucosinolate Levels

Part of Plant
Seed.

Signs and Lesions
Abnormal odor and taste in eggs, hypothyroidism, depressed growth, anemia, sudden death, ruptured liver, hepatitis, ascites, hydropericardium; periacinar hepatic necrosis, fatty change in skeletal and heart muscle (22, 26, 43, 54, 101, 121, 173, 264, 344).

Sweet Pea (Lathyrus spp., Lathyrism)

Part of Plant
Seed (pea).

Signs and Lesions
Skeletal deformity, osteolathyrism (*L. odoratus*); or neurologic disease, neurolathyrism (*L. sativus*) (50, 220, 262).

Tannins (Numerous Plant Species)

Tannins are antinutrients that occur in a variety of plants. It may be important to determine tannin levels in some feedstuffs such as sorghum (161, 316, 333).

Tobacco (Nicotiana tabacum, Nicotine Sulfate Toxicity)

Part of Plant
Leaf and stem.

Signs and Lesions
Stunting, reduced production (teratogenic) (242).

Velvetweed (Malvaceae Family, Cyclopenoid Fatty Acids)

Part of Plant
Seed.

Signs and Lesions
Pasty, rubbery yolk in eggs (178).

Vetch (Vicia spp., Cyanogenic Glycoside)

Part of Plant
Seed (pea).

Signs and Lesions
Excitability, respiratory distress, convulsions (138, 269).

Yellow Jessamine (Gelsemium sempervirens)

Part of Plant
Whole plant.

Signs and Lesions
Depressed growth (242, 348).

*Yew (*Taxus *spp., Taxine Toxicity)*
Part of Plant
All parts.

Signs and Lesions
Labored breathing, incoordination, and collapse; cyanosis.

VI Other Diseases

Chapter 33

Emerging Diseases and Diseases of Complex or Unknown Etiology

---

Introduction

Y. M. Saif

The emergence of new diseases and the re-emergence of recognized diseases are familiar events in the annals of poultry medicine. Some of these emerging diseases could have been present earlier but were not recognized because of low prevalence, mild signs and lesions, lack of diagnostic techniques, or misdiagnosis. In other situations, genetic changes in the microorganisms could have rendered them more virulent or pathogenic. Similarly, genetic changes in the bird could have altered its susceptibility and resistance to disease. In addition, changes in environmental conditions or management could result in conditions that are favorable for a microbe to express pathogenic properties. Because of the global activities of the poultry industry, resulting in the continual movement of live birds, eggs, and poultry products across political borders, it is difficult to contain an emerging or re-emerging disease to a country or a continent. Hence, it is necessary to maintain a vigilant attitude toward poultry health and to sustain capable diagnostic facilities.

There are disease conditions that have multifactorial etiologies including combinations of microbes and, at times, microbes plus nutritional or environmental factors. Examples abound of seemingly harmless microbes that do not cause disease in healthy individuals but can become pathogenic following an insult, although it might be mild, to the host. *Escherichia coli* is a prime example of such a microbe, earning it a designation as a universal secondary infection in poultry. In the commercial poultry environment, viruses and bacteria, including some that have the potential of causing disease, are common. Live vaccine viruses, some of which are very mild pathogens, may also be present.

In addition, flocks that are immunocompromised because of infectious or noninfectious agents could present unusual disease syndromes, increased susceptibility to disease, or lack of responsiveness to vaccination. The combinations of etiologies of disease could result in additive or synergistic effects. The pathogenesis of the multiple etiologies is not completely understood, but some mechanisms have been suggested or shown to occur.

The upper respiratory tract and the gastrointestinal tract are bombarded continually by a variety of microbes; yet, disease is not nec-

essarily a common event. Natural and acquired defense mechanisms function efficiently to eliminate infections, inhibit replication, or prevent colonization of tissues by microbes. The mucociliary apparatus of the respiratory tract is a highly efficient system for the elimination of microbes and particulate matter. Some viral infections result in the deciliation of parts of the respiratory tract and lysis of infected cells, resulting in accumulation of cellular products and debris, creating an environment favorable for bacterial multiplication and attachment to cells, which are important events in the pathogenesis of bacterial infections. In the gastrointestinal tract, similar events initiated by viruses have been described, including villous atrophy and consequent increased bacterial replication and adherence to cells. It is a common finding in respiratory and enteric diseases of poultry to encounter a variety of infectious agents. Because of the possible complex etiology of respiratory and enteric disease, it is important to understand the role of the different agents in the disease process. Such understanding should be helpful in designing logical control or prevention strategies.

This chapter was first introduced in the 10th edition with the realization that there will be continuous change in its content. Some of the diseases recognized as emerging at a point of time become either established entities or fail to have a sustained impact. In either case, the outcome will be the removal of these diseases from this chapter.

In this chapter, information is presented on the complexity of respiratory and enteric diseases. In addition, the newly recognized diseases are described.

Two subchapters, Big Liver and Spleen Disease and Hepatitis Splenomegaly Syndrome that were included in this chapter in the 11th edition were moved to Chapter 14 of this edition. This follows the recognition that both designations refer to one clinical entity. In addition, the work of Meng *et al.* elucidated the etiology of the condition being hepatitis E virus.

Poult enteritis–mortality syndrome is included in the subchapter on Multicausal Enteric Diseases in recognition of the etiology of the condition being multifactorial and to avoid confusion in nomenclature.

Multicausal Respiratory Diseases

Stanley H. Kleven

Although much is known about the individual agents responsible for respiratory diseases in poultry, uncomplicated infections with single agents are the exception. Under commercial conditions, complicated infections involving multiple etiologies with viruses, mycoplasmas and other bacteria, immunosuppressive agents, and unfavorable environmental conditions are more commonly observed than simple infections. In addition, respiratory reactions induced by routine vaccination programs may themselves play a major role in the development of respiratory disease.

Interactions among Respiratory Pathogens

Perhaps the best understood examples of multiple respiratory infections are those involving mycoplasmas; this subject has been reviewed previously (10, 32). Although uncomplicated *Mycoplasma gallisepticum* infections in turkeys ordinarily result in respiratory signs, sinusitis, and airsacculitis, simple infection with *M. gallisepticum* or *M. synoviae* in chickens often results in mild or even subclinical disease. Interactions with Newcastle disease (ND) virus or infectious bronchitis virus (IBV) are known to increase the severity of *M. gallisepticum* infection (3, 13, 16, 51, 60, 67, 74). Similar interactions also occur with *M. synoviae* (28, 29, 34, 37, 65, 71).

The virulence of respiratory viruses may influence the severity of mycoplasma infections. With *M. synoviae,* concurrent challenge with high-passage field and vaccine strains of IBV resulted in milder respiratory disease than did exposure to field strains (28), and chicken-passaged vaccine virus resulted in more severe airsacculitis than did the original vaccine when birds were concurrently challenged with *M. synoviae* (29).

The timing of exposure to infectious agents is important in the pathogenesis of complicated infections. Generally, respiratory virus and mycoplasma infection must occur concurrently or within a short period of time for synergism to occur (29, 37), but mycoplasma-free chickens had a milder clinical response to IBV challenge than did chickens that were chronically infected with *M. gallisepticum* (67).

Other infectious agents are also known to interact with *M. gallisepticum.* Synergistic effects between *Avibacterium paragallinarum* and *M. gallisepticum* are well known (4, 33, 39, 48); control of *M. gallisepticum* results in milder respiratory disease due to infectious coryza. Interactions are also known between *M. gallisepticum* and adenovirus (5), reovirus (31), and laryngotracheitis (9).

Three-way interactions between vaccine virus (Newcastle disease virus [NDV] and/or IBV), mycoplasma (*M. gallisepticum* or *M. synoviae*), and *Escherichia coli* resulted in more severe respiratory disease than any two alone. Combinations of any two of the agents resulted in milder disease than the three-way combination, and challenge with only one of the individual agents re-

sulted in very mild or no disease (46, 65). Chickens exposed to IBV and *M. gallisepticum* did not become susceptible to *E. coli* until 8 days postchallenge (24).

Interactions with various agents have also been described for *M. meleagridis* in turkeys. Enhanced airsacculitis was observed when germ-free poults were challenged with *M. meleagridis* and *E. coli* (61). An interaction between *M. meleagridis* and *M. synoviae* has been noted for turkey sinusitis (56) but not for airsacculitis (57). Combination infections with *M. meleagridis* and *M. iowae* caused more severe airsacculitis than either agent alone (57). *M. gallinarum,* ordinarily considered to be nonpathogenic, induced airsacculitis in broilers when given in combination with ND/infectious bronchitis vaccine virus (36).

Pathogenicity is increased when infectious bronchitis is combined with *M. imitans* (20); *M. imitans* also shows a similar effect when combined with rhinotracheitis virus in turkeys (21).

Interactions between *E. coli* and other respiratory agents often occur in the absence of mycoplasma infection. Exposure to *E. coli* or IBV alone resulted in little or no clinical signs or mortality, but challenge with various strains of IBV along with *E. coli* resulted in significantly increased clinical signs and mortality (52, 63, 77). Such a combination challenge with *E. coli* provided a means of evaluating the protection induced by infectious bronchitis vaccine strains against various challenge strains (12, 52). However, Newcastle disease vaccination nonspecifically stimulated resistance against *E. coli* at 2–8 days postvaccination, as measured by the number of *E. coli* recovered from the spleen (30). Turkeys exposed to the LaSota strain of NDV had a decreased tracheal mucus transport rate and reduced tracheal clearance of *E. coli* (19). A highly significant positive correlation between the number of infectious agents encountered during primary exposure and the incidence of colibacillosis after *E. coli* challenge was demonstrated (54). Studies on interactions between *E. coli* and *Bordetella avium* in turkeys have shown that *B. avium*-infected turkeys had higher numbers of *E. coli* in their tracheas and less ability to clear *E. coli* from the tracheas and lungs than did birds free of *B. avium* (69, 70). *B. avium* also adversely affected vaccinal immunity of turkeys to *Pasteurella multocida* (59).

Other respiratory agents may also interact; for example, the pathogenicity of Newcastle disease was enhanced when occurring in combination with *Ornithobacterium rhinotracheale* (68).

Effects of Immunosuppressive Agents

Immunosuppressive agents, especially infectious bursal disease in chickens and hemorrhagic enteritis virus in turkeys, are well known to affect adversely susceptibility to respiratory infections. Challenge of chickens with infectious bursal disease virus has been shown to affect adversely antibody response and resistance to ND (18, 22, 23, 27), infectious bronchitis (22, 53, 75), *M. synoviae,* (22), and *Aspergillus flavus* (50). "Intermediate" vaccine

strains of infectious bursal disease virus were highly variable in their interference with development of ND antibodies following ND vaccination (42).

Specific-pathogen-free chickens infected with infectious bursal disease virus and *E. coli* and then challenged with various adenovirus strains developed respiratory signs and lesions, and those infected with infectious bursal disease virus and *E. coli* without adenovirus did not (14). Infectious bronchitis virus exacerbated the infectious bursal disease virus-induced suppression of opsonization by *E. coli* antibody in chickens (47). Control of infectious bursal disease in the field is an essential factor in controlling respiratory disease in broilers.

The association between signs and mortality of colibacillosis in turkeys and the presence of hemorrhagic enteritis lesions and viruses in the spleen led to the hypothesis that hemorrhagic enteritis infection often exacerbates colibacillosis (64). This association was subsequently proved in laboratory challenge studies (40). Inclusion of hemorrhagic enteritis virus along with *E. coli* challenge has been useful for the induction of colibacillosis in laboratory studies (49). Control of hemorrhagic enteritis is considered to be an essential factor in controlling colibacillosis in turkeys.

Although Marek's disease herpesvirus is well known as an immunosuppressive agent, its role in respiratory disease has not been extensively studied. Chickens infected with Marek's disease virus, however, did not respond as well serologically to *M. synoviae* as chickens that were not challenged (35). Marek's disease virus infection may also enhance the virulence of *Cryptosporidium baileyi* (1, 2).

Chicken infectious anemia virus is also recognized as an immunosuppressive agent that may be a risk factor in respiratory and other diseases (26) and may be involved with interfering with vaccinal Newcastle disease antibody production in the field (55).

Role of Environmental Factors

It is evident that environmental factors play a significant role in interacting with infectious agents in the production of respiratory disease in poultry, but there are relatively few published studies of such interactions. Environmental factors that have been studied include atmospheric ammonia, dust, and temperature. Chickens and turkeys continuously exposed to 20 ppm of ammonia showed gross or histologic signs of damage after 6 weeks of exposure, and exposed chickens were more sensitive to infection with NDV (7). Turkeys exposed to 10 or 40 ppm of ammonia had deterioration of their normal mucociliary apparatus, excessive mucus production, matted cilia, and deciliation in tracheal tissue (44) and exhibited impaired clearance of *E. coli* from air sac, liver, and lung (45). Chickens exposed to 70 or 100 ppm of ammonia for 4 days exhibited increased thickness of atrial walls and shrinking air capillaries in their lungs (6). Ammonia levels of 25 or 50 ppm resulted in reduced body weights, feed efficiency, larger lung size, and increased airsacculitis in chickens challenged with IBV (38).

Atmospheric dust has also been shown to have a detrimental effect on the response to respiratory infections. Atmospheric dust

significantly increased the severity and incidence of air sac lesions in turkeys with high or low rates of infection with *M. meleagridis* (8). In a broiler house study, losses from colisepticemia generally peaked 1 week after coliform numbers peaked in dust samplings (11). More microscopic lesions in the bronchi were observed when chickens were kept at 27°C than at 16°C. It was postulated that this may have been due to mouth breathing rather than the higher dust levels in the air of the warmer rooms (58).

Hatchery fumigation of day-old chicks may damage the tracheal epithelium (15, 62), possibly increasing susceptibility to early respiratory disease.

Respiratory disease and airsacculitis condemnations are well known to increase during the winter months, but there have been few studies on the effects of temperature on susceptibility to respiratory disease. Chickens challenged with *M. synoviae* and IBV had more extensive air sac lesions when housed at temperatures of 7–10°C than when housed at 29–24°C or 31–32°C (76).

A common observation is that increasing "down time" between broiler flocks has a beneficial effect on reducing respiratory and other diseases. In a recent field study in Delmarva, larger flock sizes were associated with increased early respiratory disease, and increased down time decreased early respiratory disease (66).

Vaccination Reactions

Protection of chickens and turkeys against viral respiratory diseases is dependent upon the widespread use of live respiratory virus vaccines. The live respiratory virus vaccines that have been most widely used are ND vaccines and infectious bronchitis vaccines. Among the live ND vaccines, there are naturally occurring apathogenic strains such as VG/GA, Ulster, and QV4, naturally occurring mild respirotropic lentogenic strains such as B_1 and LaSota, and very limited use of mesogenic strains. Live infectious bronchitis vaccines are typically chicken embryo-passaged field IBV isolates. Chicken-embryo passage is used to attenuate the virulence of virulent field IBV isolates. A single IBV isolate, for example Massachusetts 41, may be available as a live vaccine at several different embryo passage levels (virulence attenuation levels).

All of the live respiratory viral vaccines replicate in the bird and cause some degree of cell damage. The clinical manifestation of this viral replication, and its resultant pathology, is called the "vaccination reaction." The live respiratory virus vaccines are intended to induce an immune response while inducing only minimal pathology or a minimal vaccination reaction in a healthy bird in a good environment. A normal vaccination reaction for IBV or NDV should become clinically apparent 3–5 days after vaccination and should persist for an additional 3–5 days. If the vaccination reaction appears clinically to be unusually severe or prolonged, it is often referred to as a "rolling" vaccination reaction or, more simply, as a severe vaccination reaction.

Severe or prolonged vaccination reactions following the use of live ND or infectious bronchitis vaccines are a very common occurrence in the commercial poultry industry. Most typically, flocks that undergo a severe vaccination reaction develop respiratory col-

ibacillosis. The pathogenesis of this complex disease interaction follows the same pattern described for the interaction of virulent wild respiratory viruses with *E. coli* (63, 77). Most poultry health specialists agree that respiratory disease that results from the interaction of viral respiratory vaccine viruses with *E. coli* is the most common respiratory disease of commercial poultry.

Several different sets of circumstances can culminate in a severe respiratory vaccination reaction, although regardless of the inciting factors, severe respiratory reactions typically culminate in the development of respiratory colibacillosis. Immunosuppression has been demonstrated to enhance the ability of pathogens to induce disease (18, 22). Likewise, immunosuppression can impede a bird's ability to limit replication of a respiratory virus vaccine, allowing a severe vaccination reaction. Several modified live virus vaccines containing infectious bronchitis virus interfere with the ability of the gland of Harder and head associated lymphoid tissues to respond to antigenic stimulation (43). Short-term nonspecific immunity against *E. coli* induced by intravenous inoculation of inactivated bacteria or silver nitrate is suppressed by cold stress or by treating with corticosterone (41).

Vaccinating birds with respiratory virus vaccines whose respiratory tracts are contaminated with other pathogens can produce a severe vaccination reaction. The most noted examples are *M. gallisepticum* and *M. synoviae* (10). Birds contaminated with *B. avium* or *E. coli*, however, fit a similar pattern. Newly hatched chicks that have hatched in an environment heavily contaminated with *E. coli* may develop severe respiratory reactions when vaccinated at a young age with live ND or infectious bronchitis vaccines.

Some live ND, infectious bronchitis, and infectious laryngotracheitis vaccines may become more virulent if allowed to spread from bird to bird (17, 25, 29). This vaccine "backpassage" can occur in commercial poultry houses if only a portion of the birds are provided with an immunizing dose of the vaccine and the remaining birds in the house become infected by spread of vaccine virus. This type of vaccine reaction appears to be both prolonged in duration and of increased intensity.

Environmental factors can influence the intensity of a vaccination reaction. As discussed previously, ammonia and dust can interact with respiratory pathogens to enhance the severity of disease (38). This interaction is similar with respiratory vaccine viruses. Improper application of viral respiratory vaccines can enhance the severity of vaccination reactions. Spray application with a very fine spray can allow access of vaccine virus to the deep respiratory tissues and result in excessive viral replication in lungs and air sacs in addition to eliciting a stronger immune response (72). Aerosol vaccination also resulted in more severe airsacculitis after challenge with *M. synoviae* (73). Improper application of vaccines in the drinking water can prevent all birds in a house from receiving an immunizing dose of vaccine, thus providing an opportunity for spread of vaccine virus with a concomitant increase in virulence of the virus.

Because respiratory vaccine viruses of various virulence levels are available, it is important to use the proper vaccine for specific conditions. Typically, very young birds are vaccinated with highly attenuated vaccine viruses, and less attenuated vaccine viruses are used in older birds and in birds that have been previously immunized. Severe vaccination reactions can occur, for example, if chicks are vaccinated at the hatchery with a live ND or infectious bronchitis vaccine intended for use in older birds.

Multicausal Enteric Diseases

Donald L. Reynolds

Introduction

The intestinal tract is a highly complex system that has numerous functions and integrates with other body systems and their functions. The intestinal tract provides the mechanism(s) by which the body can derive nutrition from its environment while simultaneously safeguarding the host. The enteric tract itself serves as an environment for other living organisms. The pathogenesis of an enteric disease is a complex entity. Likewise, the etiology of an enteric disease may be as equally complex. Combinations of, and interactions between, different viruses, bacteria and other infectious and noninfectious agents may be necessary to elicit an enteric disease or increase / decrease its severity. Similarly, combinations of, and interactions between, the intestinal tract and other body systems may not only increase / decrease the severity of enteric disease but may play key roles in the treatment, alleviation or modulation of the disease process.

Etiologies

Rarely, is a single agent the sole contributing factor of an enteric disease. Although an agent may be identified / diagnosed as the primary agent or cause of an enteric disease, other agents and factors usually contribute to the pathogenic process of the diseased intestine. Similarly, when an agent is isolated and introduced into a susceptible host under experimental conditions, the resulting disease may not be representative of the same infection caused under field conditions. Many viral agents have been reported to infect poultry, and many have been associated with enteric disease conditions. The reader is referred to Chapter 12 for a review of these viruses. There have also been reports revealing that more than one virus can infect a host or flock either simultaneously or within a narrow period of age (22,23, 26).

The exact role each infectious agent plays in inducing enteric disease either by itself, or in combination with other agents, is not well understood. For example, it has been reported that when turkey poults were inoculated with enteric coronavirus, the result was either no clinical disease, or a mild disease was induced. Similarly, when the poults were inoculated with a strain of enteric *E. coli*, a mild to moderate enteric disease was induced. However, when this same virus was inoculated in combination with the same bacteria (i.e., *E. coli*) the resulting disease was severe with increased mortality, increased growth depression, and more severe intestinal lesions (10). Similarly, studies exploring the interactions of torovirus and bacteria in turkey poults have been reported (2). In these studies, turkey embryos were first inoculated with turkey torovirus and then at 24–36 hours postinoculation were inoculated with different bacteria. Live and inactivated (with ultraviolet radiation) *Escherichia coli* strains (one strain was isolated from the intestines of normal turkeys, and the other was the pathogenic strain O157:H7), *Streptococcus faecalis* and *Campylobacter jejuni* were used. Both live and inactivated *E. coli* and *S. faecalis* bacterial isolates did not cause lesions or disease in the intestines of dually inoculated embryos. However, when turkey torovirus inoculated embryos were inoculated with live *C. jejuni*, there was a significant increase in intestinal disease. Embryos co-inoculated with virus and UV inactivated *C. jejuni* did not cause increase in intestinal disease. Embryos inoculated with live bacteria alone did not experience any intestinal disease and were similar to embryos that were inoculated with sterile tryptose phosphate broth. It was concluded that the outcome of enteric disease during dual infection largely depends on the agents involved and that the bacteria must be live in order to produce the effect. Another example of interactions between enteric agents was illustrated in a study in which marble spleen disease virus, used as a vaccinating agent against hemorrhagic enteritis, was administered concurrently with the coccidium *Eimeria meleagrimitis* (19). This combination of agents resulted in an exacerbation of the pathogenic effect attributed to the vaccine virus. Paradoxically, results from the same study revealed that when *E. meleagrimitis* was administered concurrently with virulent HEV, the pathogenic effect attributed to the virulent HEV virus was diminished.

The observation that more than one infectious agent, noninfec-

tious agent and / or host response may be involved in eliciting an enteric condition has prompted the use of the term multifactorial disease. In turkeys, a multifactorial enteric disease of young poults is described as poult enteritis–mortality syndrome or PEMS. PEMS has been thoroughly described in a previous edition of this textbook (6). In broiler chickens, a multifactorial enteric disease of young chicks has commonly been referred to as malabsorption syndrome. Like PEMS, numerous infectious agents have been incriminated in malabsorption syndrome of broilers (28). Both PEMS in turkeys and malabsorption syndrome in broilers still occur, are problematic for producers, are infectious and the etiology has not been determined.

Pathogenesis

The mechanism(s) by which infectious agents cause enteric disease has been reviewed by Moon (17). In his review, Moon elucidated the mechanisms that produce diarrhea. Four categories, or principal mechanisms, were identified. The first was hypermotility and was defined as the increase in intensity, frequency, or rate of intestinal peristalsis that leads to the accelerated transit of ingesta or intestinal contents through the intestines. It was also noted that decreased motility occurs in some diarrheal diseases and that alterations in motility may be an indirect effect of the enteric disease process instead of the primary cause. An alteration in intestinal permeability was identified as another mechanism of diarrhea. When alterations occur in intestinal permeability that allows the net secretion to exceed absorption, the result is increased fluid within the lumen of the intestinal tract, resulting in diarrhea. Hypersecretion was identified as the third mechanism of diarrhea. Hypersecretion was defined as the net intestinal efflux of fluid and electrolytes into the intestinal lumen that occurred despite changes in permeability, absorptive capacity, or osmotic gradients. It was further noted that mature intestinal epithelial cells, which line the distal portion of the villi, are responsible for the absorptive capacity of the intestine; whereas, the immature crypt cells are responsible for secretion. Therefore, alterations in the balance of these cells can contribute to diarrhea. For example, loss of mature cells alters the absorptive capacity and often stimulates the formation of new immature cells to replace the lost cells, thereby altering the ratio of mature to immature cells in favor of the secreting immature cells. The net result is secretory diarrhea.

Additionally, Moon reported on the effects of certain bacterial toxins that stimulate secretion of the crypt cells beyond the absorptive capacity of the mature intestinal epithelial cells that results in diarrhea. The mechanism by which bacterial toxins produce secretory diarrhea has also been observed with some enteric viruses. In the case of rotaviruses, a nonstructural viral protein (termed virotoxin) was found to be the cause of diarrhea (4, 5, 9, 11, 18).

Malabsorption was the fourth mechanism identified by Moon. Malabsorption is the process by which the absorptive capacity of the intestines is altered. This may be due to impaired absorptive capacity such as loss of mature epithelial cells. However, malabsorption is often a sequela of maldigestion because the undi-

gested feedstuffs cannot be absorbed (even though the absorptive capacity of the intestines is not impaired). In cases of malabsorption / maldigestion, nutrients within the intestinal lumen may contribute to the diarrhea by creating an osmotic effect. As is pointed out by Moon, agents that produce diarrhea are not restricted to inducing only one mechanism, but generally a combination of these various mechanisms occur.

The involvement of immune cells, and/or their products, in inducing diarrhea and enteric disease is well established. It has been reported that cytokines such as interleukins IL-1 and IL-3 (7) contribute to hypersecretion in chickens. IL-4 has been reported to influence epithelial cells and increase secretion (8). Various cytokines and biochemical mediators have been implicated in inflammatory processes leading to enteric disease and diarrhea (27). Powell suggests a neuroimmunophysiologic paradigm describing a generic model for all forms of infectious diarrhea (20). In his model, cytokines liberated from intestinal epithelial cells affect various other cells including immune cells, nerve cells, intestinal mesenchymal cells, etc. The end results include crypt hyperplasia, hypersecretion, malabsorption, alterations in permeability, etc., with the final sequela being diarrhea. It was also pointed out that this is a host defense mechanism, and although there may be points to intervene and counter the process, one must be careful not to further jeopardize the host by overzealous intervention strategies. There has been increased evidence supporting the role of the enteric nervous system (ENS) in inducing diarrhea (12). The role of the ENS has been explored with regards to bacterial and viral infections (toxins) (13,14).

In view of the aforementioned information, it was hypothesized that immune cells (or their products) may play an important role in contributing to the pathophysiology of enteric viral infections of turkeys and that the ENS may also be involved (Reynolds and Ali, personal communication). To test the hypothesis regarding immune cell involvement, turkey embryos were injected with supernatants from cultures of turkey peripheral blood lymphocytes (from normal, healthy, uninfected turkeys) that had been stimulated with conconavalin A (Con A) or with sterile media (negative control). Other embryos were injected with torovirus to serve as a positive control. Embryos injected with the Con A stimulated PBL supernatants had accumulation of fluid in the intestinal tract and decreased maltase activity that was nearly identical to the torovirus infected embryos. These studies provided evidence that products of immune cells can cause a disease in embryos that is very much like torovirus infection (1, 2, 3). Following these experiments, turkey embryos were injected with cyclophosphamide to render them immune deficient (24). The immune competent (untreated) and immune deficient (cyclophosphamide treated) embryos were inoculated (by the amniotic route) with either torovirus or with sterile media. As expected, the torovirus infected immune competent embryos developed fluid accumulation in their intestines and had decreased maltase activity as compared to noninfected control embryos. However, torovirus infected immune deficient embryos had little, if any, accumulation of fluid in their intestines, and their maltase activities were not decreased. Torovirus infection, in both the immune competent and immune deficient infected embryos, was confirmed by FA staining of the

intestines (25). These studies provided further evidence that some enteric viral diseases of poultry may be a manifestation of immune cells and / or their products. To test the hypothesis regarding the role of the ENS in torovirus infections, lidocaine (a neural blocker) was injected into embyros at 48 hours and 72 hours following torovirus. It was found that the embryos that received lidocaine had a decreased secretory response (i.e., less fluid accumulation within the intestines) than those embryos that did not receive lidocaine. These results support the involvement of the ENS in diarrheic disease caused by torovirus and provide a basis for further exploring the neuroimmunophysiologic paradigm proposed by Powell for poultry. As is pointed out by Powell and others (15, 16), the relationships between infectious enteric agents, various cells, cell mediators, and body systems are extremely complex and integrated.

More recent studies have shown a role of the immune response in eliciting enteric disease in broiler chickens with malabsorption syndrome (MAS) (21, 29, 30, 31). There is evidence to indicate that a variety of immune cells, including numerous types of T cells and heterophils are involved (29, 31). Additionally, the ability to genetically select broiler chickens that are less susceptibility to MAS may be closely linked to the genetic expression of immune cells and their products (29).

Continued efforts to delineate the various factors will be needed to identify strategies for the control and remedy of diarrheic diseases. Future strategies for controlling enteric diseases may rely on drugs and biologics that may modulate the immune and neurologic component of the disease in addition to those treatment regiments directed toward specific pathogens.

Hypoglycemia-Spiking Mortality Syndrome of Broiler Chickens

James F. Davis

Introduction and History

Hypoglycemia-spiking mortality syndrome (HSMS) is a disease of uncertain, but probable, infectious etiology, characterized by low morbidity and abrupt onset of high mortality (>0.5%) for at least 3 consecutive days with concurrent hypoglycemia in clinically affected birds. Seven-day-old to 14-day-old broiler chicks are usually affected (1); however, it is also frequently diagnosed in 14- to 21-day-old chicks, and the disease has been identified in commercial broilers as old as 42 days (4). Clinical signs include fine head tremors, apparent blindness, ataxia, and coma. Recovery often occurs spontaneously, but rickets and runting-stunting frequently develop in survivors.

Hypoglycemia-spiking mortality syndrome was first recognized in broiler flocks on the Delmarva Peninsula in the United States, in 1986 (3). The disease was subsequently described in 1991 (1) from 41 flocks with naturally occurring disease and 3 flocks with experimental disease. Occurrence of the disease has declined in the Delmarva area but subsequently has increased in the southeastern United States and other areas of the world.

Because the etiology is unknown and there is no specific identifying characteristic of the disease other than severe hypoglycemia, which makes only a clinical definition possible, and because young broilers experience infections with a variety of agents, the relationships among various outbreaks of HSMS remain uncertain. Two clinical forms of the disease have been identified. Type A, which was initially described, is more severe but of shorter duration than type B, a milder form occurring over a longer period, which was identified later (3). This suggests that either HSMS is one disease caused by a specific etiologic agent that occurs in different forms (possibly because of additional modifying factors) or that similar clinical diseases result from different causative agents.

Incidence and Distribution

Hypoglycemia-spiking mortality syndrome has been reported in Canada, Colombia, Europe, Great Britain, Guyana, Jamaica, Malaysia, Puerto Rico, South Africa, Thailand, Trinidad, and the United States. Although broiler chicks are most commonly affected, broiler breeder replacements and leghorns are also susceptible.

Etiology

The etiologic agent(s) of HSMS has not been identified conclusively. A serotype-12 avian adenovirus isolated from affected flocks was pathogenic for embryos and chicks but did not cause HSMS (15). Inclusion body hepatitis caused by an adenovirus was identified in a broiler flock with excess mortality and hypoglycemia (12). However, evidence for adenovirus infection in other flocks with HSMS has not been found (1, 4, 7, 8, 9).

Oral inoculations of unprocessed fecal-intestinal-saline homogenates, fecal-saline homogenates passed through 0.45-mm filters, or crude brain-phosphate buffered saline homogenates from affected chicks have been used to reproduce the disease in susceptible chicks (6, 7, 9). Hypoglycemia-spiking mortality syndrome has also been reproduced using 1) virus-like particles extracted from intestines of affected chicks and banded in a discontinuous Renograffin gradient, or 2) filtered (0.22-mm porosity filter), homogenized, dead specific-pathogen-free (SPF) embryos, which had been inoculated via the yolk sac route with the Renograffin-banded particles 72 hours earlier (8). Recently, crude pancreas homogenates have also been used to reproduce HSMS (4).

These findings indicate that at least one type of HSMS appears to be caused by an infectious, filterable agent, which may be replicated in SPF chicken embryos via the yolk sac route of inoculation (8). Attempts to replicate the agent in cell cultures have been unsuccessful (4). The agent has yet to be identified, but has no known public health significance. Arkansas strain of infectious bronchitis virus (IBV) and avian encephalomyelitis virus have been identified in some of the inocula used to reproduce HSMS experimentally (4, 8). The significance of these 2 common viral agents of chickens in the disease is currently unknown. Because particles similar to arenaviruses have been found by direct EM in droppings from affected chicks, immunohistochemistry (IHC), using polyclonal antibodies against New World and Old World arenaviruses, has been used to examine formalin-fixed tissues from naturally and experimentally infected chicks. Positive staining was found in the cytoplasm of pancreatic islets (Fig. 33.1) and acinar cells, Purkinje cells, neurons, hepatocytes, Kupffer cells, macrophages, histiocytes, and fibroblasts of infected birds but not in these cells of uninfected, matched controls (6, 7, 8). SPF embryos, inoculated via the yolk sac with Renograffin-banded virus-like particles 72 hours previously, were also IHC-positive (8). Specificity of the IHC reaction in these HSMS-infected embryos and chicks still needs to be determined. It is possible that the antibodies are cross-reacting to an epitope that is present on both arenaviruses and another un-
Fig. 33.1. Sections of formalin-fixed pancreas from experimentally-infected 14-day-old broiler chicks with severe HSMS, processed for immunohistochemistry (IHC). Antibody was Mouse Ascites Fluid, anti-Tacaribe (ATCC, Rockville, MD, 20852). Counterstain was Nuclear Fast Red (Sigma). Positive staining was enhanced with nickel chloride. Note the IHC positive staining (black) in pancreatic islets. The same tissues were IHC negative using negative control Mouse Ascites Fluid (ATCC, Rockville, MD 20852), and sections of pancreas from uninfected control chicks were also IHC negative.

identified agent(s). IHC (on the tissues positive with arenavirus antibodies) was negative using 2 monoclonal anti-IBV antibodies and a polyclonal antibody produced against turkey coronavirus (4).

To reproduce HSMS, 1-day-old to 2.5-day-old chicks are inoculated orally. Approximately 2 weeks later, chicks are fasted for 2–6 hours and, in some cases, sprayed with a cool (25°C) water mist to cause mild stress. Clinical signs of HSMS begin 1.5–4 hours after fasting and stressing. Plasma glucose levels are severely depressed in affected chicks; occasionally as low as 17 mg/dL. Unexposed controls remain unaffected by fasting and stressing, and plasma glucose levels remain greater than 150 mg/dL (7, 8, 9).

Hypoglycemia-spiking mortality syndrome also resulted when

birds were fed darkling beetles (*Alphitobius diaperinus*) collected from built-up litter on farms where the disease had occurred repeatedly (8). Whether beetles or other similar insects may serve as mechanical or true vectors of the agent(s) causing HSMS is still unknown.

Other factors, which some have suggested contribute to HSMS, are certain diets, especially ones with high amounts of animal by-products labile to oxidation. In the initial publication on HSMS, an all-vegetable diet was described which resulted in the highest mortality and a marked increase in susceptibility to *Escherichia coli* septicemia (3). Management errors that would lead to birds being without feed or cause them to experience other stressful events will precipitate HSMS in infected birds. Although mycotoxins or other toxic substances might be suspected in the disease because of its abrupt onset and high mortality, these substances have not been identified in affected chicks (3). Feeding cockleburs (*Xanthium* spp.) to chicks did not cause clinical disease or hypoglycemia (11).

Pathogenesis and Epidemiology

Clinical signs include huddling, trembling, blindness, loud chirping, litter eating, ataxia, prostration with outstretched legs, and coma. Rapidly growing males in good condition are often most affected (3). Chicks may or may not have diarrhea, but orange mucoid droppings are commonly found.

Gross lesions are nonspecific. Rarely, hemorrhage and necrosis are evident in the liver. There are changes consistent with mild enteritis, especially excess fluid accumulation in the lower intestines and orange mucoid enteritis in the jejunum. Similarly, microscopic changes are nonspecific and consistent with those expected from the gross lesions. Chicks with gross liver lesions have necrotic hepatocytes secondary to fibrinoid necrosis of hepatic arteries (1, 6, 8). Rarely, similar vascular changes also can be seen in the intestines and gut-associated lymphoid tissue. Rickets and severe lymphoid depletion/necrosis of the bursa of Fabricius have also been observed in affected chicks (1), although these lesions have been rare in more recent cases (4, 6, 7, 8, 9).

Experimentally, the disease seems to have a 10–12-day incubation period. At this time, chicks begin passing wet droppings containing undigested feed and they huddle together. If chicks are not fasted or stressed, this digestive disorder and the runting-stunting sequelae associated with it may be the only clinical signs seen. Surviving chicks often remain permanently stunted (7). Plasma from stunted or hypoglycemic chicks is often colorless or pale yellow compared with the deep yellow color of plasma from unaffected controls (8). Insulin-like growth factor-1 (IGF-1), a growth-related hormone (18, 20), is significantly depressed in affected chicks (7).

Acutely hypoglycemic chicks, both from the field (5) and from experimental trials (4), have significantly depressed pancreatic glucagon levels. Pancreata from these chicks are histologically normal with no evidence of cell necrosis. It has been theorized that the apparent viral infection of pancreatic islets in HSMS-affected chickens is responsible for blocking the production of pancreatic glucagon without histologically damaging the glucagon-producing islet cells (5, 7). This effect has been reported with certain arenavirus infections in other species that involve different hormone producing cells (2, 10, 16, 17, 19).

Stress and acute fasting trigger the glucagon-glycogen pathway (glycogenolysis) to maintain adequate blood glucose levels (13, 14). If chicks are deficient in glucagon and/or glycogen, they can rapidly become hypoglycemic. Chicks with HSMS are deficient in both glucagon (5) and glycogen (4, 8), which makes them extremely susceptible to development of hypoglycemia when acutely fasted and/or stressed.

Diagnosis

A high spike in a mortality curve at 7–21 days of age is suggestive but not diagnostic for HSMS. Varying numbers of chicks may be affected, or a high mortality spike may be caused by some other condition. Diagnosis of HSMS is based on the typical clinical findings and demonstrating hypoglycemia (blood glucose <150 mg/dL) in affected chicks. Plasma and/or whole blood can be used for glucose determinations; plasma levels determined with a chemical analyzer are considered to be most accurate. However, glucose test strips can be used in association with a hand held monitor (FreeStyle Blood Glucose Monitoring System, TheraSense, Inc.—Abbott Diabetes Care, Inc., Alameda, CA, 94502) as a fairly accurate screening method for determining blood glucose levels in the field or the laboratory (4). Severely affected chicks typically have blood or plasma glucose levels between 20 and 80 mg/dL. Fasting alone will not result in hypoglycemia in uninfected chicks.

Treatment, Prevention, and Control

There is no specific treatment for the disease. Supportive care based on minimizing stress due to excessive heat, cold, ammonia, poor ventilation, noise, or feed and/or water deprivation is the most important factor (4). Affected chicks should be left alone and allowed to rest as much as possible in good environmental conditions with continuous availability of feed and water. Multiple vitamins, electrolytes, and liquid vitamin E have been used successfully to reduce mortality (3, 4).

Controlled light-dark exposure programs prevent HSMS, both in the field and experimentally (8). Light-dark programs have been used successfully in the prevention of HSMS worldwide in broilers fed a wide variety of diets (4). The physiologic basis for this is attributed to melatonin release and a shift from glycogenolysis to gluconeogenesis by the birds exposed to darkness. Control of darkling beetles is important in preventing carryover of HSMS from one flock to the next. Vaccination of broiler breeder hens with an experimental formalin-inactivated autogenous vaccine produced from SPF embryos inoculated with the fourth egg passage of Renograffin-banded virus-like particles (designated The Oakwood Agent) failed to provide protection against experimental challenge of progeny from the hens (4, 7, 8). Experimental trials with "live" vaccines have not yet been attempted.

Proventriculitis and Proventicular Dilatation of Broiler Chickens

Scott Hafner, Mark A. Goodwin, James S. Guy, and Mary Pantin-Jackwood

Introduction

Definition and Synonyms

Proventriculitis is a microscopic diagnosis characterized by the presence of inflammation in this organ. Transmissible viral proventriculitis (TVP) is an infectious, transmissible viral disease of chickens that results in enlarged, fragile proventriculi. TVP is characterized by specific microscopic changes that include glandular epithelial (oxynticopeptic) cell necrosis, ductal epithelial cell hyperplasia, and inflammation where lymphocytes predominate (2,3,11,13,19,30,33). Experiments show that TVP can be transmitted to both broiler and specific-pathogen-free leghorn chickens by a filterable agent that appears to be a non-enveloped virus (13,33). Differential diagnoses for TVP include proventriculitis caused by the ingestion of toxins such as biogenic amines, copper sulfate, or mycotoxins (4,6,17,32,36,37) or proventriculi-

tis associated with the finding of infectious agents that include bacteria, fungi, cryptosporidia, and viruses (1,5,8,10,15,16,22, 25,28,40,42,43). In contrast, proventricular dilatation is characterized by an enlarged, but thin-walled proventriculus with no microscopic evidence of inflammation. The dilated proventriculus generally is accompanied by a small ventriculus (gizzard) and these changes are physiologic responses to diets that are low in fiber (26,34,38).

Economic Significance

Chickens affected by TVP may cost more to produce than unaffected chickens due to poor food digestion, poor feed conversion, and stunted growth (7,11,15,19,24,33). Rupture of the proventriculus or gastric isthmus during carcass evisceration results in carcass contamination and significant economic loss (13,15,23, 28,29,31).

Public Health Significance

When chickens with either proventriculitis or proventricular dilatation are slaughtered and processed there may be contamination of the carcass and processing equipment with ingesta or intestinal contents (2,13,15,31). Increased reprocessing and condemnation costs are incurred in an effort to remove potential human pathogens (23,39).

History

Proventricular dilatation (enlargement of the proventriculus without inflammation) was first described in chicks that were fed a purified ration (26), and later described in commercially raised broiler chickens that were fed a ration low in fiber. In these chickens the proventriculi were dilated and thin-walled and gizzard musculature was underdeveloped (34). Later, it was discovered that proventricular enlargement, with inflammation, could also be induced in chickens that were fed toxins such as biogenic amines (36), copper sulfate (32), and mycotoxins (6). A transmissible proventriculitis that produced a runting syndrome affecting broilers was first identified in Holland (19). A similar syndrome associated with stunted growth and proventriculitis was then described in the United States of America (27) and later recognized in Australian broiler chickens (33). Other features of this illness included whole-body pallor, fragile proventriculi, a dilated and weakened gastric isthmus, poor feed conversion ratios, and the passage of undigested or poorly digested feed in the feces (7,9,11,13,15,24,31,33). In an examination of field cases of proventriculitis in the USA, Goodwin *et al.* (11) identified 60–70 nm adenovirus-like viruses in the nuclei of degenerating alveolar epithelial cells, leading to the designation of this condition as transmissible viral proventriculitis (12).

Incidence and Distribution

Definitive prevalence data regarding the global incidence and distribution of proventriculitis and proventricular dilatation are not available. However, with regard to TVP, a single study in the USA identified the typical microscopic lesions of this disease in nearly half of the broiler chicken proventriculi examined microscopically (11). A similar proventriculitis had been previously identified in Holland (19,20,21) and has been more recently described in Australia (33).

Etiology

Classification

The cause of TVP is a virus that has not been conclusively characterized. Some investigators have identified a distinctive adenovirus-like virus in naturally occurring (11,33) and experimentally induced TVP (13). PCR examination of nucleic acids extracted from this virus using primers specific for group I, II, and III avian adenoviruses did not result in an amplified product (13).

Morphology

In some thin sections of proventriculi affected by TVP, distinctly hexagonal (icosahedral), nonenveloped virions (average particle size 65–70 nm) have been identified in the nuclei of glandular epithelial cells (11,13). Virions of a similar size and shape also have been detected in proventricular glandular epithelial cells of some Australian chickens affected by TVP (33) and similar, but larger (100 nm) hexagonal virions have been noted in experimentally infected chickens (15). In glandular epithelial cells with fragmented nuclei, virions were present in the cytoplasm associated with unbound condensed chromatin (11).

Laboratory Host Systems

Chickens commonly have been utilized as laboratory host systems for TVP. The disease has been experimentally reproduced by inoculation of SPF and commercial broiler chickens with filtered or nonfiltered homogenates of proventriculi collected from TVP-affected chickens (2,13,15,29,30,31,33). An adenovirus-like virus associated with TVP has been isolated from the proventriculi of TVP-affected chickens by sequential passage in SPF embryonated chicken eggs inoculated via the amnionic route, but attempts at culturing this virus on confluent cell culture monolayers have not been successful (13).

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Naturally occurring TVP has only been reported in commercially-raised broilers; however, the disease is transmissible to both broilers and SPF leghorns (2,13,15,29,30,31,33).

Age of Host Commonly Affected
TVP is primarily a disease of young (3–8 week old) broiler chickens. The disease has been reported to occur most commonly in 4–5 week old chickens (2); however, in some experimental studies, the highest lesion prevalence was observed 4 weeks after inoculation (33). In two separate studies, broiler chicks inoculated at 1 day of age and SPF chickens inoculated when they were 2 weeks old both developed proventricular enlargement between 1 and 2 weeks post-inoculation. The source material for these experimental studies were proventriculi obtained from 2- to 4-week, TVP-affected commercial broiler chickens (13,30).

Transmission

Routes of natural infection of TVP are not known; however, chickens can be infected experimentally by oral gavage or oculonasal instillation of either crude or filtered (0.2 μm) proventricular homogenates (2,3,13,15,19,29,30,31,33). The disease has also been experimentally reproduced using filtered proventricular homogenates that had been treated with chloroform to eliminate enveloped viruses (13,33).

Incubation Period

The incubation period of naturally occurring TVP has not been defined although grossly enlarged proventriculi have been reported in 3 week old broiler chickens with naturally-occurring TVP, but not in 1–2 week old broiler chickens (13). Experimental studies involving day-old chicks suggest that homogenates of proventriculi from these chicks were infectious 2 weeks after in-
Fig. 33.2. Proventriculus from a virus-infected broiler chick is enlarged and mottled gray-white-yellow. Close examination of the serosal surface reveals numerous polygonal pale foci that represent enlarged individual glands (inset).

oculation (33). In some studies proventricular enlargement occurred within 10 days post-inoculation (13).

Clinical Signs

The predominant signs in chicks with TVP include stunted growth, pallor, unthriftiness, and passage of undigested or poorly digested feed in their feces (11). Naturally occurring cases are associated with poor flock production performance data (9,33). No clinical signs are apparent in chickens with proventricular dilatation (38).

Morbidity and Mortality

There is no increased mortality in TVP affected flocks (33), but an estimated 1% may require reprocessing due to carcass contamination at slaughter (39).

Pathology

Gross Lesions

Chicks with naturally-occurring or experimentally-induced TVP may be significantly smaller than their uninfected counterparts (7,15,33). At necropsy, the isthmus between the proventriculus and ventriculus is widened and the proventriculus is enlarged with thickened walls that are mottled gray-white-yellow (Fig. 33.2). The lobular pattern is often pronounced with each pale polygonal focus representing an individual gland (11,31,33). Some glands are distended and a viscous white material can be expressed by gentle digital pressure. The luminal mucosa may appear thickened and rugose and papillary orifices may be indistinct (Fig. 33.3).

In chickens fed excessive levels of copper, proventriculi are enlarged, walls are thick, and the mucosal lining is flattened and stippled brown-black (17). Histamine produces enlarged, flaccid proventriculi with mucosal erosions (36). Similar mucosal erosions are present in chickens exposed to some mycotoxins (6).

Fig. 33.3. The proventricular mucosa of a virus-infected chick appears thickened and rugose. Papillary orifices are not distinct.

Proventriculi from chickens that have been fed low fiber diets are dilated and thin-walled and gizzard musculature is poorly developed (34,38).

Microscopic Lesions

Light Microscopy. Microscopic lesions in TVP-affected chickens change during the course of infection. At 5 to 7 days postinfection (DPI) experimentally infected chicks exhibit acute necrosis of the glandular epithelial cells that produce pepsinogen and hydrochloric acid. The cytoplasm of these cells is amorphous, granular, or vacuolated and there are pyknotic or fragmented nuclei. In the nuclei of a few attached or sloughed glandular epithelial cells, nuclear chromatin is marginated and central areas are pale-staining, but there are no distinct hyaline or basophilic inclusion bodies. This necrosis is accompanied by accumulations of lymphocytes, macrophages, and fewer plasma cells in the adjacent connective tissue stroma (tunica propria). Collecting ducts (secondary ducts) are dilated and filled with necrotic cells (Fig. 33.4) and there may be hyperplasia of the gut-associated lymphoid tissue (GALT) that normally occurs in the proventricular glands. During the transitional stage of infection (14 DPI) there is regeneration of the glandular epithelium by a cuboidal to low columnar duct-like epithelium. In later stages, glandular epithelial cells are partially replaced by hyperplastic ductal epithelium (Fig. 33.5), and there is an accompanying lymphocytic proventri-
Fig. 33.4.   In acute naturally-occurring proventriculitis, collecting ducts (secondary ducts) are widely dilated by accumulations of necrotic alveolar epithelial cells. H&E 40×
Fig. 33.5.   In chronic lesions, there is marked hyperplasia of duct-like epithelium that extensively replaces alveolar epithelial cells with accompanying interstitial aggregates of lymphocytes and plasma cells. H&E 200×

culitis with GALT hyperplasia and occasional B cell aggregates that form germinal centers (13,30,31). In naturally-occurring and experimentally-induced disease, there may be destruction of up to 80% of the glandular epithelial cells.

Proventriculitis in chickens can occur secondary to ingestion of excessive levels of histamine with lesions consisting predominantly of mucosal erosion and edema (36). Dilated proventriculi with erosion or ulceration of the luminal mucosa coupled with submucosal inflammation are seen in chickens with experimental cyclopiazonic acid intoxication (6).

There are no light microscopic lesions in physiologic proventricular dilatation.

Electron Microscopy
In some chickens with naturally- or experimentally-produced TVP there are intranuclear hexagonal (icosahedral) viral particles (Fig. 33.6) that have been reported to range in size from 60–70 nm (11,13). Viral particles in intact nuclei tend to be larger than those found in the cytoplasm of cells with fragmented nuclei (11). Adenovirus-like viruses associated with TVP (Fig. 33.7) appear to be approximately 70 nm in diameter; these viruses resemble adenoviruses, but lack characteristic surface structures and electron-dense cores (13).
Fig. 33.6.   There are intranuclear, crystalline arrays of adenovirus-like viruses in the nucleus of a proventricular epithelial cell from an experimentally infected chick. Icosahedral, approximately 70 nm virions are present in crystalline arrays (inset). (*Avian Diseases*)
Fig. 33.7. Negatively stained viral particles from an experimentally infected chick are icosahedral and are approximately 70 nm in diameter. (*Avian Diseases*)

Immunity

Nothing is known about immunity to TVP.

Diagnosis

Isolation and Identification of Agent

Studies of TVP that used 0.2 μm filtered and chloroform-treated proventricular homogenates to reproduce the disease suggest that the etiologic agent is a non-enveloped virus (13,33). In some experiments that successfully reproduced the proventriculitis, there was no evidence of either reovirus or Newcastle disease virus (31,33). While some trials have indicated the variable presence of infectious bursal disease virus or infectious bronchitis virus (2,15,31), other studies have not detected either one (13,28,29) or both (33) of these agents. Several studies have indicated the presence of avian adenoviruses (31,33) or adenovirus-like virus particles (11,13,15).

The intranuclear 60–70 nm hexagonal (icosahedral) adenovirus-like virus identified in the proventricular epithelium of chickens naturally (11,33) and experimentally (13) infected with TVP has been successfully propagated by serial passage in embryonated eggs inoculated by the amnionic route (13).

Serology

There is no serologic test for TVP.

Differential Diagnosis

A tentative diagnosis of TVP is made on the basis of the typical microscopic lesions in the proventriculus. TVP must be differentiated from a broad spectrum of offending agents reported to cause proventriculitis or proventricular enlargement in chickens.

These include copper sulfate ingestion (3,32), dietary biogenic amines and mycotoxins (4,6,10,36,37), bacteria (10,15), fungi (10,35,40), reovirus (18,22,27), adenovirus (19,22), infectious bronchitis virus (43), tumor-inducing viruses (1,16,25,41,42), *Cryptosporidium* sp. (8), and idiopathic proliferations of cells interpreted to represent histiocytes (14). A diagnosis of proventricular dilatation relies on observing a dilated, thin-walled proventriculus without microscopic evidence of inflammation (34,38).

Treatment

There are no specific treatments for proventricular dilatation or TVP.

Prevention and Control

There are no specific prevention or control measures for TVP.

Proventricular dilatation may be prevented by ensuring proper ration formulation, specifically by providing adequate dietary fiber.

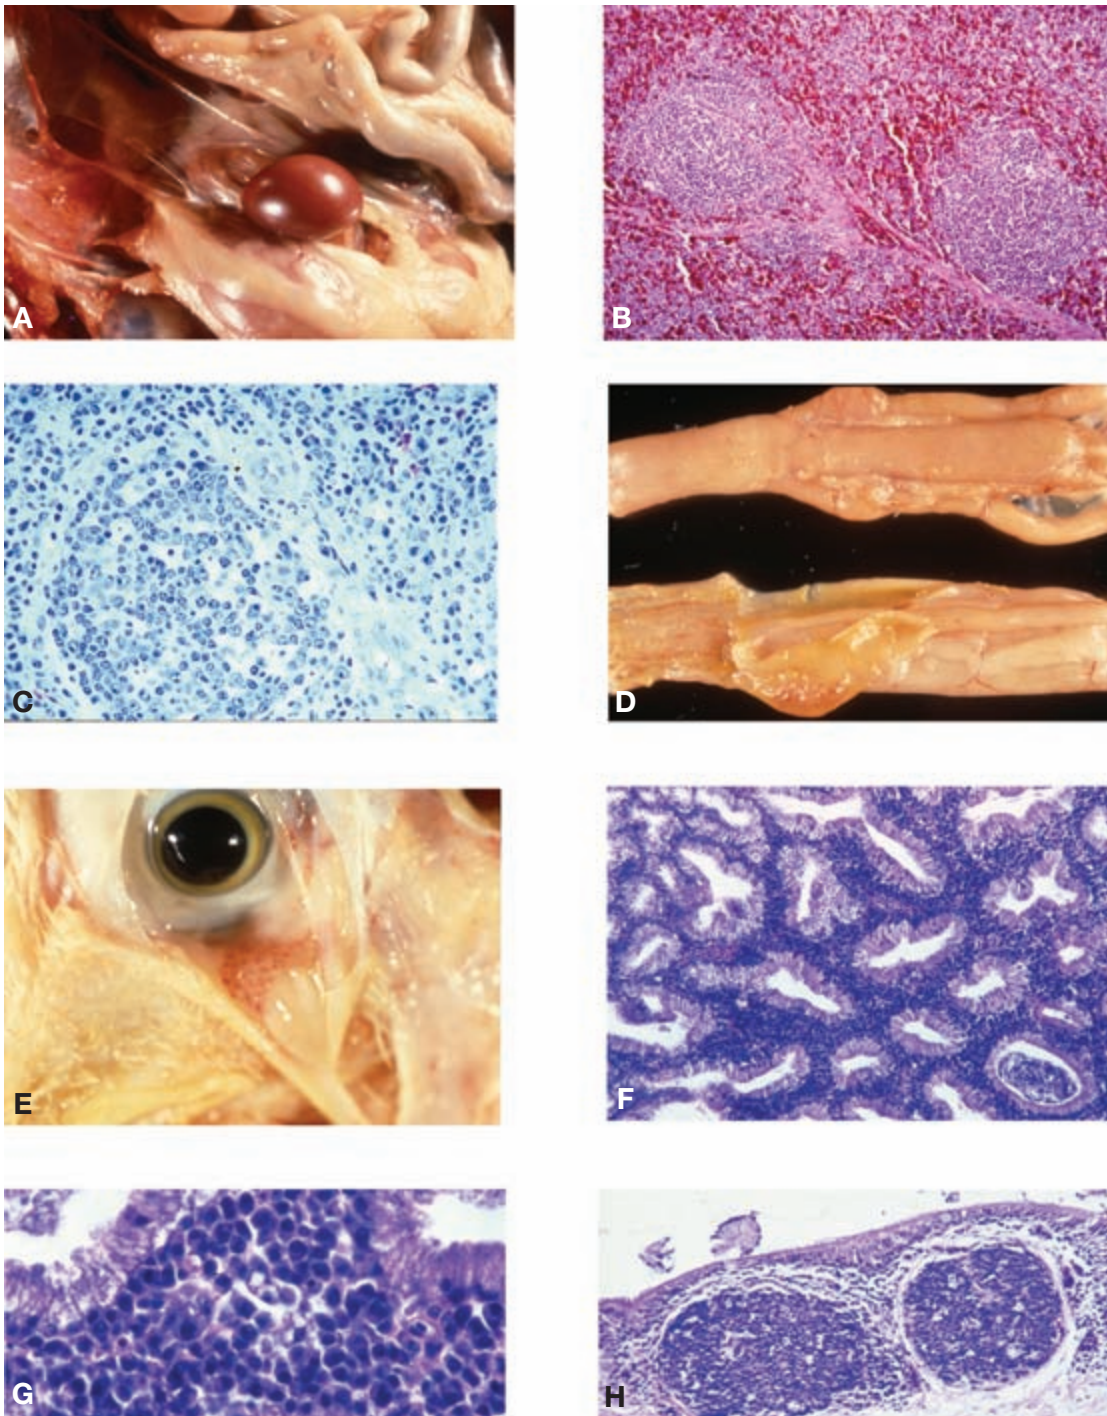
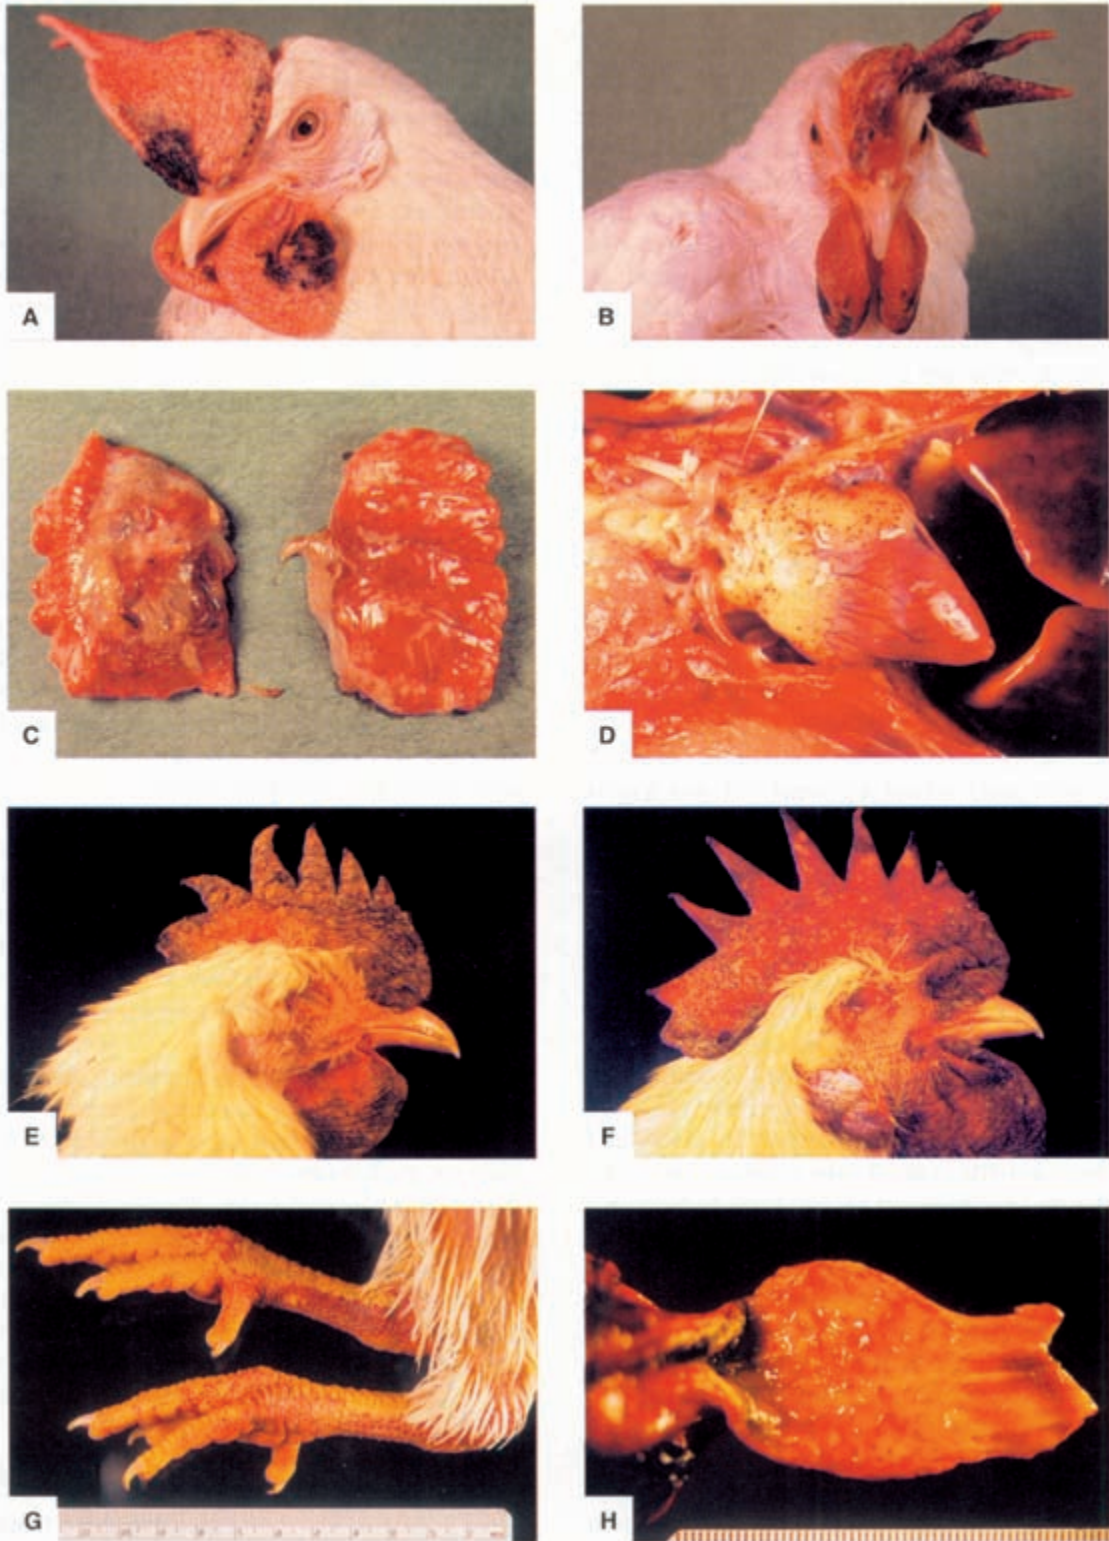
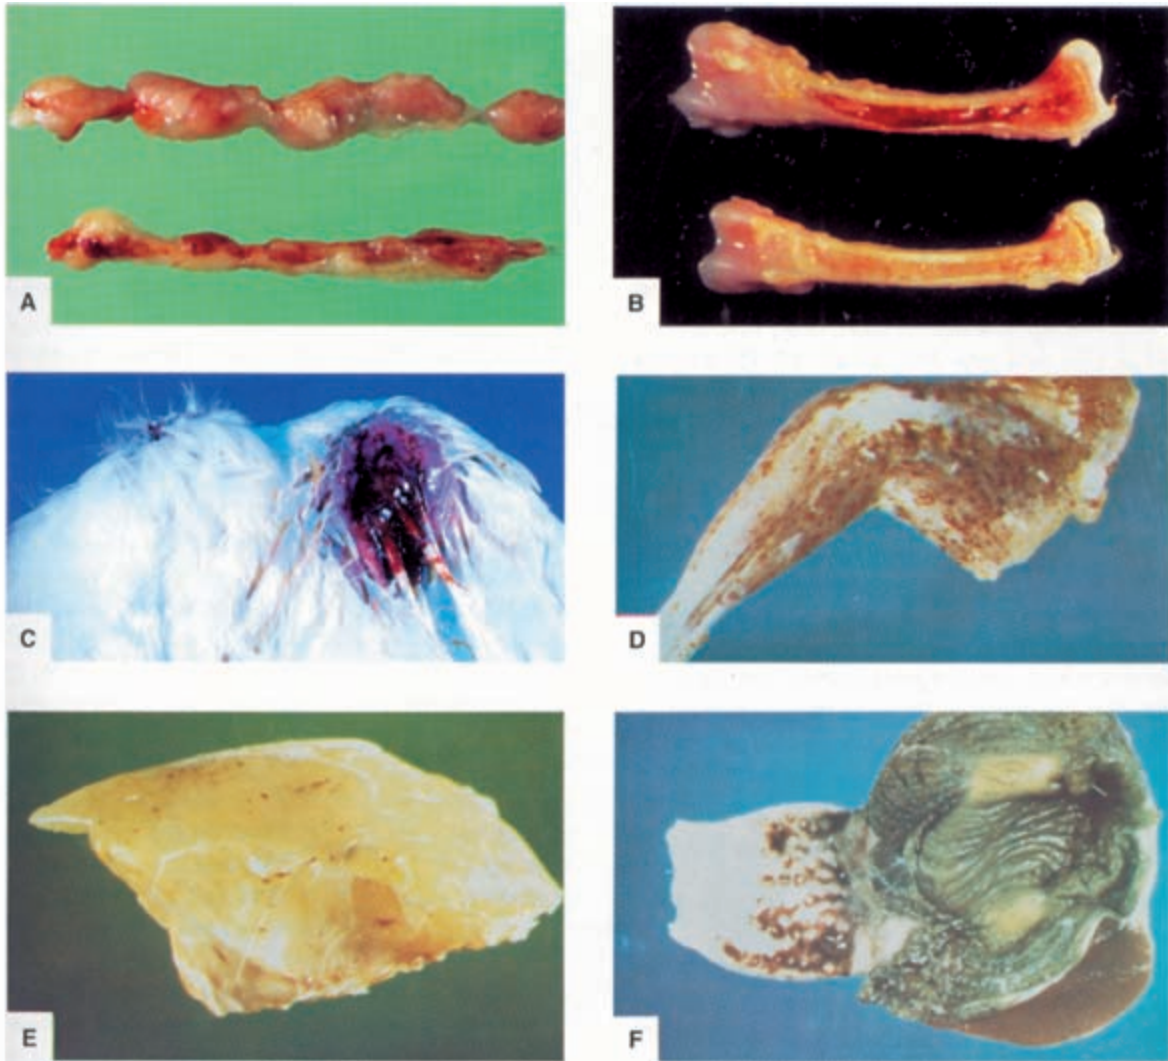
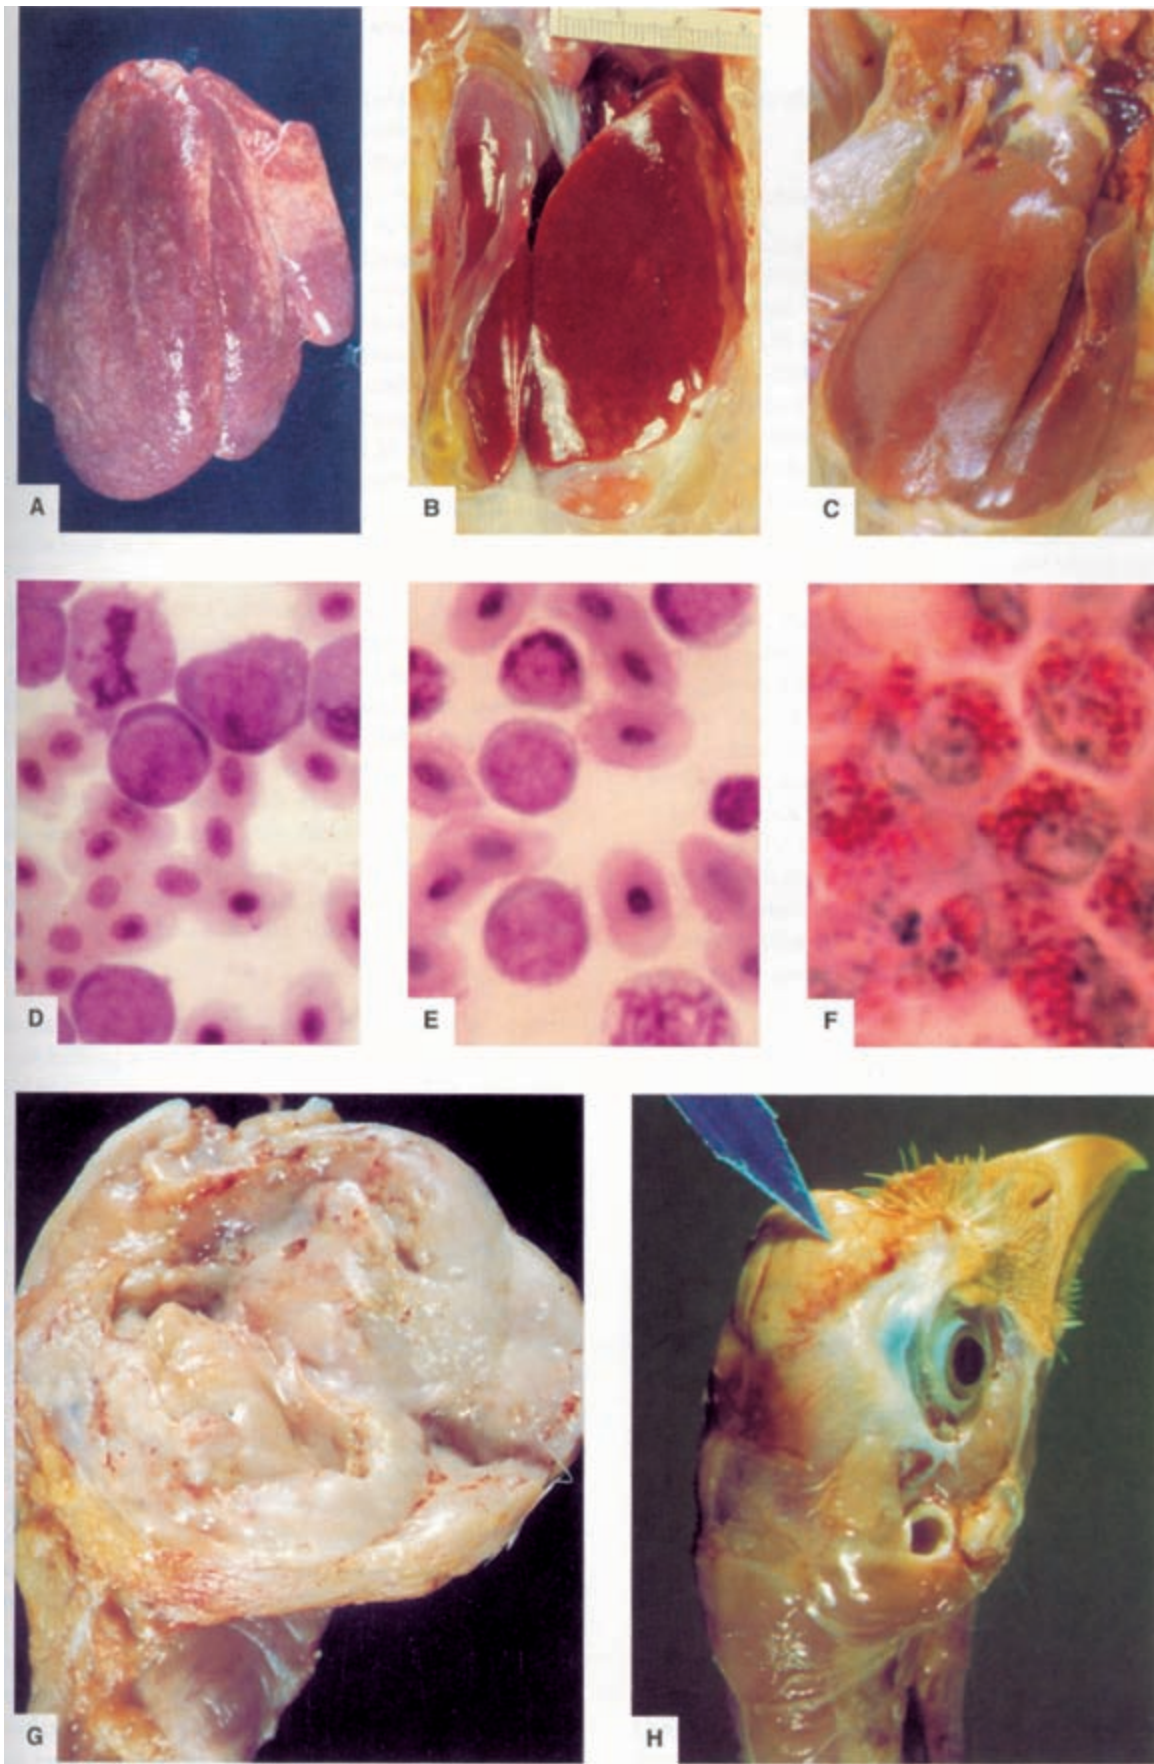
Index

2.1. A. Multiple lobes of the thymus lie on each side of the trachea. B. The bursa of Fabricius is the sac-like structure extending from the end of the intestine. C. The multilobular histologic structure of the thymus is evident; each lobule is composed of the dark-staining cortex and the pale medulla. D. Bursal lymphoid follicles are separated by thin connective tissue septae. (From Fletcher, O. J., and H. J. Barnes. 1998. Lymphoid organs and their anatomical distribution. In J. M. Sharma (section ed.). Avian immunology. In P. P. Partoret, P. Griebel, H. Bazin, and A. Govaerts (eds.). *Handbook of Veterinary Immunology.* Academic Press. With permission.)


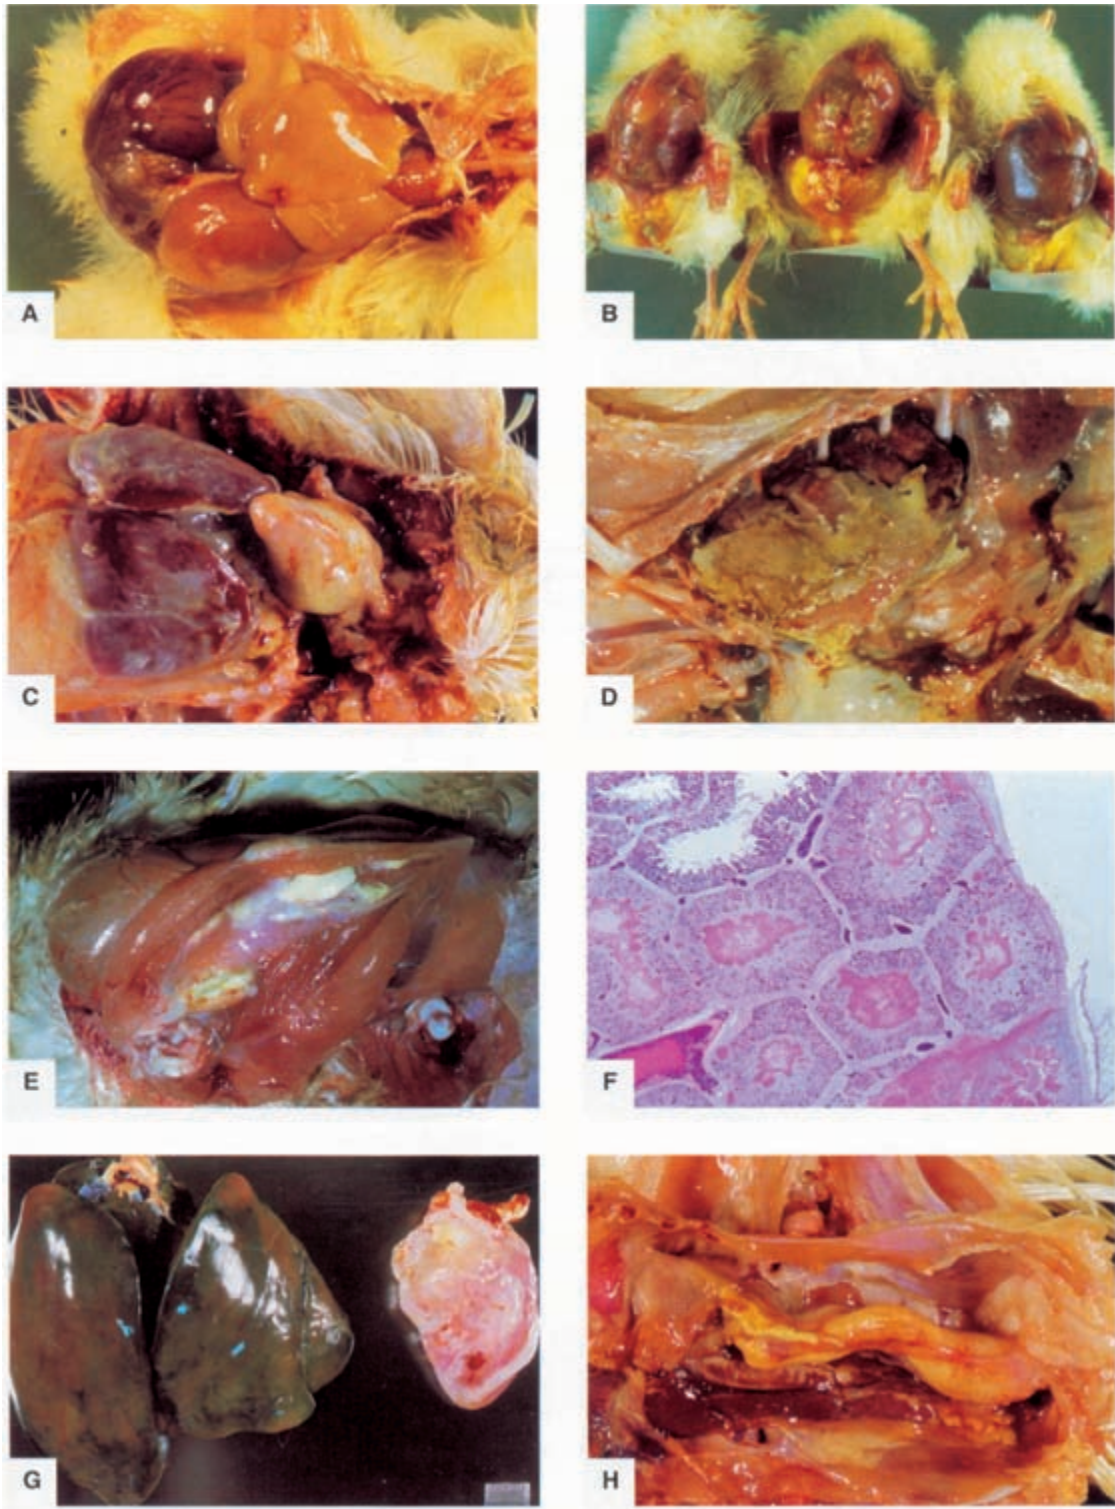
2.2. A. The spleen is the oval organ in the central area of the photograph. B. Periarterial lymphoid sheaths are located in the white pulp of the spleen. C. A bursa-dependent lymphoid follicle is located adjacent to a small artery and surrounded by thymus-dependent lymphoid cells. D. Cecal tonsils, unopened (top) and opened (bottom). E. Small nodules in the conjunctiva and the conjunctival-associated lymphoid tissue (CALT). F. The Harderian gland contains lymphoid cells in the connective tissue between the glands. G. Plasma cells are the predominant cell population in the Harderian gland. H. Nodular deposits of lymphoid tissue are located in the mucosa of the trachea. (From Fletcher, O. J., and H. J. Barnes. 1998. Lymphoid organs and their anatomical distribution. In J. M. Sharma (section ed.). Avian immunology. In P. P. Partoret, P. Griebel, H. Bazin, and A. Govaerts (eds.). *Handbook of Veterinary Immunology*. Academic Press. With permission.)
3.2. Gross lesions of velogenic viscerotropic Newcastle disease in susceptible chickens inoculated by the eyedrop route. A. Facial edema. B. Hemorrhage, congestion, and conjunctivitis in reflected eyelid. C–D. Splenic necrosis on the capsular surface (C) and cut surface (D). E–F. Necrosis and hemorrhage in intestinal lymphoid aggregates evident from the serosal surface (E) and mucosal surface (F). G. Enlarged and necrotic cecal tonsils. H. Peritonitis with fibrin deposition. I. Ovarian follicles with hemorrhagic stigmata. J. Hemorrhage in the mucosa of the proventriculus. (A–I, King and Swayne; J, Beard)
4.6. A. Foamy airsacculitis associated with an early field infection with the Delaware 072 strain of IBV (University of Delaware; Ed Odor). B. Airsacculitis from a severe IBV field vaccine reaction in a four-day-old broiler. Inflammation related thickening of the air sac wall with heterophils and macrophages present in the air sac lumen. Peripheral to the air sac wall is soft tissue inflammatory edema to include lymphocytic perivascular cuffing around congested blood vessels. C. Viral trachitis related to an experimental infection with the Arkansas Strain of IBV at post-innoculation day 3. Visible are cilial loss, partial mucous gland depletion, and mucosal epithelial degenerative changes to include rare heterophil infiltration, mucosal epithelial hyperplasia, congestion, lymphocytic perivascular cuffing, and submucosal edema. D. Normal trachea from sham innoculated negative control at post-innoculation day 3 for comparison with C. Cilia and mucous glands are prominent, and there is a lack of inflammation-based mucosal thickening.
4.6 *(continued)*   E. Trachea from an experimental IBV infection at post-innoculation day 14. There is a lack of acute inflammation. Cilia are apparent; the mucosa contains a developing germinal center; and lymphocytes are present in the submucosa. F. Broncho-pneumonia related to an experimental infection with the Arkansas strain of IBV at post-innoculation day 6. A heterophilicbronchopneumonia involves a parabronchus resulting in the filling of the parabronchial lumen with heterophils and heterophilic infiltration of associated exchange tissue. A portion of a normal parabronchus is adjacent to the parabronchus with the bronchopneumonia. G. Tubulointerstitial nephritis of a medullary cone at post-innoculation day 10 following exposure to the nephrogenic PA/Wolgemuth/98 strain of IBV. Degenerated-necrotic misshapened, often dilated, tubules containing urate, heterophilic, and degenerated epithelial casts are accompanied by an interstitium expanded by mostly plasma cells, lymphocytes, and a few heterophils. H. Germinal centers in and at the margin of a medullary cone are an indication of an area of near complete healing at post-innoculation day 10 following exposure to the nephrogenic PA/Wolgemuth/98 strain of IBV (University of Delaware; Conrad R. Pope, Brian S. Ladman, and Jack Gelb, Jr.).
5.5. *A.* Fibrinohemorrhagic tracheitis in chickens with laryngotracheitis. (Munger). *B-F.* Microscopic tracheal lesions of laryngotracheitis. *B.* Early laryngotracheitis lesions in the trachea. Mucosa is slightly thickened. There is a mild infiltration of lymphocytes in the mucosa and submucosa especially around vessels. A large multinucleated syncytial cell has developed in the mucosa. *C.* Numerous syncytial cells have separated from the mucosa, which is now heavily infiltrated by lymphocytes. Presence of syncytial cells in the tracheal lumen is characteristic of laryngotracheitis. *D.* High magnification of sloughed syncytial cells showing numerous intranuclear inclusions. *E.* Later in the disease, epithelium, blood, and inflammatory exudate form a membrane that separates and sloughs into the lumen. This may occlude the trachea and cause death from asphyxiation or serve as a medium for bacterial proliferation. Expelling the exudate by coughing is a classic clinical sign of laryngotracheitis. *F.* The amount of epithelium that survives depends on virulence of the strain. This bird was infected with the Illinois strain, which is highly virulent. As a result, there has been complete loss of epithelium, leaving lamina propria exposed.


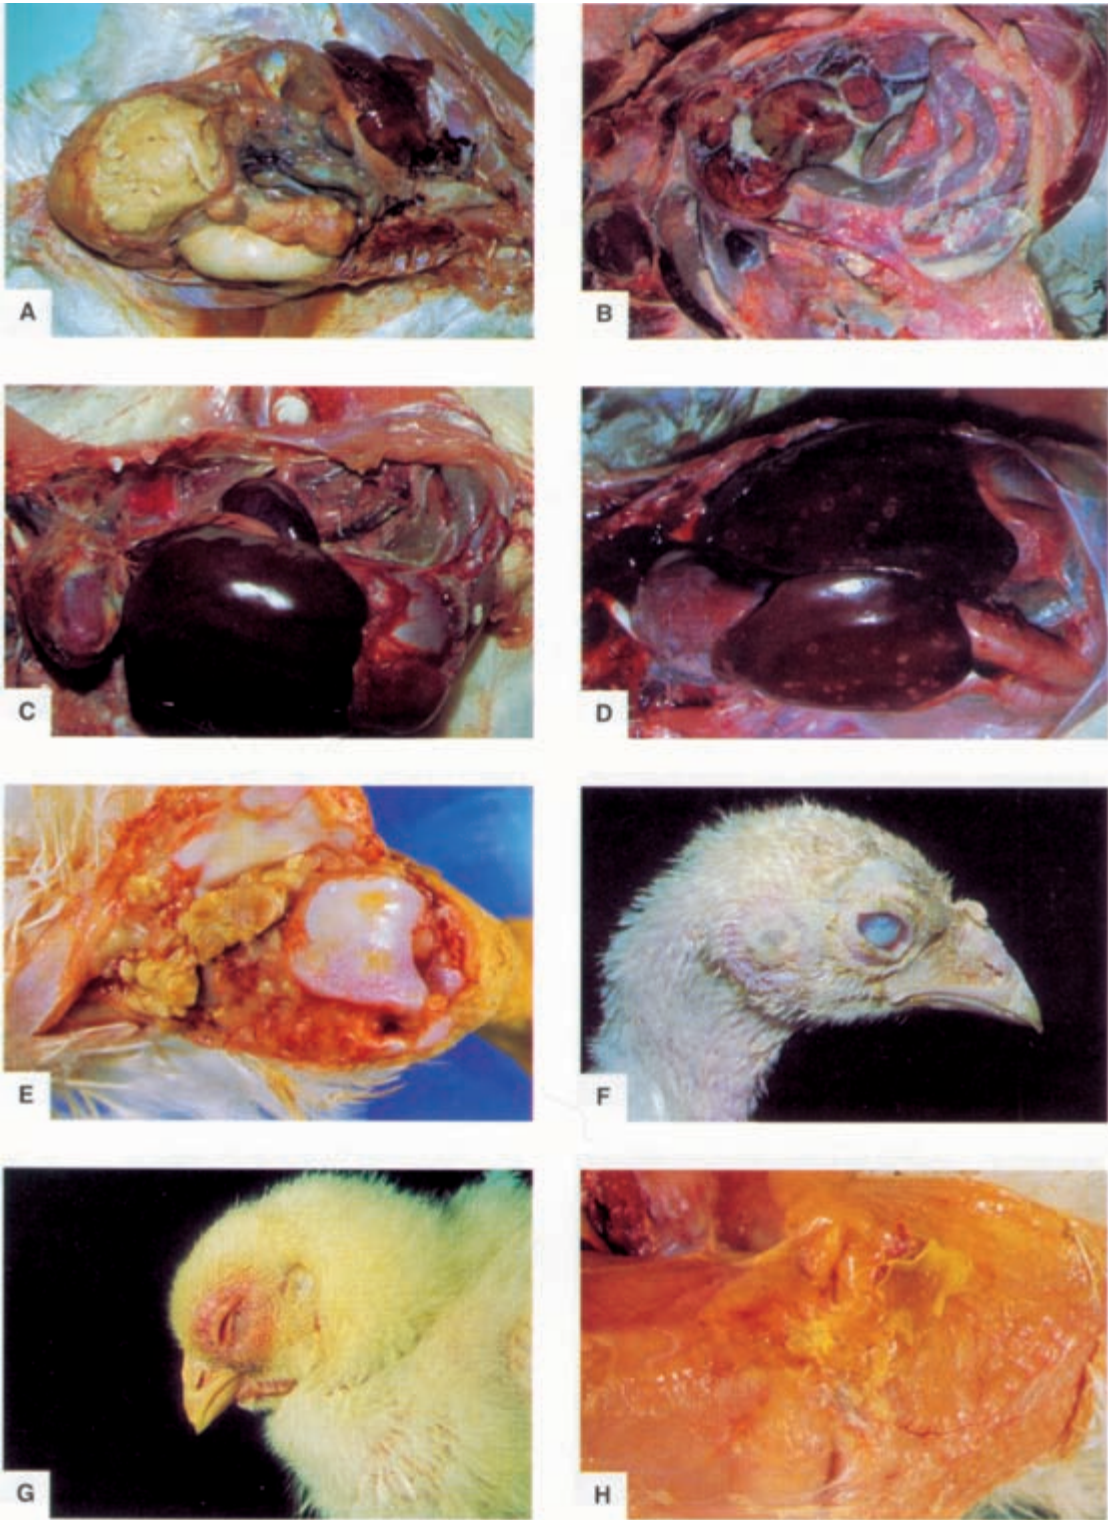
6.2 Gross lesions associated with experimental infection of white leghorn (WL) or White Rock (WR) chickens with highly pathogenic (HP) avian influenza viruses. A–D. Lesions in adult WL chickens, 47–59 weeks of age, exposed to HP A/chicken/NJ/12508/86 (H5N2) derivative influenza virus by the intranasal/intratracheal routes. A. Multifocal necrosis and hemorrhage of comb and wattles 7 days post infection (DPI). (USDA—Brugh) B. Severe edema, necrosis, and hemorrhage of comb and wattles, 7 DPI. (USDA—Brugh) C. Bilateral ventral medial pneumonia with edema, 3 DPI. (USDA—Brugh) D. Petechial hemorrhages in epicardial fat, 4 DPI. (USDA—Brugh) E–H. Intranasal (IN) or intravenous (IV) exposure of immature chickens to HP A/chicken/Queretaro/14588-660/95 (H5N2) virus stock. E. Severe necrosis of comb and wattles, 12-week-old WL, IN exposure, 4 DPI. (USDA—Swayne) F. Severe edema and necrosis of comb and wattles 12-week-old WL, IN exposure, 4 DPI. (USDA—Swayne) G. Severe subcutaneous hemorrhages of leg shanks, 4-week-old WR, IV exposure, 4 DPI. (USDA—Swayne) H. Petechial hemorrhages around the ducts of the proventricular glandular region, 16-week-old WL, IN exposure, 4 DPL. (USDA—Swayne).


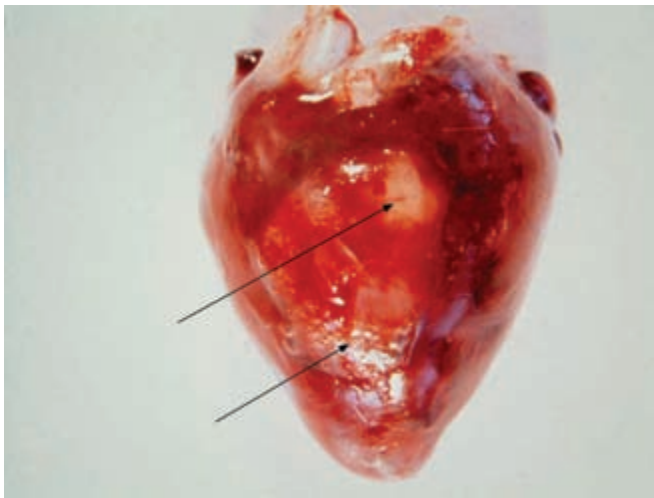
8.2. Lesions in chickens associated with chicken infectious anemia and hemorrhagic anemia disease. A. Control thymus (top) and thymus with chicken infectious anemia virus (CIAV)-induced atrophy (bottom), 14 days postinoculation with the CIA-1 strain of CIAV. (*Lucio and Shivaprasad*). B. Femur with normal dark red bone marrow (top) and femur with pale aplastic bone marrow (bottom), 14 days postinoculation with the CIA-1 strain of CIAV. (*Lucio and Shivaprasad*). C. Gangrenous dermatitis (blue wing disease). (*Shivaprasad*). D. Hemorrhages in thigh and leg muscles. (*Peckham*). E. Hemorrhages in breast muscle. (*Peckham*). F. Hemorrhages in proventriculus. (*Peckham*).
9.11 A–E. Quail bronchitis. A. Trachea from a young quail chick infected with quail bronchitis virus (QBV). There is opacity of the trachea due to the presence of necrotic exudate. B. Cross section of trachea from a young quail chick infected with QBV. The mucosa of the section on the left is extremely thickened, causing partial obstruction, and the section on the right is minimally affected. C. Microscopic section of trachea from a QBV-infected quail. There is epithelial deciliation, cell swelling, necrosis, desquamation, and leukocyte infiltration. D. Quail chick infected with QBV. The lungs are congested and contain red consolidated areas surrounding the bronchial hilus. E. Microscopic section of pulmonary bronchus from a quail infected with QBV. There is epithelial cell proliferation, leukocyte infiltration, and luminal exudate. Basophilic intranuclear inclusions are within epithelial cells. F, G. Hemorrhagic enteritis. F. Turkey, 7 weeks old. Duodenal loop is dark purple because of bloody contents (one section opened to show contents). Note splenic enlargement and mottling. There is also inflammation of a thoracic air sac (left) typical of acute colisepticemia, which often follows hemorrhagic enteritis virus (HEV) infection. G. Markedly enlarged and mottled spleen in turkey with HEV infection. (Barnes)
10.2. A. Cutaneous FPV lesions on the comb of a chicken. (Shivprasad). B. Diphtheritic FPV lesions in the mouth of a chicken (Shivprasad). C. Cutaneous fowlpox virus lesion on the eye and nostril of an experimentally infected chicken. D. Pocks (arrows) produced by FPV on the chorioallantoic membrane of developing chicken embryo. E. Microscopic examination of a cutaneous lesion produced by canarypox virus. Eosinophilic cytoplasmic inclusion bodies (arrows) are present in most of the infected cells. Infected cells are enlarged, and some infected cells have lost their nuclei. F. Microscopic examination of a section of "pock" (as seen in D) stained with Acridine Orange (AO). Cytoplasmic inclusion bodies containing DNA stain green (arrows) with AO.
13.1. A. Normal 15-day-old chick embryo (right). Fifteen-day-old chicken embryo inoculated 6 days previously with duck hepatitis virus (DHV) type 1 (left). Note small size, hemorrhage, and edema. B. Duckling dead from infection with DHV type 1. Note typical opisthotonos. C. Liver with hemorrhagic lesions caused by DHV type 1 infection. D. Microscopic lesions in liver of duckling 24 hours after infection. Note massive liver cell necrosis and hemorrhage. H & E, ×1000. E. Microscopic lesions in liver of duckling 7 days after infection. Note extensive bile duct proliferation. H & E, ×250.
13.4. Duck virus enteritis (DVE) lesions in a duck. A. Petechial hemorrhages in the epicardium. (Munger). B. Extensive ulceration of esophageal mucosa. (Munger). C. Bursal lesions; hemorrhages (center) and cheesy exudate (right and left) (Shawky, Sandhu, Shivaprasad). D. Multifocal necrosis of gut-associated lymphoid tissue resulting in ulceration covered by fibrinous pseudomembranes. Note also the reddened ring visible on the external surface of the intestine. (Munger). E. Multiple pale focci in liver and slightly smaller dark-colored spleen. F. Normal thymus (middle) and thymus (DVE) showing hemorrhages and atrophy (top and bottom), 4 dpi (Shawky, Sandhu, Shivaprasad). G. Microscopic appearance of esophageal ulcerations. Not lack of inflammatory response and presence of intranuclear inclusion bodies. ×225. (Munger and Barnes). H. Microscopically, liver shows focal areas of necrosis filled with fibrin. Intranuclear inclusion bodies can be seen in hepatacytes near areas of necrosis. ×360. (Munger, Barnes).
14.6. Microscopic lesions in turkeys and chickens experimentally infected with eastern equine encephalitis virus. A. Heart of turkey, 3 days postexposure. A large focal area of myocardial necrosis is present, with no inflammatory reaction. B. Thymus of turkey, 3 days postexposure. Aggregates of pyknotic nuclei within clear spaces indicate acute lymphocyte necrosis. C. Bursa of Fabricius of turkey, 3 days postexposure. Atrophy of bursal follicles with marked lymphoid depletion is present. D. Brain of chicken, 2 days postexposure. A focal area of necrosis is present with mild perivascular cuffing. Note emigration of mononuclear cells from an adjacent venule distended with erythrocytes. E. Heart of chicken, 5 days postexposure. Myocardial degeneration and necrosis with a mononuclear cell infiltrate. F. Liver of chicken, 5 days post-exposure. Focal necrosis is present with minimal inflammatory cell response.

14.23. Enlarged and hemorrhagic liver from a 63-week-old chicken with hepatitis-splenomegaly syndrome. Note the liver is not fatty.
14.24. Two enlarged and mottled white spleens from 56-week-old chickens with hepatitis-splenomegaly syndrome. The spleen on the left is of normal size.
14.25. Photomicrographs of a liver from a chicken with spontaneous case of hepatitis-splenomegaly syndrome showing accumulation of homogeneous eosinophilic material, amyloid in the interstitium stained with H and E (a), Congo red stain positive shows orange colored amyloid (b), and apple green birefringence property of amyloid under polarizing filter (c).
14.26. Gross lesion of a liver from a specific-pathogen-free chicken experimentally infected with avian HEV showing subcapsular hemorrhages (arrows). Reproduced with permission from American Society for Microbiology (4).
14.27. Microscopic lesions of the liver from chickens experimentally infected with avian HEV. A. A liver section from an oronasally-inoculated chicken, showing lymphocytic and scattered heterophilic portal vein periphlebitis. B. A liver section from an IV-inoculated chicken showing focally intense lymphocytic venous phlebitis and periphlebitis. C. A liver section from an IV-inoculated chicken showing locally extensive hepatocellular necrosis with lymphocytic inflammatory cell infiltration. D. A liver section from an IV-inoculated chicken. Note architectural disruption and coalescing deposition of hypocellular homogenous eosinophilic matrix with displacement of hepatocellular cords. E. A liver section from an oronasally-inoculated chicken. Note large focus of acute hemorrhage with local architectural disruption of hepatocellular cords and hepatic sinusoids. H&E staining. Reproduced with permission from American Society for Microbiology (4).
15.9. A. Leukotic tumors involving feather follicles (skin leukosis). (Peckham) B. Experimentally induced Marek's disease (MD) lymphoma in immature ovary (bottom) compared with normal ovary (top). (Whitter) C. Ocular lesions of MD. Note that the normal eye (left) has a sharply defined pupil and well-pigmented iris. Affected eye (right) has a discolored iris and very irregular pupil as a result of mononuclear cell infiltration. (Peckham). D. Gizzard from a chicken infected with CU-2 isolate of MDV. Note the grossly obvious atherosclerotic change in the arteries. (C. Fabricant). Microscopic changes from similar arteries are shown in Fig. 15.18B. E. Multiple lymphomas in lungs. F. Multiple lymphomas in heart. (Shivaprasad)


15.33. Comparison of leukosis. A. Lymphoid leukosis (LL). Diffuse form affecting the liver. Lesion is grossly indistinguishable from those in Marek's disease. B. Erythroblastosis. Enlarged cherry red liver and spleen. Note the fibrinous exudate. C. Myeloblastosis. Note enlarged gray-red liver. D. Erythroblastosis. Note basophilic cytoplasm and perinuclear halo. Blood smear, Giemsa, ×975. E. Myeloblastosis. Myeloblasts are slightly smaller than erythroblasts; cytoplasm is not as basophilic, nucleus is less vesicular, and nucleoli are not as frequent or conspicuous. Blood smear, Giemsa, ×975. F. Myelocytomatosis. Note myelocytes packed with acidophilic granules. Section of tumor, Giemsa, ×075. (Beard) G. LL tumors in the bursa of Fabricius (from the same bird as the liver shown in (A). H. Myeloid leukosis tumor on the surface of the skull. (Peckham)
16.1. Gross lesions associated with Salmonella pullorum (A–I) infections in chicken. A. Enlarged and congested spleen and liver with pale yellow fibrinonecrotic cast in the lumen of cecum in a 10-day-old chick. B. Enlarged liver showing pale foci of necrosis (Glass). C. Heart from young chick with white nodules representing myocarditis. Such nodules can be confused for tumors, such as Marek's disease (Chin). D. Swollen hock joint containing yellow viscous fluid (Peckham). E. Ovarian lesions, salpingitis, and peritonitis. F. Lungs with pale exudate due to pullorum disease in a chick (Peckham). G. Nodular lesions in the heart due to chronic infection; note the thickened yellowish pericardium (reflected). H. Gizzard with yellow nodules of various sizes on the serosa in 6-week-old chick. I. Ovary with multiple misshapen grey nodular follicles.

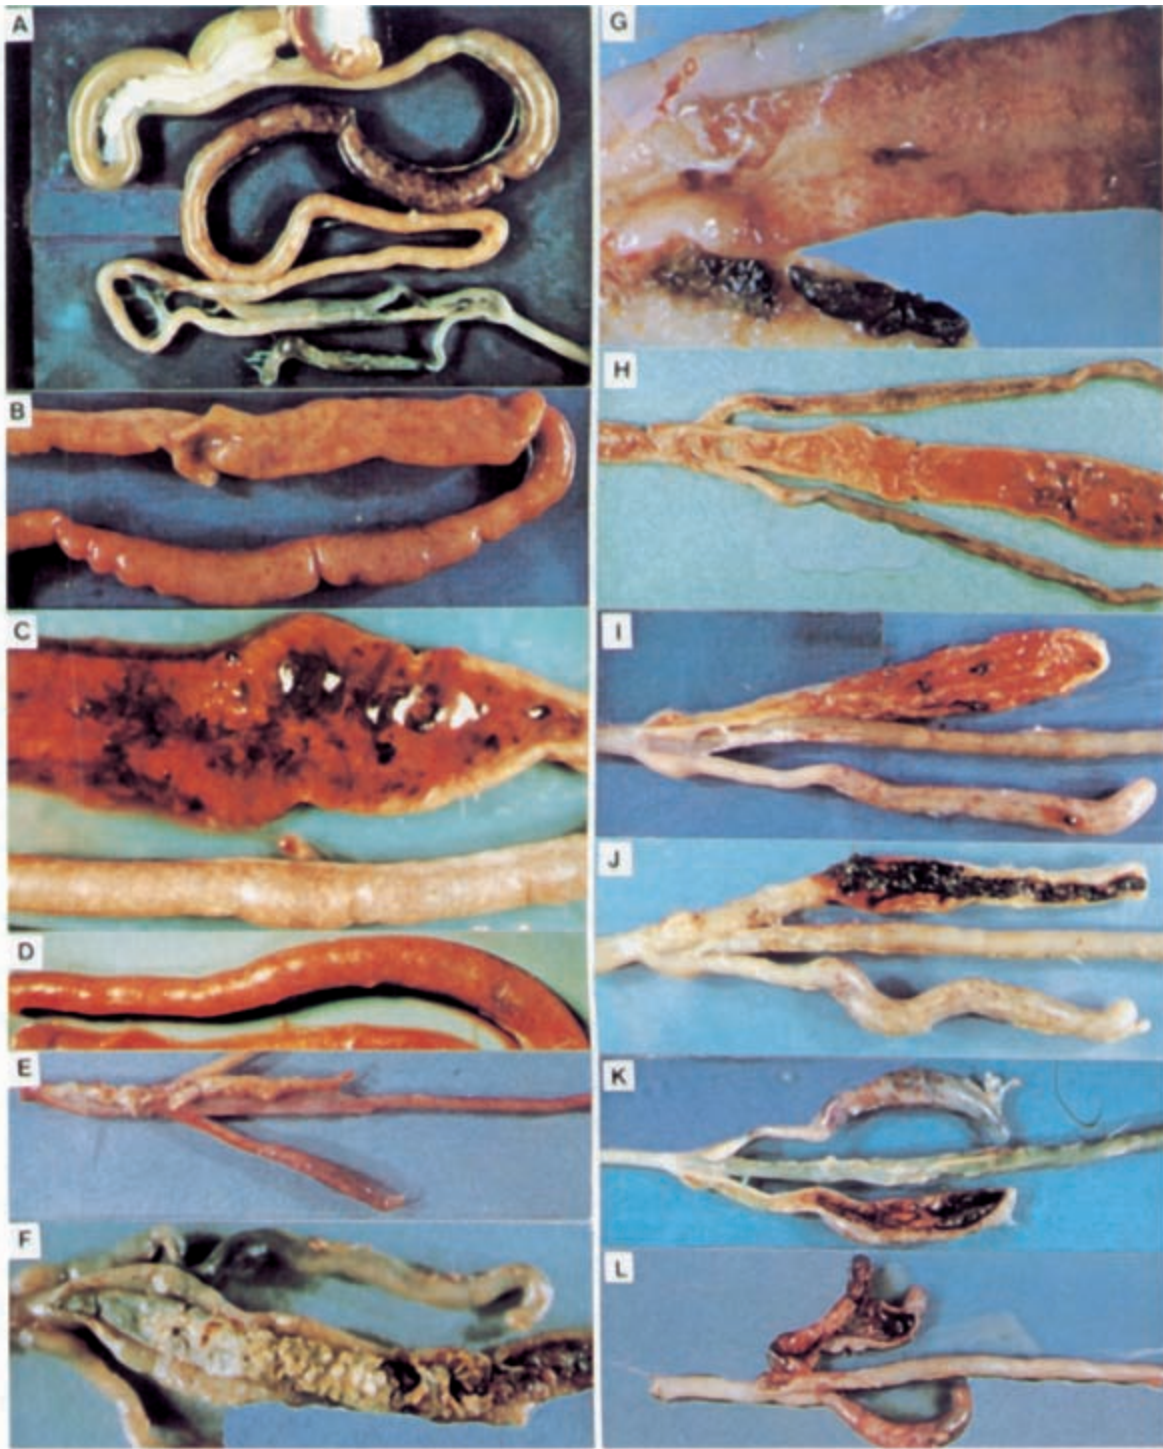
16.1 *(continued)*


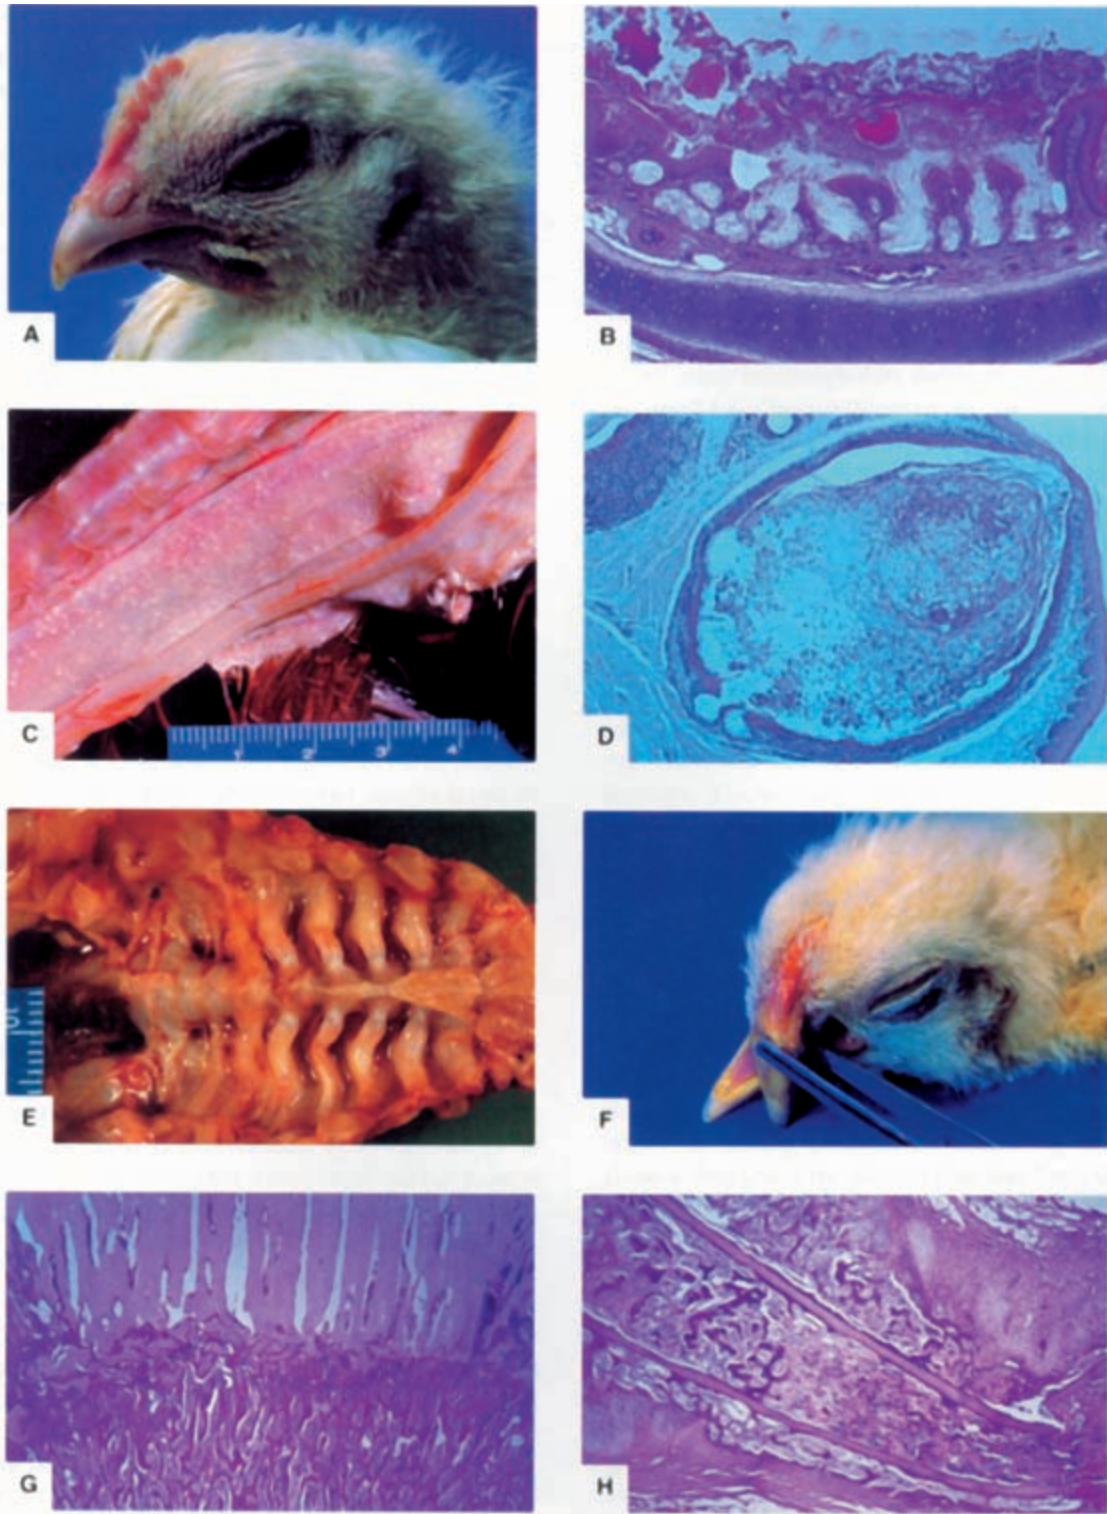
18.1. *Colibacillosis.* A. Yolk sac infection in a 4-day-old leghorn chick. Yolk sac is distended, hyperemic (note prominent vessels), and filled with abnormal brown, watery contents. B. Omphalitis and yolk sac infection in a group of 3-day-old leghorn chicks. Navels are inflamed, and yolk sacs are distended with abnormal contents. C. Advanced air sac disease in a 20-day-broiler chicken. Polyserositis (pericarditis, perihepatitis, peritonitis, airsacculitis) have occurred as a result of systemic spread of *Escherichia coli*. D. Pleuropneumonia and airsacculitis in a broiler chicken caused by *E. coli* infection. E. Experimental colibacillosis in a turkey. Extension of inflammation between superficial and deep pectoral muscles from airsacculitis involving the interclavicular air sac. Detecting this type of lesion is important during inspection at processing. F. Microscopic appearance of pneumonia caused by *E. coli* in a broiler chicken. Exudate fills the lumen of several affected parabronchi (compare with unaffected parabronchi at the top of the figure). Exudate has expanded some atria. Some atria have ruptured, permitting extension of the inflammatory process through the capillary bed into the interstitium. The process has involved almost all of one lobule with extension to the adjacent pleural surface. ×10. G. Pericarditis and green discoloration of the liver in a turkey that survived the acute septic phase of colibacillosis. Pericardium is thickened, and exudate in the pericardial sac is beginning to undergo fibrosis. Green discoloration of the liver can indicate inflammation elsewhere in the bird, especially in turkeys. H. Salpingitis in a young bird caused by *E. coli*. This lesion occurs infrequently but is often associated with airsacculitis involving the left abdominal air sac. (Figures A–C courtesy of Dr. L. Munger.)


18.2. *Colibacillosis.* A. Large caseated masses distending the oviduct of this mature laying hen are characteristic of salpingitis caused by *Escherichia coli.* Salpingitis in the adult female most likely results from an ascending infection from the cloaca. B. Goose breeder with acute peritonitis. Yolk was demonstrated in the peritoneum and *E. coli* was isolated. C. Acute *E. coli* septicemia in a turkey. Spleen is markedly enlarged and congested. Note it is approximately the same size as the proventriculus. Liver is also enlarged and congested, and there is evidence of early pericarditis and peritonitis. D. Experimental colibacillosis in a turkey. Liver from a bird that survived the acute septicemic phase has multiple pale foci, which were determined microscopically to be focal areas of early heterophilic, granulomatous hepatitis. E. Advanced tenosynovitis/arthritis involving the hock joint and flexor tendons of a lame commercial broiler. *E. coli* and *Staphylococcus* spp. were isolated from the lesion. F. Panophthalmitis affecting the eye of a turkey that survived an earlier episode of colisepticemia. This lesion is uncommon and affects only one eye. The organism can be isolated from the eye for an extended period after it is no longer present in other tissues. G. Swollen-head syndrome in a broiler chicken. There is conjunctival inflammation and periorbital swelling due to cellulitis. Evidence of exposure to high ammonia levels and infection with infectious bronchitis virus and *E. coli* were found in this flock. H. Avian cellulitis (inflammatory process). Subcutaneous yellow, caseous exudate is present over the abdomen of this affected bird. (Figures E, G courtesy of Dr. L. Munger)
19.10. A. Acute FC; subepicardial hemorrhages in a turkey. B. Acute FC; multiple necrotic foci in turkey liver. C. Acute FC; turkey lung with extensive hemorrhage and patchy areas of necrosis (arrow) and emphysema. D. Submassive necrosis with fibrous exudate on pleural surface. E. Acute FC; flaccid ovarian follicle (arrow) with thecal blood vessels less evident than normal. F. Chronic FC; caseous exudate in sternal bursa (A) and hock joint (B) of a turkey.
22.2. Ulcerative enteritis lesions in quail. A. Early intestinal ulceration visible from both mucosal and serosal surfaces. Note the hyperemia around some lesions and occasional ulcers with marginal hemorrhage. B. More advanced ulcers filled with diphtheritic, necrotic membranes. C. Transmural ulcer containing necrotic tissue and inflammatory exudate with adjacent focal peritonitis. D. Higher magnification of C. Note the sharp demarcation between viable and necrotic tissue by a zone of inflammation, inflammatory exudate, and bacterial colonies. E. Gram-stained, high magnification of inflammatory zone showing numerous large gram-positive bacilli typical of *Clostridium colinum.* F. Areas of necrosis in chicken liver. G. Microscopic appearance of liver lesion. Note the spreading areas of necrosis without distinct separation for normal tissue, minimal inflammatory response, and bacterial colonies. H. Gram stain of liver lesion. Note gram-positive staining colonies in necrotic foci.
22.4 A. Mild to moderate necrotic enteritis in a 7-week-old broiler breeder chicken with concurrent coccidiosis. Note the hyperemia and diffuse necrosis of the mucosa with multifocal ulcerations. (Dr. Laddie Munger) B. Intestine of a turkey showing uniform diffuse coagulation necrosis of mucosa. Deeper viable mucosal tissue is demarcated from necrotic luminal mucosal tissue by a zone of intense hyperemia, hemorrhage, and inflammation. ×20 (Dr. John Barnes) C. Severe necrotic enteritis in a commercial broiler. Note the "Turkish towel" appearance to the necrotic pseudomembrane covering the intestinal mucosa. (Dr. Chuck Hofacre). D. Necrotic enteritis in a 6-week-old ostrich caused by *C. difficile*. Note the severe diffuse coagulation necrosis with separation from the underlying viable tissue by an intense zone of inflammation with numerous large Gram-positive bacilli located at the interface of the necrotic and viable tissue. (Drs. Laddie Munger and John Barnes) E. Gangrenous dermatitis affecting the wing of a 12-day-old broiler. Spontaneous separation of epidermis revealing edematous, hyperemic, acutely inflamed dermis. (Laddie Munger) F. Broiler, 6-week-old, with gangrenous dermatitis. Extensive discolored patches of necrotic skin are present on the abdomen. (H. John Barnes) G. Same bird as in (F). Skin reflected to show discolored muscle and serosanguinous fluid expanding underlying dermis. (H. John Barnes) H. Skin from a turkey with gangrenous dermatitis. Dermis beneath a normal epidermis is markedly expanded by fluid and gas. Cutaneous muscle is undergoing rhadomyolysis. Cellular changes are minimal to absent, ×13. (H. John Barnes)
23.1. Lesions of staphylococcosis. A. Osteomyelitis of proximal tibiotarsus (×5). (H. John Barnes) B. Focal osteomyelitis subjacent of physis of proximal tibiotarsus (×5). (H. John Barnes) C. Bilateral osteomyelitis of femoral head due to *Staphylococcus aureus* infection in a 2-week-old turkey. Note the extension through the joint into the body cavity. D. Three-week-old turkey. Swollen hock joint with extension of inflammatory exudate along tendon sheaths. (Laddie Munger) E. Leghorn, 20 weeks old. Multiple foci of necrosis in liver following septicemic staph infection. (Laddie Munger) F. Green liver discoloration seen in turkeys wit osteomyelitis. (H. John Barnes)
23.18. A–D. Tuberculous lesions in intestine (A), liver (B), bone marrow (C) (Peckham); and spleen (D) of naturally infected chickens. Note the variation in size of granulomas in the liver and spleen. E. Positive reaction in the left wattle of tuberculous chicken 48 hours after intradermal infection of avian tuberculin. (M. C. Peckham)


24.9. Turkey experimentally infected with a *C. psittaci* serovar A strain isolated from the lungs of a budgerigar. A. Notice the thickened abdominal air sac totally covered with fibrin plaques (arrow). B. Notice the presence of serous fluid and fibrin in the pericardial sac (arrows) together with C. severe hepatomegaly (C.).
24.10. Hematoxylin and eosin staining of experimentally infected turkeys. A. Conjunctiva with infiltration of lymphocytes and heterophils together with epithelial vacuolization and hyperplasia (×172). B. Congested lung with infiltration of lymphocytes (arrow A) and dilated bronchi and parabronchi (arrow B) (×69). C. Fibrinous necrotizing airsacculitis (×172). .
25.3. Aspergillosis (A–G). Thrush (H). A. Ocular aspergillosis. This form is characterized by extensive keratoconjunctivitis. Panophthalmitis is another form of ocular aspergillosis in which internal structures, especially those in the posterior chamber of the eye, are affected. The latter is considered to result from hematogenous spread. B. Respiratory aspergillosis in the lung showing large and extensive caseous nodules. (M. C. Peckman) C. Caseous nodules due to aspergillosis in the air sac. D. Caseous exudate in the syrinx of a bird affected with aspergillosis. (M. C. Peckman) E. Mycotic encephalitis. Focal lesions in the brain can be extensive. F. Experimentally induced granulomatous lesion in the air sac due to aspergillosis. A central caseous core is bordered by a narrow, uniform palisade of macrophages and small giant cells surrounded by a less distinct broad zone of macrophages and scattered heterophils. ×90. (H. John Barnes) G. Gomori's methenamine silver-stained section of (F) demonstrating extensive black-staining fungus. ×90. (H. John Barnes) H. Candidiasis (crop mycosis). Crop is markedly thickened by a soft, yellow-white to gray irregular pseudomembrane, which has a curdlike-appearance. (M. C. Peckham)

26.1. Common poultry pests. A. Mating house flies (*Musca domestica*). B. House fly (*Musca domestica)* puparium and larva. C. Darkling beetle (*Alphitobius diaperinus*). D. Lesser mealworm (*Alphitobius diaperinus*).
26.1. (*continued*) E. Chicken body louse (*Menacanthus stramineus*). F. Chicken body lice (*Menacanthus stramineus*). Photos A, B, E, F by Nancy Hinkle. Photos C, D by Aubree Roche.

28.3. A. Oocysts and a microgametocyte (center) of *Eimeria maxima* (Long et al. [British] Crown copyright 1976). B. *E. acervulina* (+2). C. *E. acervulina* (+2). D. *E. acervulina* (+3). E. *E. acervulina* (+4). F. 1. Sporulated *E. maxima* with distinctive brownish walls; 2. Unsporulated *E. maxima* showing roughened outer wall; 3. Probably E. *tenella*; 4. End view, probably *E. mitis*; 5. Side view, probably two *E. mitis*. G. 1. normal midgut; 2. *E. maxima* midgut (+1). H. *E. maxima* midgut (+2 or +3) (Long et al. [British] Crown copyright 1976). I. *E. maxima* (+3). J. *E. maxima* close-up view (+4).


28.4. A. *Eimeria necatrix* showing ballooning in midgut. B. *E. necatrix* (+2). C. *E. necatrix* (Long et al. [British] Crown copyright 1976). D. *E. necatrix* (4+). E. *E. brunetti* (+4). F. *E. brunetti* (+4). G. *E. brunetti* (+3). H. *E. brunetti* (+4) (Long et al. [British] Crown copyright 1976). I. *E. tenella* (+2). J. *E. tenella* (+3). K. *E. tenella* (+4). L. *E. tenella* (+4) with cecal core.
28.11. A. Normal uninfected poult (left); histomoniasis-infected poult of the same age (right). Sickly appearance occurs later in the course of infection and is not distinctive to histomoniasis. (Hilbrich) B. Brilliant yellow material in feces often constitutes the first sign of histomoniasis outbreaks in turkeys. C. Liver and cecum from poult 14 days after feeding on *Heterakis gallinarum* ova. Note engorgement of ceca and diffuse nature of liver lesions. (McDougald) D. Intestinal tract from experimentally infected turkey showing engorged cecum, core, and inflamed mesenteries. E. Chicken and turkey ceca 10 days PI with *Histomonas meleagridis*. Note cecal cores (arrows). F. Discrete pathognomonic lesions with raised surface from a turkey infected with histomoniasis. G. Liver section showing histomonad PAS stain (arrows). H. Liver sections showing histomonads (arrow). H & E. ×1000. (Page)


29.2. A–D. Vitamin A deficiency. A. Periorbital edema and lack of pigmentation. (Swayne) B. Squamous metaplasia of nasal mucosa. (Swayne, Barnes) C. Vitamin A deficiency. Distended, impacted mucosal glands resembling pustules in the esophagus. (Barnes) D. Squamous metaplasia has replaced all but a few focal areas of normal mucosa in the base of this esophageal gland. Distention has resulted from occlusion of opening and accumulation of keratin and cellular debris in the lumen. Inflammation resulting in formation of a pustule will occur if contents contact surrounding tissues. (Barnes) E–G. Rickets. E. Soft, thick ribs form a flattened thorax in this severely affected 8-day-old broiler chicken. Vertebrae are also short and thick. In less affected birds, enlargement at junctions of ribs with vertebrae and sternum, folding of sternal portions of caudal ribs resulting in a flat, broad thorax, and occasionally pathologic rib fractures may be seen. (Munger) F. Beak of affected chicken is soft and easily bent. (Swayne) G. Field or infectious rickets in turkeys occurs secondarily to intestinal disease. In this affected poult, there is excess, hypertrophic cartilage that is poorly vascularized because of a compression-induced fold fracture involving trabeculae at the physeal-metaphyseal junction. (Barnes) H. Osteopenia ("cage layer fatigue"). Pathologic fracture of rib with imperfect callous formation. There is minimal mineral being deposited at the fracture site. (Barnes)
29.4. A–F. Nutritional encephalomalacia (vitamin E deficiency). A. Paresis in one poult and another with pronounced neurologic signs. While either clinical manifestation can be seen in turkeys, the latter is seen in chickens ("crazy chick disease"). (Barnes) B. Birds with neurologic signs have cerebellar swelling, edema, hemorrhage, and attenuation of folia. Coning of the swollen cerebellum into the foramen magnum is often seen. Lesions in the cerebrum also may occur but are not common. (Barnes) C. This bird with chronic nutritional encephalomalacia survived 3 days after onset of signs. Affected areas are now pale and shrunken. (Barnes) D. Severe malacia of cerebellum. Variable portions of affected outer folia are sharply separated from inner normal tissue. There is congestion and hemorrhage. At higher magnification characteristic fibrin thrombi in small vessels would be seen. Inflammatory cells are minimal to absent. (Barnes) E. Increased swollen astrocytes replace much of the normal cerebellar architecture in this bird with chronic encephalomalacia. Only isolated parts of the granular layer and individual Purkinje cells remain. (Barnes) F. Poults with paresis usually do not have brain lesions but have bilateral poliomyelomalacia as seen here. (Barnes) G. Nutritional myopathy. Degeneration of muscle fibers can result from inadequate vitamin E and/or selenium. These are seen as pale, often fusiform, linear streaks in skeletal muscle. Fibrosis, intramuscular fat deposition, and other myopathies can produce similar changes. (Barnes) H. Ventricular myopathy. Deficiency of vitamin E and/or selenium can produce myopathic changes in smooth muscle as well as cardiac and skeletal muscle. Lesions are seen as extensive, pale areas in ventriculus musculature. Turkeys are more commonly affected. (Munger)

30.5. Amyloid arthropathy in 32-wk-old brown chicken layers caused by *Enterococcus faecalis*. From left to right, normal control to most severely affected. There is accumulation of yellow-orange material (amyloid) in the lumen of the tibiotarsal joint. Note the articular cartilage is partially destroyed. (Barbara Daft)
30.6. Histologic section of liver with amyloidosis. A. Amyloid appears as homogenous eosinophilic material deposited extracellularly. Most hepatocytes have disappeared. H & E, bar = 65 μm. B. When amyloid is stained with Congo red it appears as brownish-orange under day light, Congo red, bar = 65 μm. C. Amyloid stained with Congo red emits apple green birefringence under polarized light, Congo red, bar = 30 μm.
