Introduction

The editorial board asked a distinguished colleague and former editor-in-chief of this book, Dr. Bruce Calnek, to write the Foreword to this edition containing a historical account of *Diseases of Poultry*. We are indebted to Dr. Calnek for providing a comprehensive account of the history of this book, which indeed should be preserved. Thank you, Bruce.

This edition is fittingly dedicated to Dr. John Barnes, who served on the editorial boards of the eighth, ninth, tenth, and eleventh editions of *Diseases of Poultry*. Dr. Barnes' contributions have been instrumental in maintaining the high quality of this book, and, indeed, we are highly grateful for his efforts. Dr. Lisa Nolan joined the editorial board, and we are very appreciative of her services.

This edition represents a continuation of the tradition established earlier of providing the latest information on poultry diseases. Earlier trends of expansion of authorship to include authors from around the globe continued in this edition. Efforts continued to standardize the format of the chapters to enhance the search for specific items in a given chapter.

All the book chapters were updated. There is one less chapter in this edition; some chapters were combined; and a new chapter was created. These changes were dictated by the increasing or decreasing significance of some diseases or the increasing knowledge on a given disease. Some subchapters have been moved to different chapters because of recent findings indicating that they fit within different areas.

The last chapter, "Emerging Diseases and Diseases of Complex or Unknown Etiology," has always been in a state of flux because of the nature of the topics included. Two subchapters of this chapter in the eleventh edition, labeled "Big Liver and Spleen Diseases" and "Hepatitis Splenomegaly," were recently associated with avian hepatitis E virus infection and moved to Chapter 14. In addition, the subchapter on viral proventriculitis was moved to this chapter because of the uncertainties of the etiology of the disease. The subchapter, "Poult Enteritis and Mortality Syndrome," was combined with the subchapter, "Multicausal Enteric Diseases," in recognition of the fact that it is a condition resulting from multiple infections.

Chapter 1 was split in two, and a new chapter, "Host Factors for Disease Resistance," was created. This was done in recognition of the importance of the subject matter for a book on diseases and because of the increasing knowledge on the subject. The chapter on avian encephalomyelitis was combined with Chapter 14 in which coverage of similar infections is placed. The chapter on bordetellosis was combined with the chapter on pasteurellosis and other respiratory bacterial infections.

A collective thank you goes to the authors who contributed to earlier editions of the book and those that contributed to the current edition. It has been a delightful experience working with all of you.

The personnel at Wiley-Blackwell that worked on this edition have been most helpful and accommodating, and we sincerely appreciate their support.

This is the second time that I served as editor-in-chief of *Diseases of Poultry,* and I (YMS) am indebted to my colleagues, the associate editors, for their tireless efforts in the review process and their support and advice.

Finally, I would like to acknowledge a special person, my associate Ms. Hannah Gehman. Her organizational skills, patience, speed, attention to details, and pleasant demeanor have been most helpful and appreciated.

Editor-in-Chief
Y.M. Saif

Foreword

Previous forewords for *Diseases of Poultry*, beginning with the first one written by John R. Mohler in 1943, have briefly described the nature and contents of the edition, along with substantive reasons for its publication and distribution to potential users. He pointed out that for a profitable poultry industry "... knowledge of the characteristics of each disease is necessary ... as the first step in building up an effective barrier against it." He further noted that "... this unusually comprehensive book is intended for students, veterinarians, pathologists, and workers in specialized fields." These words are as applicable today as they were 65 years ago.

For the sixth edition in 1972, Dr. P. P. Levine offered an accounting of some of the changes in the poultry industry that moved it from a small-scale farm activity to "... a highly sophisticated industry marketing products worth over $6 billion per year in the United States alone." He correctly attributed some of the many advances in disease control through eradication, genetic selection, immunization practices, management improvements, and so on to major advances founded in research. Such new knowledge strongly dictates a need for revised texts. Levine further predicted that "... infectious diseases will decline in importance; toxicologic, nutritional, genetic, and husbandry problems will demand increasing attention. Change is the order of life, and avian diseases are no exception." In the seventh edition (1978), he pointed out many of the important new advances in identifying the etiology of several conditions, and the need for *Diseases of Poultry* to "... keep up with the rapid developments in avian diseases."

Ben Pomeroy, in the eighth (1984) and ninth (1991) editions, reiterated the need for new editions to keep up with the "... explosion of knowledge on the prevention and control of avian diseases." The inclusion of contributions from experts from many countries of the world and the importance of such in the face of global issues of disease control were emphasized by Charles Beard in the tenth (1997) edition. He pointed out that understanding the molecular genetics of causative agents is also important and that the use of molecular methods is necessary for poultry disease researchers to understand and control infectious diseases; yet another reason for timely updates.

The message is clear: a changing and global poultry industry and its many allied industries need the most recent information available to keep pace with the challenges of providing adequate health care and disease prevention. It is important not only to poultry flocks, but also to the consumers who expect safe, as well as nutritious, poultry products. This, the twelfth edition, upholds the long-standing reputation of this book for keeping scientists, breeders, poultry producers, and poultry health professionals supplied with the latest and most comprehensive information available.

Sixty-five years have passed since the first edition was printed. Before all details are lost forever, it is fitting to look back at how this "bible" in the field of poultry diseases came to be and how it has evolved into what it is today. It all began in the 1930s. In a memorandum addressed to the American Association of Avian Pathologists (AAAP), dated December 22, 1965, H. E. Biester related the events that preceded the decision by the Iowa State College (now University) Press (ISU Press) to undertake the publication of *Diseases of Poultry*. During the 1930s, Louis DeVries, a member of the Department of Modern Languages at the college, translated a 1929 German book entitled *Handbuch der Geflügelkrankheiten und der Geflügelzucht*, published by Ferdinand Enke, Stuttgart. The translation lay dormant for several years until Dr. Campbell, the Chicago publisher of *Veterinary Medicine*, saw the translation and expressed some interest in it. Dr. Biester, who described himself as an "innocent bystander, having no special interest in the project" told Dr. Campbell that the manuscript was unacceptable for a variety of reasons, and he suggested that if he were serious about publication, then selected specialists should edit or rewrite the material. Dr. Biester later was pulled into the project, and he ultimately concluded that the German book was obsolete. Apparently, a number of contributors had accepted invitations to cooperate in developing an American book, and, according to Biester, they agreed that "... it would be better to prepare a totally new book based on American conditions."

Thus, the die was cast. Dr. Campbell gave up his plans, and ISU Press decided to publish an original text. Drs. Biester and DeVries served as editors, and 34 American investigators were engaged in the project. There were chapters on general subjects such as anatomy, digestion, genetics, hematology, hygiene and sanitation, nutrition, and surgery as well as those dealing with specific infectious and noninfectious diseases and conditions. A separate chapter dealt with diseases of turkeys. In 1943 the first edition was ready. The publication costs were considerable for a book that was thought to have limited distribution, so it was decided to omit royalties and accept a subsidy for illustrations from the dean of the college. Fifteen hundred copies were printed and placed on sale for $7.50. To everyone's surprise, a second printing of 2,500 copies was needed after less than nine months, and there was yet another printing of 2,500 copies two years later.

Royalties were then instituted! ISU Press was concerned that without some remuneration, the authors might be reluctant to remain "dedicated."

The inclusion of Dr. DeVries as an editor is a bit puzzling since he had no medical background. Perhaps it was in recognition of his effort with the translation of the German text. In any case, he was replaced in subsequent editions by Dr. L. H. Schwarte, a member of the Veterinary Research Institute in Ames who had written four chapters in the first edition. The book was thereafter referred to by many as "Biester and Schwarte" even for a period after they were no longer associated with it. They continued at the helm through the fifth edition published in 1965. Although Dr. Schwarte contributed several chapters in each of the first five editions, Dr. Biester apparently confined his efforts to editorial tasks. Their memo to the AAAP stated that they both were responsible for making the index, and they personally checked practically all of the references because they felt that they "owed to the reader accuracy." A total of 61 people served as authors under their editorial supervision; 12 of them contributed to all five editions.

Ultimately, the passage of time dictated that Drs. Biester and Schwarte should relinquish their roles as editors, and they decided that the fifth edition (1965) would be their last. As noted in the preface to the sixth edition, it was their wish ". . . that future editions of the book become the responsibility of the AAAP. . . .", which had become a strong and representative organization to which many of the users of *Diseases of Poultry* belonged. Also the AAAP was already in the business of publishing the journal *Avian Diseases*, so it was considered a logical move. The AAAP appointed a committee, chaired by Dr. M. S. Hofstad who had been one of the book's authors and who was on the faculty in Ames. Drs. Biester, J. E. Williams, B. S. Pomeroy, and C. F. Helmboldt filled out the committee, and, in June 1966, they recommended that the AAAP sponsor future editions of *Diseases of Poultry,* which would continue to be published by ISU Press in Ames. They asked the board of directors to appoint an editorial committee consisting of an editorial chairman and four associate editors by January 1, 1967. A letter from Dr. G. H. Snoeyenbos (AAAP secretary-treasurer) to Dr. C. A. Bottorff (AAAP president) dated November 23, 1966, suggested that Dr. P. P. Levine had declined a proposal that he assume the editorship of the book. Dr. Hofstad was subsequently named editor, and he personally requested that Drs. Helmboldt, B. W. Calnek, W. M. Reid, and H. W. Yoder, Jr., be invited to be the associate editors. Each was given responsibility for a group of chapters that largely represented their individual interests and strengths. An agreement between the AAAP and the ISU Press was executed on May 8, 1967, and it was agreed that manuscripts would be delivered to the publisher by September 1, 1969. So the transfer was complete and official.

The sixth edition, under totally new editorial support, underwent some significant changes. The length of the book was beginning to be of concern and there was some discussion about perhaps needing to split it into two volumes. To avoid this, several chapters (anatomy, nutrition, genetics, and hematology) were eliminated based on good coverage in other publications. Also,

there was a consolidation of other material; for instance all neoplastic diseases were placed in a single chapter, and turkey diseases were incorporated in other chapters based on etiology. There were sweeping changes in authorship. Only 14 of the 40 contributors to the sixth edition had participated in the fifth edition. Clearly, a new era had arrived!

Also, following concern for the book's length, Dr. Hofstad asked that the number of listed references be reduced by *selective citation.* He agreed that the reader should *find,* or *be directed to,* all pertinent literature on each of the covered topics, the latter through citation of review papers, etc. Space allocated to references became an issue in subsequent editions as well. In the seventh and eighth editions, titles of all references were removed. This was controversial and not all editors agreed—including the author of this review—and reference titles appeared again beginning with his tenure as editor of the ninth edition. Interestingly, based on the number of pages, the third edition (1,245 pages) was actually longer than the eleventh (1,231 pages). But by increasing page size, decreasing type size, and splitting into two columns per page, it was possible to include more than twice the amount of written material in the latter.

Unlike the situation with Drs. Biester and Schwarte, citations and their accuracy became the responsibility of the individual authors. When it was observed that many errors existed, authors of the ninth edition were asked by Dr. Calnek to check every single reference against the original work so as to assure accuracy. This met with an enormous number of groans and considerable resistance until each author (with perhaps an exception or two) followed this strict instruction. The subsequent turn-around in their attitude was truly amazing when nearly all of them found errors, including the citation of references that did not even exist. It was not uncommon to detect mistakes in as many as 10 percent of citations in some chapters, probably due in large part to a common practice of copying reference citations from other lists.

Beginning with the ninth edition, the book entered the electronic age. All material was submitted or copied into a word processing program that allowed spell-checking and reformatting. Initially, it was a tedious job, particularly because personal computers at that time were slow, and the skill of the individual authors in mastering a new approach varied considerably. However, improvements in software and computers and the possibility of rapid transfer of texts between authors, editors, and the publisher made the preparation of a new edition pleasurable compared to the old "hard copy" approach.

There has been a continuum of changes that have improved *Diseases of Poultry* and kept it relevant over the years. For the tenth edition, the editors carefully reviewed and upgraded illustrations, and, for the first time, included a number of color plates. Another major improvement that was gradually incorporated was the inclusion of molecular biology in many of the chapters. This was particularly important with regard to new applications of molecular techniques in diagnostic procedures, descriptions of etiological agents and significant elements of their molecular makeup, understanding the significance of selected genes in the pathogenesis of the diseases, and the development of genetically engineered vaccines. Our understanding of the fundamental na-

ture of many diseases is now founded on the use of molecular approaches in the research laboratory.

Another of the more significant evolutionary changes was the addition of foreign authors to make the book truly international in flavor. One of the original AAAP-appointed editors argued strongly that *Diseases of Poultry* should be an "American" book, and the authorship was so aligned. The sixth edition had the first "foreign" contributor, although he (Bela Tumova, from Prague, Czechoslovakia) was actually a visiting professor at the University of Wisconsin working with B. C. Easterday on avian influenza at the time. It wasn't until the eighth edition that invitations to contribute to the book were extended to workers outside of the United States. Drs. P. M. Biggs and L. N. Payne from England and Drs. J. B. McFerran and M. S. McNulty from Northern Ireland thus paved the way by providing parts of the chapters on neoplastic diseases, adenoviruses, and miscellaneous viral infections. The next edition (ninth) was truly international with 17 contributors from 9 countries outside of the U.S., and by the eleventh edition, there was a total of 34 different contributors from 13 countries. The world-wide reputation of the book was certainly enhanced by the selection of authors based on their knowledge and contributions to our understanding of individual diseases and conditions without regard to their geographic location.

The importance of *Diseases of Poultry* as a text for the world also is reflected in its translation into foreign languages or publication in a "copied" form in other countries. There have been several authorized translations into Spanish, Chinese, and Russian, and an agreement between the publisher and India has allowed what is essentially a photocopied version of the original to be made.

An ongoing review of the relative importance of individual diseases or conditions has led to a good deal of reshuffling over the years. Chapters have been added, combined, split, or eliminated to meet the changing picture of what is important to the field of avian diseases and disorders. Periodically, and especially with a change in authorship, major rewriting of some sections takes place. New chapters such as one dealing with new and emerging diseases appear when needed.

Changes in editors occurred over the years so that by the eleventh edition, none of the 1968 group appointed by the AAAP remained. After riding herd on three editions (sixth–eighth), Dr. Hofstad retired and was replaced by Dr. Calnek (ninth and tenth), and he, in turn, passed the baton to Dr. Y. M. Saif beginning with the eleventh edition. Likewise, associate editors who have replaced or been added to the original group appointed by the AAAP in 1968 include Drs. H. J. Barnes (eighth–eleventh), C. W. Beard (ninth and tenth), L. R. McDougald (tenth), Y. M. Saif (tenth), J. R. Glisson (eleventh), A. M. Fadly (eleventh), D. E. Swayne (eleventh), and Lisa K. Nolan (twelfth).

In summary, it is obvious that the "bible" in the field of avian diseases is an evolving, vibrant, and ever-current source of information relevant to all practitioners in the field of poultry medicine. It continues to be a reference source of significance to a vast number of people with many different relationships to the poultry industry.

Diseases of Poultry

Chapter 1

Principles of Disease Prevention: Diagnosis and Control

Introduction

Alex J. Bermudez

This chapter acquaints the reader with the general concepts of poultry disease prevention, diagnosis, and treatment. It specifically introduces the reader to management practices used in disease prevention and poultry vaccination, principles of antimicrobial therapy, and basic necropsy procedures. This chapter also provides information on insecticides and disinfectants. For information on specific diagnostic techniques and control measures, the reader is referred to the respective chapters covering specific diseases in this text.

This chapter does not cover all the detailed disease control methods or all types of poultry but attempts only to outline and illustrate some fundamental concepts. Each poultry enterprise is different; therefore, these basic concepts must be applied according to conditions and facilities existing in individual situations. To keep abreast of the flow of research and information, a constant review of current literature and recommendations applicable to specific diseases, special enterprises, and various geographic areas is necessary. Excellent journal sources of current information are *Avian Diseases*, *Avian Pathology*, *Poultry Science*, *Journal of Applied Poultry Research*, and *World's Poultry Science Journal*, and many publication and trade journals provide special emphasis on particular segments of poultry husbandry (e.g., *Poultry International*, *International Hatchery Practice*, *Industria Avicola*, *Egg Industry*, *Watt Poultry USA*, *International Poultry Tribune*, *Poultry Times*, and others, including publications in a variety of languages). Standard textbooks on chicken and turkey production, husbandry, and nutrition are other sources of information. A good practical manual on commercial chicken production is North and Bell (2).

During the last three decades, the poultry industry has experienced many changes that have had a significant effect on the prevention and control of poultry diseases. One of the most significant changes has been the continued integration of poultry production companies and the consolidation of these companies and the allied industries that serve them. These changes have a profound effect on the poultry industry as the decision-making process becomes more centralized in poultry companies and fewer products and services become available with the mergers of biologic and pharmaceutical companies.

While the poultry industry has changed significantly as the re-sult of internal market forces, it also experiences significant external forces that are largely beyond its control. Examples of such forces include the globalization of the world economy, food safety issues, environmental concerns, animal welfare issues, and concerns about the use of antimicrobials in food animals. These external forces have a very direct impact on the activities of poultry health professionals as they certify poultry or products for export, address consumer concerns, and work to ensure the production of safe and wholesome poultry products. Although many of these topics are beyond the direct scope of this text, they can have a significant indirect or direct impact on the disease agents that affect poultry.

Host-Parasite-Environment Relationship

Disease results when normal body functions are impaired, and the degree of impairment determines the severity of the disease. It may result from the consequences of harmful actions of infectious and parasitic agents, or it may be caused by injury or physical stress with which the bird cannot cope. Disease may also occur as the result of a deficiency of a vital nutrient or the ingestion of a toxic substance.

Diseases caused by infectious and parasitic agents are frequently complex and depend upon characteristics of the host, agent, and environmental conditions on the farm. Nutritional deficiencies may be temporary and reversible when the nutrient is supplied in adequate amounts; others are irreversible. Disease resulting from stress is related to its severity and duration. Injuries, such as extreme beak trimming, tend to persist for a long time and may be permanent.

Whether disease results from parasitism depends on the number, type, and virulence of the parasite; the route of entry to the body; and the defense status and capabilities of the host. The latter depends partly on the host's prior disease encounters (e.g., infectious bursal disease or IBD), nutritional status, and genetic ability to organize resistance mechanisms; environmental stresses; and the kind and timing of countermeasures employed (drugs or changes of environment).

Some virulent organisms, such as highly pathogenic avian influenza, rapidly overcome the resistance of even the healthiest hosts. Less virulent strains or types cause moderate to severe ill-

ness, but most birds respond and return to a state of health. Still other strains or types cause no marked reaction, and the host shows little or no obvious signs of ill health. Some infectious agents may not cause dramatic effects themselves but predispose the host to more serious infections by other agents. Some microorganisms are not considered pathogenic because they usually are found in and around individuals considered "normal;" it must be recognized, however, that so-called nonpathogenic and low pathogenic organisms can also cause serious losses when the right environmental circumstances exist. Severe physical stresses such as chilling, overheating, water deprivation, starvation, and concurrent infection by other disease agents can reduce the host's ability to resist and, thus, may precipitate a disease condition that can be detected (e.g., clinical mycoplasmosis following infectious bronchitis or clinical salmonellosis in chilled or water-deprived chicks).

Coccidiosis provides a good example of the relationship between the number of invading organisms and the severity of the resulting infection, because the morbidity and mortality of the host species are usually proportional to the number of sporulated coccidial oocysts ingested. Environmental conditions still play a significant role, however, as litter conditions will affect both the rate of oocyst sporulation and survival. A similar situation exists for many other infectious diseases. A mild roundworm infection may not be serious; whereas a severe infection can be very detrimental. A good reason for removing moribund and dead birds from a flock is to reduce the number of infectious organisms available to penmates. Thorough washing and disinfecting of a building may not render it sterile, but it can reduce the number of infectious organisms to such a low level that they cannot cause disease.

By following sound disease-preventive practices before and after the arrival of new flocks; making sure that the flock has adequate, properly placed, good quality feed and water; applying judicious and timely vaccines and medications; and providing a less stressful environment, the poultry producer can control the probability of a flock becoming infected, as well as the severity and outcome of an infection.

Influence of Modern Practices

Avian disease specialists continually must seek new knowledge about the nature and control of specific diseases. Meanwhile, persons responsible for the production of poultry meat, table- and hatching-eggs, chicks and poults, feed ingredients, and mixed feeds should practice the basic techniques and management principles that will prevent occurrence of disease. They should also provide the physical facilities and quarantine capabilities necessary for control and elimination of diseases that occasionally gain entrance so that they do not become a continuing problem. Economic losses, sometimes relatively subtle, resulting from disease can mean the difference between success and failure in the poultry business. Those who disregard the basic principles of disease prevention may succeed in times of a favorable market but do not remain competitive when the margin of profit is very small. A new modern enterprise with many good buildings and labor-saving equipment, but constructed and operated without re-

gard to fundamental disease control and eradication principles, may function free of disease for a few years. All too frequently, a troublesome disease gains entrance and thereafter becomes a constant costly burden because of the extreme cost of depopulation required to eradicate it.

When new farms and buildings are designed and constructed and production is programmed with the objective of excluding diseases or eradicating them when they gain entry, poultry can be maintained free of most harmful diseases in a practical manner with reasonable effort. The poultry producer who uses fundamental management practices that prevent disease outbreaks has little need for detailed knowledge of the many infectious diseases affecting poultry.

Facilities need not be new to be adequate. Frequently, old farms can be enlarged and production reprogrammed to exclude or eradicate disease. Many old poultry buildings, hatcheries, and feed mills can be redesigned to favor exclusion, eradication, or control of disease. Strict application of disease-preventive management techniques has enabled producers to maintain specific-pathogen-free chickens on farms of standard design and construction (1).

The trend in all agricultural industries continues toward larger units, fewer farmers, and corporate enterprise. The chicken and turkey industries have been leaders in this trend, which has placed emphasis on efficiency and lower costs of production. Survival in the industry has depended upon continual adoption of newer and more efficient practices. It is sometimes forgotten that efficiency in disease prevention is as important as efficiency in cleaning, feeding, bird handling, and egg processing. The resulting evolution of management systems has altered the emphasis in disease-control practices and will continue to do so (e.g., the shift in placing layer flocks in multi-flock complexes rather than single-age farms has eliminated the possibility of all-in, all-out production and provides a much greater challenge to the flock manager in the control of respiratory disease).

Corporation farming accelerated the move toward integrated control and operation of two or more segments of the industry, such as feed manufacturing, breeder flock management, hatchery operation, pullet rearing, broiler and turkey grow-out phases, laying farm production, egg processing, turkey and broiler slaughter and processing, retail distribution, and further processing of poultry products. Integration of the industry has concentrated under one decision-making body the disease control practices for millions of birds, as well as several phases in the production chain of eggs and meat. Thus, sound health practices and emergency quarantine measures decided upon by one or a few individuals can be applied quickly and effectively to large numbers of birds. Through integration, it has become economically practical to employ veterinarians full time and to place responsibility for disease control directly in the hands of specialized poultry veterinarians. Disease considerations are sometimes reduced to simple cost accounting, whereby the economic loss from a disease and the costs of treating it are weighed against the costs of its eradication and of maintenance of the clean status, before determining the course of action. Poultry production managers must be careful not to make decisions that produce short-term cost savings

but potentially greater negative long-term cost effects as the result of a higher disease incidence. Examples of such potential shortsighted cost savings are the excessive dilution of Marek's disease vaccine, reusing litter in turkey brooding facilities, and excessively shortening the turn-around time between production flocks.

The poultry industry can no longer be considered to be composed of localized businesses limited to certain states or areas. It is characterized by multistate and often multinational companies that move products daily between widespread locations and markets. Because of the high cost of scientific poultry breeding, producers throughout the world depend on a few organizations for their highly efficient breeding and production stocks. In the case of turkeys, most of the world's breeding stock originates from one of three locations in North America. For such a system to function smoothly and efficiently, widespread and daily shipments of hatching eggs, poults, chicks, started pullets, and adult fowl across state and national boundaries are essential and necessitate reevaluation of old concepts of health regulations. Specialized poultry veterinarians and state and federal livestock health officials have evolved to guide the course of health control measures. Diagnostic facilities, both private and government, are available in major poultry-producing areas of the world. Except where importation and use are restricted by government regulation, high-quality vaccines and drugs are available wherever poultry is raised commercially. Good quality feed is the rule, not the exception, in the modern poultry industry.

Despite significant advances, disease still takes a heavy toll from all types of poultry enterprise. Those who exercise farm management decisions (caretaker, owner, flock supervisor, corporate manager, money lender) have the power to reduce these losses through management for disease control. They must be made aware of the responsibilities and continually encouraged to develop a philosophy of disease prevention through management and to concentrate on amortized long-term advantages and not just short-term savings.

With better control over diseases of all kinds, providing optimum bird comfort throughout the house has become a very important management factor in obtaining maximum performance. That is not achieved solely by windowless, insulated, light- and temperature-controlled houses. Such factors as overcrowding, poor beak trimming, uneven temperatures, and uncomfortable air currents on caged birds that cannot move to a more comfortable location also adversely affect performance. Proper orientation of feeders, waterers, and light promotes good performance; slight, seemingly insignificant changes from proven systems can have a pronounced adverse effect on performance of both caged and floor-housed flocks of chickens and other commercial fowl. Poor performance of adults is often traceable to detrimental events that occurred during the rearing period. An attentive and skilled farm manager is of great importance in the successful production of poultry flocks.

Disease Prevention and Diagnosis
Alex J. Bermudez and Bruce Stewart-Brown

Breeder Flock Management

The breeder flock must be managed in such a way so as to optimize the production of clean fertile hatching eggs in an economic fashion. This management program must ensure that the chicks or poults produced will be viable from both an immunologic and nutritional perspective when they are placed in the production setting. The science of effective breeder flock management is somewhat beyond the scope of this text, and a reference on this topic has been published by Leeson and Summers (34). Disease prevention measures must also be in place to prevent diseases that will result in morbidity and mortality in the breeder flock itself. Finally, the breeder flock should be managed so that egg-borne diseases are prevented by whatever techniques are available.

Diet, Health, and Parental Immunity
A breeder ration must contain a higher level of many nutrients than does a laying ration. Laying rations sufficient to sustain egg production are not adequate to sustain good hatchability and health of young offspring. In some cases, production is satisfactory in breeder hens, but their embryos or chicks show symptoms and lesions of vitamin deficiency. The breeder ration must be adequate for development of the embryo and the chick as well as egg production performance of the breeder hen. The minimum nutritional requirements of breeder flocks are well characterized in the *Nutritional Requirements of Poultry* (44) published by the National Research Council. Poultry nutritionists responsible for the nutrition of commercial breeder flocks frequently supplement the nutrient inputs of breeder flocks beyond these minimum requirements to provide an additional margin of safety in the ration.

Meat birds are bred to grow fast and large, but the flocks kept for breeding must have feed intake restricted to prevent obesity and poor adult performance. Feed restriction must be carefully controlled to prevent aggressive birds from getting most of the available feed. Two systems are widely used: daily restriction and skip-a-day feeding. The former requires special feeding equip-

ment or procedures to ensure that feed is presented to the entire flock simultaneously so that all birds begin eating at the same time. In the skip-a-day system, feed is given in larger quantities on alternate days, permitting the recessive birds to obtain their share even if they have to wait their turn to eat. In either system, special provision must be made in formulating feeds to provide adequate coccidiostat and essential nutrients in the reduced amount consumed.

Breeder hens in poor health for any reason frequently fail to supply the embryo with some vital nutritional factor(s) or perhaps pass some toxic material to the egg; thus, the hatch is poor or chicks are of low quality and must be culled. A good example of such a problem is breeder hens infected with capillaria worms; they may produce progeny that are deficient in vitamin A. While this occasionally happens with apparently healthy birds also, a clinically healthy breeder flock is the best insurance of good quality offspring.

Young poultry are delivered into many types of environments. In some areas, husbandry methods are such that birds are exposed to disease from the first day of life. In some cases, exposure of very young poultry lacking any maternal antibodies to a disease can lead to significant mortality or economic loss (infectious bronchitis, avian encephalomyelitis, IBD, or duck virus hepatitis). Where exposure is apt to occur at a very early age, maternal antibody can be a significant aid to prevention of disease. However, a high level of maternal antibodies can interfere with early immunization. How much maternal immunity is desirable and against how many diseases are debatable subjects and will vary according to the area where poultry are raised and the type of rearing facility (cage versus floor).

Maternal immunity is dissipated gradually and usually does not last more than 2–4 weeks after hatch. In modern, well-run layer and breeder replacement-rearing facilities chicks and poults are well protected, not only against the elements, but also against introduction of disease from outside sources for several weeks or beyond the time that a high initial maternal immunity would be protective. Maternal immunity in chicks is of less concern in such cases. This is not so likely to be true of inadequately sanitized and poorly managed pullet-rearing or broiler grow-out farms, where exposure can occur as early as the first day of life to a disease agent carried over from the previous brood in reused built-up litter. In these cases, protective maternal antibodies become a very important consideration in preventing disease or reducing losses, and vaccinating breeder dams with killed vaccines to give high maternal antibody protection for the offspring has become common practice. Lesions and residues from the carrier for killed vaccines injected into the breast muscle have been cause for carcass condemnation at slaughter.

Interior Egg-Borne Diseases

Various techniques are used for preventing disease agents from being transmitted from dam to offspring via the egg. The ideal situation is to have breeders free of all pathogens. For most viral diseases, there is still no practical way of obtaining this utopian situation. For others (avian encephalomyelitis), the probability of the infection occurring during the egg-laying period, with result-

ant egg transmission, is too great to permit the clean but susceptible status (see Chapter 14).

Immunization

In addition to immunization of breeders against several common diseases to prevent adverse effects of inopportune infections on egg production, they are immunized against avian encephalomyelitis during the growing period to ensure that they do not become naturally infected during the period they are producing hatching eggs. Although this may not be an absolute guarantee against egg transmission of the virus, it has been a practical means of preventing its serious dissemination through infected offspring.

Testing and Removal of Carriers

Carriers of some transovarially transmitted diseases can be detected by serologic or other means, and this procedure has been used to eliminate possible egg shedders from breeding flocks. Historically, this has proved to be an important starting point in the successful eradication of pullorum disease and fowl typhoid. Similar programs currently are practiced by primary breeder companies to reduce the vertical transmission of lymphoid leucosis.

Testing and Slaughter of Infected Flocks

Where infected breeders are detected, the entire flock may be destroyed. This method is indicated in circumstances whereby testing is not likely to detect all infected birds. It is a costly procedure and not warranted unless there is a definite advantage for the offspring and reasonable assurance that they will not become infected from other sources after delivery to the farm. It has been used successfully for eliminating mycoplasma-infected turkey and chicken breeder flocks.

Destruction of Agent inside the Egg

A pressure differential between the atmosphere and the inside of the egg has been used to force antibiotics through the shell of incubating eggs to prevent transmission of pathogenic *Mycoplasma* species from dam to offspring. This is done by dipping warm eggs into cold antibiotic solutions or using special vacuum machines (2). Antibiotics have also been injected directly into eggs for this purpose (40).

Elevating the egg temperature has also been used to destroy mycoplasmas inside the egg (76). In this procedure, incubator temperature (and internal egg temperature) gradually is raised over a 12–14-hour period to the maximum embryo survival temperature, approximately 46.9°C and then cooled immediately and rapidly to normal incubation temperatures. The procedure usually lowers hatchability.

Treatment of Offspring

Offspring from infected dams may be treated with high levels of antibiotics by injection or feeding or both. This is unreliable, but can be a significant adjunct to other methods and can greatly assist in overcoming economic losses from egg-transmitted diseases that are drug sensitive.

Eggshell-Borne Diseases

Several procedures are used to overcome shell contamination that arises from intestinal contents and other environmental sources. Control involves preventing shell contamination or destroying organisms before they penetrate the shell.

Egg penetration by bacteria occurs more readily if the shell becomes porous. This occurs in the late life of the breeder hen or when there is a deficiency or imbalance between calcium, phosphorus, and vitamin D. Respiratory virus infections can also result in porous and poor shells.

Management of Hatching Eggs

Clean Hatching Eggs

Very dirty eggs should not be used for hatching. If they must be used, they should be dry-cleaned when gathered. The cleaner the shell surface, the less likelihood there will be bacterial contamination and shell penetration.

The most important consideration in hatching egg sanitation is to manage the flock so that eggs are clean when gathered. Many factors enter into accomplishing this goal. Sloping wire-bottom rollaway nests, with or without automatic collecting devices, generally result in clean eggs and a minimum of bacterial contamination.

Clean eggs can also be produced in conventional box-type nests if nesting material is diligently kept clean by continually replacing soiled material. Egg breakage can be reduced by providing sufficient nests for the peak laying period.

The number of floor and yard eggs can be reduced by proper design and location of nests when maturing pullets need them; location and design will vary with the type of house. Nests should be darkened and ventilated, and hens must be prevented from roosting in them at night, because they contaminate the area with fecal deposits.

Keeping the litter dry is an aid in preventing soiled nests and nest material. Proper design and construction of the breeder house to create conditions conducive to keeping litter dry aids disease control at the hatching-egg level. Table-egg breeding stock perform satisfactorily in litterless housing—either all slat or sloping wire-floor houses—and this largely eliminates dirty eggs resulting from tracking litter and feces into the nests. Heavy breeds and turkeys do not perform as well on these floors, so combinations of part slat and part litter are used to aid in litter management.

Measures should be taken to prevent *Salmonella* infections by using *Salmonella*-free feed ingredients, particularly meat meal, eliminating these pathogens from mixed feed (pelleting), keeping feed clean by good feeding practices and storage facilities, and keeping natural carriers (rodents, wild birds, pets) out of pens and houses. Preventing salmonellosis and other types of enteric infections also helps prevent wet droppings, which contribute to wet litter.

Above all, eggs should be gathered frequently, especially in the early part of the day when most hens visit the nests. They should be gathered in clean, dry equipment and held in a dry, dust-free area.

Sanitization of Eggs

The shell surface of hatching eggs should be disinfected immediately after gathering. If sanitization or fumigation cannot be done on the farm, it should be done as soon as possible thereafter, preferably before eggs enter the hatchery building or at the entrance to the egg-processing area. The more delayed the sanitization, the less effective it is because the bacteria will have had longer to penetrate the shell. Unsanitized eggs raise the possibility of carrying a serious infection into the hatchery where susceptible newly hatched chicks are present (see "Disinfectants, Formaldehyde"). Because of possible adverse health considerations resulting from the inhalation of formaldehyde fumes, farm and hatchery personnel should be alert for any new and effective shell sterilization compounds and methods that may become available.

Washing and Liquid Sterilization

Washing eggs with warm detergent solution at a temperature (43–51.8°C) always higher than that of the eggs entering the washing machine—at least 16.6°C higher but not to exceed 54°C—followed by sanitizing the shells with a chlorine compound, quaternary ammonia product, or other sanitizing agent is routine for commercial eggs. The procedure has been employed successfully with hatching eggs, but some real disasters have occurred where thousands of eggs were contaminated rather than sanitized when dirty water was used, especially in recirculating washing machines. Even if eggs are washed properly, very dirty eggs should be cleaned first by sanding to prevent excessive pollution of the washing solution and equipment. If the iron content of the wash water exceeds 5 ppm, it favors multiplication of certain types of bacteria and creates a serious egg spoilage problem. A complete review of egg sanitizing agents is presented by Scott and Swetnam (57).

If egg washing is done, it should be only with a type of machine (brush conveyor type using flow-through wash water principle) that will ensure against contamination with dirty wash or rinse water. Very careful supervision is also necessary to see that all equipment is working properly at all times and is cleaned daily. In some types of machines, if the washing system fails, a few eggs can contaminate the water and, thus, contaminate thousands of others before the problem is detected and corrected. Contaminated eggs in the incubator set off a chain reaction of egg explosions that contaminate surrounding eggs, causing more "exploders" and more contamination. While washing and liquid sterilization of hatching eggs can be done satisfactorily, the procedure is subject to operational difficulties and should not be attempted without full knowledge of the hazards involved.

Whenever cold eggs are moved into a warm, humid atmosphere, moisture condenses on the cold shells (called "sweating"). This moisture provides a medium for the growth of bacteria and fungi already present on dirty or unsanitized shells or originates in contaminated warm air around the eggs. Cold eggs should, therefore, be warmed to room temperature in clean, low humidity air before placing them in an incubator.

Storage Facilities

After fumigation or other shell sterilization, hatching eggs are frequently stored in a cool room (about 10°C) at the hatchery

until set. Cool rooms should be clean and free of mold and bacteria and periodically disinfected to prevent recontamination of shells. Holding hatching eggs too long or under improper storage temperature, humidity, and environment can result in poor quality chicks. Clinical histories indicate that infection in young chicks may sometimes be traceable to fungus-contaminated hatching eggs; infections have been produced experimentally by contaminating shells with fungus spores (75).

Hatchery Management

The building and equipment in which the fertile egg is converted to a day-old chick, poult, or other fowl and the equipment used to process and deliver it to the farm must be clean and sanitary. An individual hatched from a pathogen-free egg will remain pathogen-free only if it hatches in a clean hatcher, is put in a clean box and held in a clean room where it can breathe clean air, and then is hauled to the farm in a clean delivery van.

Design and Location

A hatchery should be located away from sources of poultry pathogens such as poultry farms, processing plants, necropsy laboratories, rendering plants, and feed mills. It is not good practice to retail poultry equipment and supplies from a hatchery building, because this draws producers and service workers who may introduce contaminating material.

A good hatchery design has a one-way traffic flow from the egg-entry room through egg-traying, incubation, hatching, and holding rooms to chick-loading area. The cleanup area and hatch-waste discharge should be off the hatching room, with a separate load-out area. Each hatchery room should be designed for thorough washing and disinfecting. The ventilation system is equally important and must be designed to prevent recirculation of contaminated and dust-laden air. Gentry *et al.* (26) found that hatcheries with poor floor designs and faulty traffic patterns were highly contaminated compared with those with one-way flow.

Importance of Good Sanitation

Factors that aid in obtaining pathogen-free chicks and poults are hatchery cleanliness and sanitation, well-arranged traffic flow, and well-controlled ventilation.

Techniques have been devised for evaluating the sanitary status of commercial hatcheries by culturing fluff samples (74), detecting microbial populations in hatchery air samples (19, 26, 36), and culturing various surfaces in the hatchery (38). By relating results of these techniques to hatchery management, it has been observed by Magwood (37) that bacterial counts of eggshells dropped quickly in clean air, and low counts persisted on all surfaces to completion of hatching. Chute and Barden (18) found fungal flora of hatcheries to be related to management and sanitation programs.

To minimize bacterial contamination of eggs and hatching chicks, hatchery premises must be kept free of reservoirs of contamination, which readily become airborne (37). Trays used for hatching should be thoroughly cleaned with water and then dis-

infected before eggs are placed in them. This can be done by dipping in a tank of suitable disinfectant (see "Disinfectants"), washing with hot water or steam followed with disinfectant spray, or fumigating with formaldehyde in the hatcher. Trays and eggs are frequently fumigated together immediately after eggs are transferred to the hatcher. Fumigation is sometimes done during the hatch (at about 10% hatch), but concentrations low enough to avoid harming the hatching chick probably serve only to give the down a pleasing yellow color. Formaldehyde fumigation in one case increased the severity of mold infection rather than overcoming it (75). Wright (72) emphasized the practical meaning of hatchery sanitation and how to attain it. He concluded that no fumigation program should be used to replace cleanliness, but rather to supplement it.

As chicks hatch, the exposed embryo fluids collect bacteria from contaminated shells, trays, and ventilating air. The combination of the nutritious fluids and warm temperature forms an excellent environment for bacteria and they multiply very rapidly (26). The cleaner the air and environment to begin with, the more the bacterial buildup is delayed and, as the hatch progresses, the less likely is the navel to become infected (omphalitis).

Breeder Codes

The breeder code is a designation used to denote the source of hatching eggs. It usually denotes breeders of the same age on the same or different farms, all breeders on a particular farm, or any other grouping. There is a tendency to keep breeders in larger flocks and to avoid as much as practicable the mixing of hatching eggs from flocks of many different microbial, nutritional, and genetic backgrounds. If breeders are kept free of disease and fed a good ration, hatching eggs are produced clean and properly disinfected, and chicks are hatched and handled in clean surroundings. Keeping chicks of different breeder codes separated has little practical meaning other than providing that all have more nearly the same level of maternal antibodies against the same diseases. This may permit a more uniform response to vaccines applied to chicks the first 2–3 weeks of life when maternal antibodies have a protective effect.

Occasionally, a disease is believed to be egg transmitted from a breeder flock to the offspring. When this occurs, the disease nearly always appears in several offspring flocks derived from the same breeder flock(s) and delivered to different farms. However, a hatch of chicks is frequently divided into deliveries to several farms and a disease occurs in only those delivered to one farm. This indicates that the disease is farm associated and not hatchery or breeder-flock associated.

Chick Sexers

Unless the output of one hatchery is so great as to demand their full time, chick sexers may go from one hatchery to another, which introduces the possibility of carrying disease. Most sexers are aware of this hazard and are eager to follow proper biosecurity procedures. If sexers must also service other hatcheries, facilities should be provided so that their equipment can remain at the hatchery. They should have a clean area in which to change clothes and wash themselves and their equipment and should

have clean protective garments to wear. Their habits should be at least as clean as those of the hatchery crew.

Surgical Procedures

Poultry can be very cannibalistic under certain circumstances, and beak trimming is commonly practiced in breeder flocks as well as production turkeys and cage layers. In these production systems, beak trimming is a virtual necessity, and special machines have been manufactured for this purpose. Beak trimming is performed on birds of various ages, depending on the husbandry system in use. The extremely dim light used in light-tight poultry houses greatly reduces or prevents cannibalism, but chicks reared under natural or bright light may have their beaks trimmed lightly at 1 day of age or a few days after delivery to the brooder. This early mild trimming is not severe enough to be permanent; therefore, beaks of such flocks of breeders or commercial layers are frequently trimmed again before maturity. Some methods and ages of early beak trimming can protect chickens from cannibalism throughout life if other management factors (e.g., light intensity) are favorable. When this is done properly, there is no serious adverse effect; however, proper beak trimming is more an art than a science, and many birds are permanently handicapped when it is not done properly.

If the operation is done correctly, after the beak tip is removed, the remaining growing tip is cauterized sufficiently with the hot cutter blade to prevent bleeding and regrowth, but not so much that the bird develops a sensitive or abnormal beak that interferes with eating and drinking. Proper beak trimming promotes maximum performance. Done improperly, it is probably the greatest single management cause of unsatisfactory performance of laying and breeding stock. Poor performance resulting from improper beak trimming must not be attributed to some mysterious disease. For more detail on cannibalism and beak trimming, see Chapter 30. Similarly, other surgical procedures, such as removing wattles, combs, or toenails of certain toes, must be done by one trained in the procedure if harm to the bird is to be avoided.

Management Factors in Disease Prevention

The more important physical principles of disease prevention include favorable geographic location of the farm in respect to other poultry units, proper location of buildings in relation to each other and to prevailing wind currents, proper design of the building inside and out, and design and positioning of equipment. Long-range planning and programming of the operation, whether large or small, is very important and should consider movement patterns of various vehicles and equipment, work traffic of regular and holiday caretakers and special work crews, feed delivery and storage, and the system for moving eggs and flocks from the farm. An avian pathologist can be helpful in avoiding some common pitfalls, but to avoid high-risk disease situations, consultation should be done when the farm is being designed and the production programmed, rather than after it is developed and serious trouble is evident.

Good disease-prevention practices are perhaps best illustrated as a chain that is only as strong as its weakest link. Many sound principles can be discredited by failure to carry out one or two related ones, which are either overlooked or not considered essential. Although it may not always be possible to use all the practices, the more that are followed, the greater the chances of avoiding disease outbreaks.

Adult Flocks

Modern laying strains are bred for high egg production, and broiler stocks are bred for rapid growth and good feed conversion. The most important management factor is maintaining feed, water, and environmental conditions at the optimum condition for hen comfort, which in turn results in maximum efficient production and growth. The same is required of meat birds, turkeys, and other types of breeder hens. The egg production or efficiency of feed use will be a good indicator of the success of the management and the welfare of the flock. Many conditions arise that hamper performance, and it is important not only to keep disease out, but to prevent conditions causing discomfort.

Isolation

Not all producers follow the same disease control practices. A close neighbor may disregard sound principles and be burdened with diseases until forced out of business by economic pressures. In the meantime, disease agents present on his premises may be blown or carried by various vectors and fomites to adjacent premises; thus, a disease occasionally may gain entrance even on well-managed units. Until a disease has been eradicated, it serves as a reservoir and potential source of infection for future flocks on the same premises and those on adjacent premises. The closer the houses of one premises to those of another, the more likely is the spread of infection to healthy birds on an adjacent farm.

Some highly concentrated poultry areas have developed because of some favorable condition such as a close market, an available slaughter or processing plant, an accessible feed supply, low-cost land, or favorable climate or zoning. Usually, these areas deteriorate into problem zones of disease of one type or another and resemble huge "megafarms" with many managers, each vaccinating, treating, or exposing birds without regard to the programs of others. Because such areas are in competition for markets, several things may happen. Various advantages may offset disease losses, or the additional cost of production resulting from disease may price the product (meat, eggs) out of the market. In extreme cases, products cannot be marketed either because of the disease or the residues from drugs used to control disease. Producers who do not minimize losses go out of business, and many abandoned poultry farms are purchased or leased by other poultry producers. Some move their operations to a less concentrated area where they usually escape disease, unless they take their problems with them knowingly or inadvertently through carelessness. Those who remain usually upgrade disease-prevention practices by redesigning houses and reprogramming the production cycle. Frequently, reprogramming proceeds to a system of a single age of fowl, permitting complete depopulation at the end of each rearing or laying cycle.

Another solution to area disease problems where farms are too

close even for systematic depopulation to succeed is to develop a coordinated area depopulation and restocking program. All flocks in a reasonably defined geographic area may be marketed at the same time and the houses refilled at the same time. This is more adaptable to broiler production than egg production.

Most serious disease problems could be avoided if a philosophy of premise isolation prevailed from the beginning of an enterprise. No exact minimum distance from other poultry farms can be stated because this is influenced by prevailing winds, climate, type of houses, and other factors. The farther from other poultry farms, the less likelihood of contracting disease from them. Isolation can be effected by taking advantage of segregating space provided by natural or artificial barriers such as bodies of water, hills, cities or towns, or forests, or other interposing agriculture enterprises such as grain, vegetable, or fruit production.

One Age of Fowl per Farm

Removing carriers from a flock and premises is an effective way of preventing a recurrence of some diseases, but it is impossible or impractical for others. The best way to prevent infection from carrier birds is to remove the entire flock from the farm before any new replacements are added and to rear young stock in complete isolation from older recovered birds on a separated farm segment or preferably on another farm and in an isolated area. This practice is often called "all-in, all-out production."

Where birds of different ages exist on a large farm, depopulation seems drastic, but considering mortality, poor performance, and endless drug expense, it could be the most economical solution. Farms and quarantinable farm divisions of up to 100,000 birds of one age prove that size is no deterrent to application of the sound principle of one age of bird per farm or quarantinable segment with programmed depopulation at the end of the production cycle.

Where only one age of bird is maintained, depopulation occurs each time pullets or poults are moved to the layer or breeder premises, each time the broilers or turkeys are moved to slaughter, and each time the old layers or breeders are sent to market. Should a disease occur, the flock can be quarantined, treated, and handled in the best way possible until its disposal. Depopulated premises are then cleaned out, washed, and disinfected, and left idle for as long as possible but at least for 2 weeks before new healthy stock is introduced.

Depopulation is most effective in controlling disease agents that do not survive for long outside the bird. This applies to most respiratory infections (mycoplasma infections, infectious coryza, and laryngotracheitis). It is least effective in controlling disease agents having a resistant state that survives for long periods in nature (intestinal parasites or clostridia).

Started-pullet and pullet-rearing premises are now an established specialized enterprise in the poultry industry. This system has made layer and breeder farm depopulation more practical and successful. As on multiple-age layer farms, serious disease problems may develop and persist on multiple-age rearing farms until they are reprogrammed for a single age or divided into quarantinable, isolated units.

Fig. 1.1. This isolated breeding farm benefits from several fundamental disease prevention and control principles. It is isolated from other poultry farms, is surrounded by forest land, and is divided into quarantinable sections separated by woods as well as distance.

In addition to sanitary practices, environmental factors (temperature, humidity) play an important role in the time interval necessary to prevent carryover of disease. Disease germs begin to die out slowly after elimination from the body. Some (infectious coryza) die out very quickly; others (parasites and coccidia) survive for months or years, depending on whether they develop a resistant stage and on factors discussed in the sections on those individual diseases. In general, the longer a premises remains vacant, the lower the number of surviving pathogens.

Functional Units

For certain economic reasons (breeding farm or small specialized market trade), it is not always possible to limit the entire farm to a single age of poultry. In such instances, it should be divided into separate quarantinable units or areas for different groups of birds (rearing area, pedigree unit, production groups, and experimental birds) (Fig. 1.1). With a suitable arrangement, each area periodically is depopulated, cleaned, and sanitized or can be if necessary. Much stricter security procedures for personnel, bird, and equipment movements are necessary for this type of operation. A very rigid monitoring system is also essential to detect any disease early enough to bring it under control while it is still confined to one quarantinable segment.

No reliable formula exists for minimum distances between houses or units. Windowless and temperature- and ventilation-controlled houses appear to prevent building-to-building and premise-to-premise spread better than open houses. Greater distance can compensate for some inadequacy in building design, human traffic control, and shared equipment. Because each premise and enterprise is different from all others, the poultry producer should seek advice from specialists whose business it is to study diseases and how to prevent and control them.

The most important factor in dividing the farm into segregated units is not so much to facilitate daily separation of farm personnel, equipment, and poultry but to provide quarantinable

units to prevent spread and facilitate elimination of disease, should it occur.

Building Construction

Birdproofing

The first rule in poultry house construction is to exclude free-flying wild birds, because many carry mites and harbor them in their nests. In addition, many species have been found susceptible to some common viral and bacterial diseases of poultry and, thus, could act as carriers. Turkeys on range are especially vulnerable to infections carried by wild birds. For this reason and for generally improved sanitary practices, the trend is to house turkeys, especially breeder and young growing turkeys, in closed or partially closed birdproof houses. Ducks and other domestic waterfowl are also vulnerable to waterborne diseases and to diseases carried by wild birds, especially wild waterfowl and seabirds (gulls, terns, etc.).

Light- and temperature-controlled houses are usually birdproof by reason of their construction (Fig. 1.2). Both ventilation and birdproofing are also achievable in open-type houses in hot climates. Birdproofing is also an important feature of other buildings on the farm (e.g., clean crate and wood shavings, bedding, storage).

Entrances

An apron of concrete at the entrance to a poultry house helps prevent tracking of disease into the unit. Rain and sunshine help keep the apron cleaned and sterilized. A water faucet, boot brush, and covered pan of disinfectant available on the apron for disinfecting footwear are further aids in keeping litter and soil-borne diseases out of the house. Boots must be thoroughly cleaned before the wearer steps into the pan of disinfectant. The disinfectant is useless, however, unless renewed frequently enough to ensure a potent solution at all times.

Ventilation

Poultry buildings should be constructed to provide protection against the elements, yet not create stress conditions such as excess dust, insufficient ventilation with ammonia buildup, excessive draft, damp litter, and situations leading to injuries by mechanical equipment or sharp objects.

Windowless and temperature-controlled houses have many advantages, but one serious drawback has been development in some instances of excessively dry and dusty litter. Although Anderson *et al.* (4) could not demonstrate significant deleterious effects of short-term inhalation of dust by test chickens, it has been observed in practice that colibacillosis outbreaks are frequently associated with inhalation of excessive dust, which must be carried from the building with ventilating air. This may require increased air movement, and precautions must be taken to prevent a stream of incoming cold outside air from blowing directly onto chickens that are prevented, by pen (or cage) arrangement, from seeking shelter.

Coccidial oocysts require moisture to develop into the infective stage. Excessively dry litter inhibits their development and may so limit the number of infective oocysts that infection is too

Fig. 1.2. Light-, temperature-, and ventilation-controlled houses exclude wild birds and most flying insects. Concrete aprons and paved roadways help prevent tracking of soil-borne diseases into the premises.

light for a good immune reaction. Conversely, improper ventilation can lead to excessively wet litter, which favors the survival and development of coccidia and other parasites.

Ammonia fumes develop in damp litter and droppings. If ventilation is poor and fumes accumulate, they may reach high enough concentration to inhibit growth and performance, cause keratoconjunctivitis, and exacerbate respiratory infections.

Litter will dry better if it can be stirred frequently, but in spite of all efforts, it may remain wet in winter or in humid climates. If wetness and excess ammonia concentration persist, litter should be replaced and ventilation improved.

Proper ventilation is an engineering science; a good policy is to seek professional advice before installing any system. The influence of such environmental conditions as temperature, humidity, radiation, and atmospheric pollutants on viral disease of poultry has been reviewed by Anderson and Hanson (3).

Floors and Cages

All surfaces inside the building should be of impervious material (such as concrete) to permit thorough washing and disinfection. It is impossible to sterilize a dirt floor!

Raised slatted floors have been used successfully for years for laying chickens, both for adults and for rearing birds. Such floors have alternating wooden pieces and spaces, each about 3/4-in. wide (Fig. 1.3), to permit droppings to fall out of reach of birds and to prevent recycling infection of intestinal parasites and diseases. Because coccidial infection is thus avoided or greatly reduced, poor or no immunity to the parasite develops. This creates no problem for pullets destined for cages or slat-floored laying houses, because immunity to coccidiosis during the laying period in such units would not be an important consideration. If such pullets were transferred to litter-floored laying houses, however, they would very likely become seriously infected with coccidiosis. Commercial meat birds are inclined to develop leg problems and breast blisters if raised on completely slatted or wire floors. A modification of this system, with part of the floor or yard raised slightly and covered with slats, has been used for broiler breeders. The value of this system is increased further by placing

Fig. 1.3. Slat floors aid in the control of intestinal diseases and parasites. Droppings fall through open spaces and out of reach of the flock.

Fig. 1.4. Poultry are kept in cages in well-built, ventilated, light- and temperature-controlled houses in many countries. Good housing reduces stresses associated with variations in weather, and cages reduce intestinal diseases and parasitism.

feed and water over the slatted area, which encourages collection of more droppings out of reach of birds.

Keeping laying hens in some type of cage has become an accepted practice in closed houses (Fig. 1.4) and open-type houses found in hot climates. Cages and wire floors are widely used also to rear pullets destined for cages as adults. The system is so successful in preventing intestinal diseases that birds have no opportunity to develop immunity to them. Coccidiosis is almost certain to occur if chickens or other poultry reared in cages are transferred to litter floors. Drugs can be used successfully to control coccidiosis in these birds, but legal restrictions of their use in meat and egg-producing fowl seriously curtail drug choices for this purpose in laying hens.

Feeders and Waterers
Rats, mice, and other rodents should be kept out of feed because they may introduce and spread salmonellae or other disease agents that can be the source of an outbreak in the poultry flock.

Litter scratched into feed and water troughs and feed spilled in litter increase intake of litter and litter-borne disease agents (e.g., more coccidial oocysts and less coccidiostat are ingested, and a clinical infection may result). If poultry are permitted to consume litter, considerable mortality and depression can occur from impaction of the gizzard, and litter fragments may cause enteritis by mechanical irritation.

Feed troughs should have some type of guard to keep poultry out and should not be overfilled so that feed is spilled into litter. Feeders without guards permit defecation into feed, which encourages spread of diseases shed in feces. Wet feed in litter provides a good medium for growth of molds, which can cause liver, kidney, immune system, and other damage to the well-being of poultry. Growing and laying cages for egg production flocks in

light- and temperature-controlled houses eliminate most of the problems associated with litter. Many good automated feeding and watering systems are available commercially, but sometimes these are not installed or oriented as the manufacturer intended, and consequently health problems develop.

Roost areas over screened dropping pits are common in floor-laying and breeder hen houses to keep chickens away from their feces. Screened roost areas are also desirable in rearing houses for layers and breeders to prevent piling by the birds and excessive fouling of litter with feces, which in turn leads to packing and caking. Feeders and waterers over the pits keep the birds on the roost area much of the daytime as well as at night, so most droppings collect out of reach. Spilled water also falls under the roosts, so the litter area stays drier.

Waterers are frequently set or hung over the litter area. In this case, waterers should be managed so that spillage onto the litter is minimized. Waterers can be put into two basic categories: those that provide a constant reservoir of water, which is maintained automatically (troughs, cups, and hanging plastic bells), and nipple drinkers (Fig. 1.5), which supply water on demand when activated by a bird. Waterers that provide an open reservoir of water must be cleaned and disinfected regularly to prevent the buildup of potentially pathogenic organisms in the water supply. These waterers are also more prone to spillage and the associated problems of wet litter. Starting day-old birds is somewhat easier with waterers that have an open and visible water reservoir. The advantages of nipple drinkers are found in the significant im-
Fig. 1.5.   Nipple drinkers are effective in preventing microbiological contamination of clean water and help maintain dry litter conditions.

provement they offer in providing water free of organisms commonly found in the poultry house environment and in decreased water spillage. The drier litter conditions afforded by nipple drinkers result in decreased multiplication or maturation of coccidia, bacteria, and fungi in the litter. Broiler production managers report a decreased incidence of infectious disease with the conversion of poultry buildings to nipple drinkers. Nipple drinkers have been developed that are suitable for most types of poultry production.

Feed and Water Medication
In spite of all precautions, poultry may become sick. This should be recognized from the start, and facilities for quick treatment by medication in water or feed should be provided long before it is needed. When birds are grouped by tens of thousands in one big pen, segregation and treatment of individuals is impractical; mass medication and vaccination are essential if any treatment is to be given.

Feed medication is not the best method of treatment because of the inappetence of sick birds and their inability to compete for feed. Water medication is better because the sick will frequently drink when they will not eat. Mass medication, while not completely successful in curing the sick, may hold the disease in check until the host can respond with a successful immune response. Provision should also be made for mass vaccination through drinking water, as this is an accepted and successful labor-saving practice. If drinking water is chlorinated or otherwise treated, the sanitizing agent may destroy the vaccine, so provision must be made to permit the use of untreated or distilled water for mixing and administering water vaccines.

Several methods can be used to reduce, remove, or neutralize

chlorine in chlorinated water supplies. The only practical method for dealing with this problem on poultry farms is to add protein to the water when mixing water vaccines. A common practice is to add 1 cup of nonfat dried milk to 50 gallons water in tanks or canned liquid nonfat milk mixed with vaccine in a proportioner.

If a building is constructed with a bulk water tank for gravity-flow watering devices, the tank should be of plastic or lined with some nonreactive protective substance and be readily accessible for cleaning and for mixing medicaments. If the watering devices are operated on high pressure, the pipe leading into the pen should have a bypass system with proper valve arrangement so that a medicament proportioner can be installed quickly when needed. A metering device to measure feed and water consumption is useful to keep track of the health of the flock. Float-regulated or continuous-flow water troughs can spread disease within a house. Infectious coryza has been observed to spread down cage rows of chickens in the direction of water flow. Use of a watering system with nipple drinkers for individual cage units will aid in preventing spread of disease.

Bulk feed delivery, metal bulk storage tanks, and automatic feeders are common in modern poultry operations. These eliminate the possibility of rodent contamination, because feed is always in closed tanks rather than in bags or open bins, but the system leads to difficulties when short-term emergency medication in feed is desirable and the bulk tank is full. Two alternative systems are useful: An additional smaller bulk tank may be installed just for emergency medicated feed, or a small dispensing tank may be interposed between the bulk tank and feed troughs so that emergency medicated feed can be put in the smaller tank by hand.

Flock Placement and Management

Handling the Young
Chicks and poults hatch with a reserve food supply in unabsorbed yolk sufficient to sustain them for about 72 hours. Some offspring actually hatch 1 or 2 days before they are taken from the hatcher; therefore, they should receive feed and water as soon as possible, preferably within 24 hours after removal.

Brooder Temperature
Chilling, overheating, starvation, and dehydration are serious stress producers and can precipitate active disease from latent infections that might otherwise be overcome by the young without detectable symptoms. In a randomly split hatch of chicks from the same group of dams, those delivered to one farm can suffer much greater mortality than those delivered to others. This is associated with differences in environmental stresses and exposure to disease. Young chicks and poults should be kept at a comfortable temperature at all times. The brooder temperature is usually started at 35°C and gradually is reduced as the birds mature. Although thermometers are helpful, strict adherence to thermometer temperatures without regard to obvious discomfort of chicks or poults is poor practice. An uncomfortable bird lets the caretaker know about it. Its peeping should be heeded, and the cause of discomfort corrected, regardless of thermometer reading.

Coccidiostats

Floor-reared poultry receive coccidiostatic drugs in feed from the first day to prevent coccidiosis (broilers, turkeys, replacement pullets destined for cage adult housing) or to keep the disease under control until birds develop active immunity (breeder flocks, replacement pullets destined for floor adult housing).

Immunity, however, depends on a number of factors. The amount of feed and coccidiostat intake may vary among birds, and the number of viable sporulated oocysts will vary with differing humidity, temperature, and litter conditions, even in different areas of large buildings. Depending on the relationship of these variable factors, the coccidial infection may be too mild to elicit good immunity, or it may be so severe that a frank outbreak occurs. There is no special management formula to overcome this dilemma other than a keen awareness of the variable factors and an attempt to maintain the proper physical environment to favor the degree of infection desired (see Chapter 28).

Feed and Water Consumption and Medication

Scientific feed formulation is the business of highly trained nutrition experts, and quality feeds are the rule, not the exception. Poultry eat the feed, not the formula, however, and occasionally problems arise that are traceable to feed (accidental omission of an ingredient, low-potency vitamin supplement, moldy or toxic contamination of an ingredient).

More important in everyday disease control are variations in feed consumption associated with hot or cold weather; housing changes; breed, type, strain, and age of bird; body weight; rate of lay; energy and fiber content of feed; and particle size of feed ingredients. With a 10–20% lower feed consumption associated with one of these factors, there is also a lower intake of coccidiostat or other medicament in feed by the same amount. Conversely, an increase in total feed consumption as a result of one of these factors increases total intake of all feed ingredients, including drugs.

Increased water intake during hot weather can spell disaster through overconsumption of water medication, but a given concentration of a drug in water may fail to control a disease under circumstances in which consumption is very low, as in very cold weather. Also, if natural sources of water are available the intake by some birds from the trough may be light. Many are the tragedies from overdosing due to carelessness; miscalculation; or failure to consider feed and water intake, weather, and other variables. When drugs are used in feed, great care should be exercised in adding the same or other drugs to water.

Biosecurity

Biosecurity provides safety from transmissible infectious diseases, parasites, and pests-is a term that embodies all of the measures that can or should be taken to prevent viruses, bacteria, fungi, protozoa, parasites, insects, rodents, and wild birds from entering or surviving and infecting or endangering the well-being of the poultry flock.

The reader is referred to *Biosecurity for the Birds,* a videotape (or DVD) that illustrates biosecurity measures and the many threats to poultry health that biosecurity is designed to prevent.

This video was produced by the United States Department of Agriculture (USDA), Animal Plant Health Inspection Service (APHIS), Veterinary Services. Inquire at your state APHIS veterinary office for further information. This professionally filmed material is also available from state extension offices, state health officials, online, and major poultry industry trade associations. It provides clear biosecurity training for workers, managers, and owners of all types of birds.

Biosecurity Guidelines

Specific disease-prevention guidelines, targeted to different sectors of industry (truckers, service workers, farm owners, catching crews, and others), are often available from university poultry extension specialists, and many of these are available online.

Sources of Infection and Protective Measures Against Them

Infections gain entrance to a flock from various sources. To understand why various preventive practices are recommended, it is important to review briefly the sources and routes of infection.

Humans

Because of their mobility, duties, curiosity, ignorance, indifference, carelessness, or total concentration on current profit margin, humans constitute one of the greatest potential causes of the introduction of disease. Rarely is this because they become infected and shed the disease agent, but rather because they track infectious diseases, use contaminated equipment, or manage their flocks in such a way that spread of disease is inevitable.

Most frequently, footwear is suspected as the means of disease transport, but hands can become contaminated with exudates when lesions and discharges are examined. Clothing can also become contaminated with dust, feathers, and excrement. At least one avian disease pathogen (Newcastle disease virus) has been found to survive for several days on the mucous membrane of the human respiratory tract and has been isolated from sputum (68).

The backyard flock maintained without regard for disease control can perpetuate a disease that constitutes a threat to a large productive industry. However, because most such flocks are not vaccinated, they may be susceptible to diseases against which large commercial flocks are protected. The greatest hazard to commercial producers that is created by fancy breeds and backyard flocks is the possible perpetuation of diseases that have been eradicated from the industry. Thus, it is a sound principle of disease prevention that no employee of a commercial unit have any contact with poultry, pet, or hobby birds, at home or elsewhere.

Neighbors

A frequent source of infection is a disease outbreak at a neighboring farm. Disease inspection visits among producers are a common way of spreading disease. If a neighbor's flock is afflicted with a very interesting new disease, discuss it by telephone. It is best to warn neighbors not to visit when a disease is

in progress, and by all means, do not walk around on a neighbor's farm for any purpose.

Contract Work Crews

Much of poultry farm procedure requires sporadic use of a crew of several workers (e.g., blood testing, beak trimming, vaccinating, inseminating, sexing, weighing, and moving birds from one location to another). The producer or farm manager frequently has difficulty in assembling a crew who are available and knowledgeable about handling poultry. Therefore, crews who service many poultry enterprises are contracted. Such crews travel about the poultry community handling many flocks and must be regarded as a potential source of infection. Thus, they should take stringent precautions to safeguard the health of every flock with which they work.

Visitors

Disease outbreaks in a community have been known to follow the path of a careless visitor. If visitors do not enter premises or buildings, they cannot track in diseases.

The source of a new or dreaded disease is often puzzling. World trade and travel are becoming more commonplace. It is not uncommon for a person to leave one farm in the morning and be visiting another farm or place of business in another part of the country or another continent on the same day. Some disease agents can survive that time frame easily. All who travel should be cognizant of this and guard against introduction of disease into their own flocks or onto the premises of clients, competitors, friends, or fellow producers when returning from a trip. Protective footwear and clothing are not readily available in all countries and poultry areas. A good preventive measure when returning from a trip is to sanitize shoes and launder all clothing worn on farms.

Recovered Carriers

Carrier birds are those that have apparently recovered from a clinical infection but still retain the infectious organism in some part of the body. Although they appear healthy, the infectious agent continues to multiply in the body and to be eliminated into the environment. Like actively infected flocks, they can perpetuate a disease on a farm and constitute a disease threat to other birds. Many commonly occurring diseases are known to be transmitted by carriers. Carrier birds can be a potential source of disease through the various practices noted in the following sections.

Multiple Ages

Multiple ages on a premises constitute a serious disease potential from both actively infected fowl and recovered carriers, particularly if birds of differing ages are closely associated through management practices or proximity. Disease agents that result in chronic infections or recovered carriers are passed by various means, including direct contact, to each new susceptible flock brought onto the premises. Serious drops in production may occur in young laying flocks moved onto laying premises where carrier birds from previous disease outbreaks remain. Whenever

possible poultry producers should practice all-in and all-out production.

Started Pullets

Pullets frequently are reared to or near point-of-lay by a specialized pullet rearer or on a separate premises unit belonging to the laying-farm owner. This practice has become established in the industry for many sound reasons. Pullets can, however, be a potential source for introduction of a disease onto a layer farm if they have been exposed on the pullet farm and, as a result, have become recovered carriers of some disease not existing on the layer farm. Another hazard is assembling mature pullets reared in different geographic areas onto a single layer premises, even an all-in, all-out layer premises. Those reared in one area may have been exposed to and recovered from, but carrying, a disease agent not found in the area where the other pullets were reared.

Induced-molted Hens

Induced molting of laying hens or breeders is frequently practiced (particularly during times of economic stress) to supply a special market, meet an emergency egg demand, or improve declining shell quality, or because it is deemed economical at the time. One advantage of keeping induced-molted hens, rather than rearing new replacement pullets, is that old hens are not apt to suffer a disease that normally occurs during the rearing age. If such flocks are molted and held in the same house, there is little danger of disease problems developing. Conversely, a producer who collects spent hens for molting from many poultry farms and mixes them on one premises at one time runs a serious risk, because any of the molted groups may be carriers of a disease to which the others are susceptible.

Poultry Show Stock

Birds exhibited at poultry shows may be exposed to actively infected or symptomless carrier birds of other exhibitors from which they may contract disease. The contact-infected stock may not develop active signs until returned to the owner's farm, where they may then be a source of new infection. Breeders of fancy birds, game birds, and youths with poultry projects (4-H, Future Farmers of America) must recognize the extreme hazards of returning birds exhibited in shows and fairs and of introducing partly grown or adult birds for special breeding purposes. A cardinal rule for show stock is that it should never be returned to the owner's farm. If birds must be shown, individuals should be selected that can be sold after the exhibition. If they must be returned, they should be quarantined for several weeks. In some areas, exhibition-type poultry should be vaccinated against some diseases. A local avian pathologist or other poultry specialist can often provide appropriate vaccine schedule information.

Breeding Stock

Adult stock considered especially desirable for breeding purposes may be symptomless carriers and serve as a source of infection for the breeding farm. It is best to purchase such stock as hatching eggs or day-old chicks and to rear them in an isolated

off-farm quarantine area until there is reasonable assurance that they are free of infection.

Mixed Species of Poultry

One species that is naturally very resistant to a disease may act as a carrier of that disease for another species that is very susceptible. Some death losses and debilitation from histomoniasis may occur in chickens, but in turkeys, the losses can be disastrous. Therefore, even with the routine use of drugs to prevent histomoniasis, the two species should never be raised together, and turkeys should not be reared in a facility that has recently had chickens on it.

Also, a silent (inapparent) mycoplasma infection in chickens may spread to mycoplasma-free turkeys and erupt into a full-blown case of sinusitis and air sac infection. Other diseases may be rather innocuous in one species of fowl but very serious in another. It is also advisable to keep meat and laying chickens separated, because the same disease may have different economic importance in the two types.

Other Sources

Hospital Pen

Sick birds from several pens collected into one hospital pen or house and later returned to their respective quarters may carry back not only the condition for which they were removed, but one or more diseases contracted while in the hospital area. Therefore, hospital pens are not recommended for routine segregation of sick birds, except as a way-station en route to the diagnostic laboratory or crematorium. If and when used for a special purpose (observation, injury, or cannibalism), they should be temporary arrangements within the house and should hold birds from only one pen or house.

Backyard and Pet Fowl

Poultry kept as pets or to supply household eggs or meat are just as capable of carrying and transmitting disease as are commercial flocks. Pet barnyard fowl of a rare or interesting nature may also carry disease to commercial poultry. The risk to the invested enterprise is too great to permit such a part-time hobby by a resident owner or employee. Cockfighting is banned in many states, but these game fowl are commonly transported around the country, constituting an effective way to carry disease. Some employees may own or handle these fowl and, thus, could introduce a serious disease to the poultry enterprise where they work. Poultry farm and hatchery owners and workers should be especially cautious about contact with imported ornamental pet birds or migratory waterfowl because they can be symptomless carriers of diseases that are highly virulent for domestic poultry.

Live-Bird Markets

These are buildings usually in the inner cities in which poultry of all types, ages, and health status are assembled by small buyers to supply a demand for live fowl for those who wish to examine the fowl live prior to slaughter or prefer to kill and dress fowl at home (Fig. 1.6). Such facilities are rarely depopulated, cleaned, and disinfected, and thus are ideal situations for transmission and propagation of poultry diseases. In addition, the hauling equip-

Fig. 1.6. Urban live-bird markets are rarely depopulated and disinfected. Diseases are propagated readily and transmitted to new birds brought in to replenish the supply. Commercial production managers are sometimes tempted to deal with live-bird markets because of the increased profits afforded by this association. These short-term profits are extremely small compared to the severe losses that can occur if infectious agents of high pathogenicity are introduced into the commercial poultry industry. (University of Maryland)

ment and vehicles may not be cleaned and disinfected after each use. Such equipment, hauled throughout the poultry industry areas where a few birds of different types or age are bought at various places, is an excellent means of transmitting diseases. Good managers and owners will keep such buyers and their equipment out of their farms and offices. The live-bird market trade has been strongly associated with the propagation and spread of avian influenza and laryngotracheitis.

Egg-Borne Diseases

Egg-borne diseases are transmitted from the infected dam to newly hatched offspring by means of the fertile egg. Some disease agents are carried inside the shell as a result of shedding into the egg prior to the addition of the shell and membranes. Others are carried on the shell or penetrate from the shell surface through natural pores after the egg is laid.

The agent may gain entrance to the egg as a result of infection of the ovary and ovarian follicles (transovarian transmission), as a result of contamination of the free ovum in the peritoneal cavity, or by contact in the oviduct. After the shell and membranes are added, the organism enjoys a protected location where it is not easily destroyed. From there, it can later invade the developing embryo, and lesions are frequently observed in tissues and organs of offspring at hatching. Transovarian transmission seems to be limited to only a few of the many diseases that affect poultry, and most of these have been eradicated from breeding flocks.

When the freshly laid egg cools from body temperature to nest, room, or cool-room temperature, a pressure differential occurs between the inside of the egg and the atmosphere. Any fluid on the shell surface is drawn inward. Motile bacteria are aided by this pressure differential to penetrate the shell. The primary contami-

nation of this nature is from enteric organisms, particularly salmonellae and coliforms, but other types of bacteria and fungi also may be drawn into the egg. For preventive measures, see "Breeder Flock Management" and "Management of Hatching Eggs."

Equipment

Diseases and parasites can be carried on equipment. Cleaning equipment and vehicles usually have accumulations of litter and feces that can be a threat to other farms and houses where they may be transported for succeeding assignments. They should be washed free of litter and droppings before use in another farm area. Types of vehicular traffic that must be carefully controlled are feed trucks, live-haul trucks, vehicles used in dead bird disposal, and manure spreading equipment.

Mites frequently are found on eggs and can be transported from farm to farm in corrugations of egg cases taken into chicken houses. Wire crates and baskets do not offer these hiding places. Residues of *Salmonella*-contaminated eggs on egg flats may be a potential method of introducing disease. Use of washed and disinfected plastic egg flats and moving of stacked flats of uncased eggs on racks and pallets reduce the hazard of transmission of diseases and parasites among farms.

Fowl pox, infectious bursal disease, and Marek's disease viruses, coccidia, roundworm eggs, and other infectious material can be carried on crates, footwear, and vehicles, particularly on the floor and foot control pedals of a vehicle.

Artificial inseminating equipment, particularly reused inseminating tubes, offer an excellent method of transmitting disease.

Poultry hauling equipment can disseminate infectious material through feathers, feces, blood, exudates, and skin encrustations left in the crates or picked up at the slaughter plant. Hauling equipment should be washed and disinfected after use before being taken to another farm (Fig. 1.7).

Miscellaneous Sources

Laboratory Exposure

Frequently, a producer, particularly a small flock owner, hobbyist, or game bird owner, will want to take a bird home after the veterinarian has examined it at the laboratory. While in the receiving area or diagnostic facilities, even for a short time, live poultry have a good opportunity to contact some disease agent. Except under special circumstances (exotic birds, valuable pet), no bird should be returned from the laboratory to the farm, because it could develop disease and be the source of a new infection on the home premises. The bird should be either sacrificed and necropsied or, if a pet, referred to a private veterinary practitioner.

A disease may be tracked from laboratory surroundings to a farm by careless laboratory or service workers or the producers. Clean and frequently washed and disinfected laboratory areas are the responsibility of the veterinarian. Precautions against tracking disease from the laboratory to the farm are the responsibility of the producer and service worker.

Rodents

Rodents contaminate feed and litter with their excrement. They are particularly hazardous to *Salmonella* control, because they

Fig. 1.7.   Soiled vehicles and equipment can carry disease agents. They should be thoroughly washed and disinfected after each live haul. One gram of chicken manure can contain enough viral particles to infect 1 million birds with avian influenza.

are frequently infected with these organisms and can perpetuate the disease on a farm.

Household Pets

Dogs and cats, like rodents, are capable of harboring enteric organisms that are infectious to poultry. When these pets are not confined to the household area, but roam continually among the poultry in the pens and yards, they constitute a serious health hazard. Such pets are just as capable of tracking contaminated material on their feet and in their hair as people.

Wild Birds

Wild birds are capable of carrying a variety of diseases and parasites. Some cause infection or illness in the wild birds themselves; for others, the birds act as mechanical carriers. Every effort should be made to prevent their nesting in the poultry area. Imported zoological specimens destined for zoos are not a direct contact threat because the zoos are located in cities, but they should be considered as a potential source of introduction of an exotic disease or parasite. Exotic ornamental pet birds constitute a real hazard because they become widely dispersed and may be purchased by poultry workers. On numerous occasions, exotic birds in or destined for pet stores have been found infected with a virulent exotic form of Newcastle disease virus, which in at least one instance was the source of a serious and costly outbreak in poultry. Stringent entry quarantine requirements to apprehend and destroy infected birds provide a good barrier against the introduction and dissemination by carrier birds, but failures can occur (illegal smuggling), and producers should be wary of such personal pets. Domestic pigeons can also be a source of dangerous strains of Newcastle disease virus.

Insects

Many insects act as transmitters of disease. Some are intermediate hosts for blood or intestinal parasites; others are mechanical

carriers of disease through their biting parts. Still others, because of their feeding habits and hiding places, appear to be reservoirs of disease, whereby the infectious agent survives from one flock to the next.

Feed

Some ingredients may contain infectious agents, particularly salmonellae, from contamination at their source or anywhere along the production line or storage areas. Methods are available for sterilizing feed, but they increase the cost of the final product. Pelleting, if done properly, is a practical method of greatly reducing contaminants because of the heat generated in the process, but it is not dependable for complete sterilization. Meat meal is the feed ingredient most apt to introduce *Salmonella* spp. This hazard can be avoided by using only vegetable protein ingredients, supplemented as necessary with synthetic amino acids. Such formulations are recommended for breeder rations if pelleting capabilities are not available.

Personnel Control

Company and Farm Personnel

Managers, supervisors, and owners are sometimes the worst offenders at breaking biosecurity rules. These people frequently visit many different types of poultry enterprises, farms, and farm units, and disease agents do not respect authority or ownership. Such personnel, like veterinarians, should set a good example for the workers. One of the most important aspects of disease control is an awareness on the part of everyone—owner; workforce; feed and supply delivery people; egg, bird, and litter haulers; and all who visit or work on poultry farms—that each has an important role in the disease-prevention program. Assembling the workforce for occasional educational conferences on health goals and reasons for procedures will foster awareness. This is as important as the preventive measure established. It is also a good occasion to use the biosecurity video mentioned previously in this chapter.

In designing buildings and farm layout and in programming production and management, it is important to make every disease-preventive practice as easy and efficient as possible. Any procedures that are difficult probably will be done incorrectly.

Visitors and Customers

For some types of poultry enterprise, it is deemed necessary to show the birds, premises, or procedures to visitors. In such cases, an observation booth, platform, or fenced area should be provided. Such an area should be sealed off from the poultry pens or hatchery. For maximum security, the entry, access road, and observation area should be completely separated from the work area.

Visitors can be a minimum hazard if proper provisions are made to accommodate them and they cooperate fully with strict sanitary rules. When visitors must enter the poultry quarters, it is most important that they wear disinfected rubber overshoes and other footwear; in addition, they should wear protective clothing such as clean, laundered, or new disposable coveralls and hat. Disposable plastic boots may become punctured when used on gravel or other sharp surfaces; therefore, only heavy gauge (5 mil

or greater) plastic disposable boots should be used. These sanitary precautions are most essential when entering floor brooding and rearing houses but will help keep disease out of any facility.

Vaccination

Purpose of Vaccination

Vaccines in poultry production are used to prevent or reduce problems that can occur from infection of a field strain of a disease organism. Vaccines and vaccine programs vary widely in their effectiveness, and this is frequently by design. Some vaccines are designed to incite high levels of immunity to protect birds in the face of aggressive endemic disease challenges, such as viscerotropic, velogenic Newcastle disease. These vaccines may cause a mild form of the disease themselves but are deemed appropriate and useful because of the risk associated with eventual infection of the deadly field pathogen. Vaccine selection and how they are programmed frequently becomes an exercise in risk management and cost efficiency. Local conditions must always be considered when evaluating and critiquing a vaccination program.

A second reason for the vaccination of poultry flocks is to hyper-immunize hens to maximize maternally derived antibody passed through the egg to the hatching progeny. Chicks frequently receive up to 3 weeks of protection from maternal antibodies allowing their immune system to mature to a level capable of eliciting an efficient active immune response if exposed to a potentially harmful virus or bacteria. Antibodies are not always completely protective but for viruses such as infectious bursal disease (IBD), many areas of the world have found maternal antibodies a very useful tool in IBD prevention and control.

Types of Vaccines

Poultry vaccines are typically characterized as live or inactivated. General characteristics of vaccines are summarized in Table 1.1 (14). Live vaccines are available for numerous viral, bacterial, and coccidial organisms.

Techniques used in the development of live vaccines have varied widely. Table 1.2 shows some of the most common methods used to generate an acceptable live vaccine candidate and examples of each method.

Live vaccines are widely used throughout the world because they are commonly effective when mass applied, and they are relatively economical. Immunity from live vaccines is generally short-lived, particularly following initial exposure. Some exceptions to this exist for vaccines such as laryngotracheitis, fowl pox, and Marek's disease.

For live vaccines to work as they were designed, they must be stored, mixed, dosed, and applied appropriately. Storage of live vaccines is generally in a dark, refrigerated area. Liquid nitrogen freezing of live vaccines preserves and prolongs cell culture viability that is essential for cell-associated vaccines such as Marek's disease vaccines. Licensed live vaccines have an expiration date printed on the vial that, if stored according to label directions, ensures that the appropriate minimum dose is maintained through the dating period. Shelf life varies widely on live vaccines but most generally are licensed with 18 months to 2 years dating.

Table 1.1.   General characteristics of live and inactivated vaccines for poultry.

Live vaccines	Inactivated vaccines
Smaller quantity of antigen. Vaccination response relies on multiplication within the bird.	Large amount of antigen. No multiplication after administration.
Can be mass administered—drinking water, spray.	Almost always injected.
Adjuvanting live vaccines is not common.	Adjuvanting killed vaccines is frequently necessary.
Susceptible to existing antibody present in bird.	More capable of eliciting an immune response in the face of existing antibody.
In immune bird, booster vaccination is ineffective.	In immune bird, additional immune response frequently seen.
Local immunity stimulated (i.e., trachea or gut).	Local immunity may be re-stimulated if used as a booster but poor if not a secondary response.
Danger of vaccine contamination (e.g., egg drop syndrome, reticuloendo-theliosis virus).	Little danger of vaccine contamination.
Tissue reaction commonly referred to as a "vaccine reaction" is possible and frequently visible in a variety of tissues.	No microbe replication; therefore, no tissue reaction outside that which is adjuvant dependent.
Relatively limited combinations—due to interference of multiple microbes given at the same time (e.g., infectious bronchitis, Newcastle disease virus, and laryngotracheitis).	Combinations are less likely to interfere.
Rapid onset of immunity.	Generally slower onset of immunity.

Table 1.2.   Methods of generating live vaccine candidate.

Method	Example
Virulent organism inoculated to a less susceptible target tissue or at a controlled dose	Laryngotracheitis-cloacal route
Naturally occurring mild pathotype	*Mycoplasma gallisepticum* F strain
Egg passage of virulent parent	Infectious bronchitis—Arkansas strain
Temperature-sensitive mutant of virulent parent	Turkey coryza vaccine—*Bordetella avium*
Chemically derived mutants of virulent parent	M-9 Fowl cholera vaccine
Tissue culture / passage of virulent parent	Laryngotracheitis
Combination of egg passage and tissue culture passage of virulent parent	Infectious bursal disease—Lukert virus
Plaque selected "clones" of parent virus	Newcastle disease virus—cloned Lasota vaccines
Selection of subpopulations or organisms based on replication characteristics *in vivo*	Precocious strains of *Eimeria* spp.
Relatively virulent organisms given at an age that minimizes disease	Avian Encephalomyelitis

Mixing directions also vary widely, but many recommend the use of a water stabilizer such as powdered skim milk. Water stabilizers minimize some of the negative effects of residual chlorine, metals, and high temperature on the reconstituted virus. Cell-associated Marek's vaccines generally have very specific diluents aimed at maintaining cell culture viability through the time period between reconstitution and inoculation. The dose needed to get an appropriate immune response from a live vaccine is frequently dependent on the virus, genetic background of the bird, age of the bird, existing circulating antibody within the bird, and the method to be used when applying a vaccine. Vaccines generally are licensed based on protection studies performed in an SPF-type leghorn bird, absent of any circulating antibody to that particular agent, at the youngest age on the label, and at the minimum titer expected at the end of the dating period allowed for each given vaccine. With all these variables, it is not hard to imagine why clinical veterinarians and other health professionals may adjust dosages of live vaccines according to local field conditions.

Severe vaccine reactions or insufficient protection can result from misjudging any of these variables. As a final note, poultry house conditions and local disease risks need to be taken into account when optimizing the use of live vaccines.

A second type of live vaccine is emerging with the development of genetically engineered, live virus and bacteria vectored vaccines and gene deletion mutants of a pathogenic parent organism. The recombinant vaccines are made using live virus or bacteria, as a vector to transport the gene coding for the protective antigen of a second infectious agent, for which immunity is desired. Examples of live virus-vectored vaccines include recombinant fowl pox virus vaccine expressing genes to protect against H_5N_2 avian influenza (9), fowl pox virus expressing Newcastle disease virus antigen (13), fowl pox virus expressing infectious bursal disease virus (7), and baculovirus expressing infectious bursal disease virus (69). Bacteria-vectored vaccines described in poultry include bacteria such as *E. coli* (32) and *Salmonella* spp. (54) expressing antigens from coccidia and *E. coli*, respectively. A vaccine to reduce salmo-

nella infection, made from a gene deletion mutant of *Salmonella typhimurium* (20), is commercially available.

These recombinant and gene deletion mutant vaccines have been shown to be relatively protective, when compared to controls, against pathogenic challenge under experimental conditions. The efficacy and cost effectiveness of the recombinant vaccines under field conditions are yet to be determined. This type of vaccine may offer advantages where the spread of traditional vaccines to susceptible populations cannot be properly managed. Additionally, these technologies allow for diagnostic differentiation of vaccine from virulent field challenge. This property may be useful when utilized in eradication programs such as laryngotracheitis. Regulatory considerations when acquiring a federal license for vectored vaccines include demonstrating the genetic and phenotypic stability of recombinant viruses or bacteria and documenting any alterations in the host range or tissue tropism of the recombinant organism, as compared to the parent organism (41).

Inactivated vaccines or killed vaccines used in poultry are generally whole bacteria or virus preparations combined with an adjuvant that are designed for subcutaneous or intramuscular injection. They are frequently, but not always, used in commercial egg layer and breeding birds to stimulate long-lasting immunity and/or antibody levels to specific antigens. Inactivated vaccines generally consist of two distinct components, often referred to as aqueous and adjuvant phases, emulsified into a homologous liquid. The aqueous phase contains the antigen, and the adjuvant generally enhances the bird's response to this antigen. The ratio of antigen to adjuvant differs greatly depending on the vaccine. This ratio generally is determined by factoring in the properties of the adjuvant(s), the antigen(s), viscosity, immune response, and tissue reactivity. Mineral oil is the most commonly used adjuvant, although aluminum hydroxide is a common alternative in notoriously reactive inactivated vaccines such as fowl cholera and infectious coryza. Adjuvant technology continues to grow, and vegetable, fish, and animal oils used as adjuvants offer some opportunities for lower viscosity, immunogenic vaccines (63). Injection of humans that are administering these inactivated vaccines should be avoided. Serious injuries have been reported from accidentally injecting vaccine into a finger or hand. The site of injection can become swollen, red, and painful, and the function of the area may be affected. Victims should seek medical treatment at once and inform attending physicians of the organism(s) and adjuvant contained in the inactivated vaccine.

DNA vaccines are an entirely new type of vaccine that has evolved in the late 1990s. These vaccines can achieve both humoral and cell-mediated immunity, are similar to live vaccines, and have the relative safety associated with inactivated or vectored vaccines. DNA vaccines have been used successfully in poultry for avian influenza and Newcastle disease in chickens (24, 56) and duck hepatitis B in ducks (67). Although promising, DNA vaccines have both technological and economical challenges to overcome before they are commercially viable.

Vaccine Delivery Systems

Improper vaccine application is the most common reason vaccines and vaccine programs fail. With the success and growth of

the poultry industry throughout the world came tremendous challenges in efficient and economic application of poultry vaccines. The most commonly used application techniques in commercial poultry include *in ovo* at 17–19 days of embryonation, subcutaneous or intramuscular injection at day of hatch, spray in the hatchery, intraocular or nasal drop in the hatchery or on the farm, spray on the farm, through the drinking water on the farm, wing web stab, and subcutaneous or intramuscular injection on the farm.

In Ovo Vaccination

In ovo vaccination is performed during the process of transferring incubating eggs in the hatchery from the setter to the hatcher. After poking a hole in the shell, vaccine, most frequently Marek's disease vaccine, is injected just under the membranes at the floor of the air cell. Depending on the embryo age at transfer, generally between 17 and 19 days of incubation, approximately 25–75% of the vaccine (0.05 ml in most cases) is injected into the area of the neck and shoulder. In the remaining 25–75%, vaccine is administered into the extra embryonic compartment (27). The original experiments on *in ovo* vaccination with Marek's disease vaccine showed that chicks were protected earlier than those vaccinated after hatch (58). However, in the United States, where more than 80% of broiler chickens are vaccinated against Marek's disease *in ovo*, the primary reason for its acceptance has been the labor savings when compared to day-old injection (66). Using an egg injection system (Embrex Inovoject® Egg Injection System, Research Triangle Park, NC), one machine with three people generally inoculates 20,000–30,000 eggs per hour (Fig. 1.8). This method of vaccination leaves a hole in the egg for the final few days prior to hatch and in poorly sanitized hatcheries has resulted in poor early livability due to bacterial or fungal contamination while in the hatcher. Hatcheries must be acutely aware of their aspergillosis levels to run an egg injection system successfully (71).

Subcutaneous or Intramuscular Injection at Day of Hatch

Day-old vaccination, most commonly using Marek's disease vaccine, is generally accomplished by giving 0.2 ml of vaccine subcutaneously under the skin at the back of the neck or 0.5 ml intramuscularly in the leg. The automatic vaccination machines used in many parts of the world generally are designed for the neck injection. A skilled operator can vaccinate about 1600–2000 chicks/hour. A 20-gauge needle generally is used, as smaller gauge needles restrict the flow in cell-associated vaccines. Needles should be changed several times during the course of the day to prevent damage from burred or bent needles. Improper positioning of the chick or a bent needle can result in damage to the neck muscles or vertebrae. A dye is frequently mixed with the vaccine to allow visualization of the vaccine under the skin after injection. A quality check of technique generally means examining each bird in several boxes, 100 to a box, after vaccination looking for colored dye under the skin. The most frequent cause of missed birds is the operator trying to go too fast, resulting in chicks being pulled off the needle before proper deposition of vaccine.

Fig. 1.8.   A modern hatchery with an egg injection system for in ovo vaccination.

Table 1.3.   Visual analogy to droplet size diameter.

Analogy	Diameter (microns)
Wet fog	25–40
Visible droplets	50
Misty rain	50–100
Light rain	200–400

Distilled water generally is used to reconstitute the vaccine(s). Although the volume of water used varies depending on the spray machine selected, 5 gallons of water per 20,000 birds vaccinated is a good general recommendation. It generally is preferred to vaccinate a flock first thing in the morning. Fans should be turned off, if possible, and the lights should be as dim as the vaccinator can allow and still walk through the house. In floor houses, if another person is available, one person can split the flock while the vaccinator slowly sprays one side at a time. If possible, running fans should be minimized for the 15 minutes following vaccination.

An effective spray vaccination technique allows exposure of birds to aerosolized vaccine for approximately 5–10 seconds. This is best accomplished by spraying a relatively coarse spray, in the range of 100–150 microns, and walking slowly through the poultry house.

A visual evaluation of a spray pattern can be done with each vaccination. Look for an even distribution and consistent projection. A crude estimation of droplet size may be made using the analogies listed in Table 1.3 (62).

Intraocular or Nasal Drop in the Hatchery or on the Farm

Intraocular or nasal drop is a highly effective but labor-intensive method used to deliver respiratory disease vaccines for diseases such as laryngotracheitis. This method generally involves depositing approximately 0.03 ml of reconstituted vaccine in the eye or nares. Both techniques generally require the vaccinator to pause briefly as the vaccine disappears in the appropriate opening. A dye colored diluent helps to visualize the vaccine and allows a quality check on technique by looking around the nares or eye for dye. Frequently some dye can be seen by looking in the bird's mouth around the choanal cleft or edges of the tongue.

Drinking Water Vaccination on the Farm

A very common and useful technique in commercial poultry has been to apply vaccine through the drinking water. Proper preparation of the watering system to be used through removal of all disinfectants, such as chlorine, should be done two days prior to vaccination. It is best to buffer the system by flushing it with a weak solution of powdered skim milk, generally 1 cup powdered skim milk to 50 gallons of water (16). This type of buffer generally also is used while administering the vaccine.

Best results are achieved through a process that creates a mild degree of thirst by eliminating access to drinking water for approxi-

Spray in the Hatchery

Spray vaccination of birds in the hatchery generally is done using a spray box that is triggered each time a box of chicks is placed inside or an in-line spray cabinet that sprays boxes as they move down a controlled speed conveyor line in an automated hatchery. Both methods, frequently used to deliver Newcastle disease virus, infectious bronchitis virus, or coccidiosis vaccine, attempt to mimic eye-drop vaccination. Spray vaccination in the hatchery generally works well if the droplets generated have a particle diameter of approximately 100–150 microns. Particle size is very important. Low relative humidity may decrease the particle size by the time it reaches the bird, resulting in too fine a spray. Fine spray, generally something less than 20 microns in diameter, can travel deep into the respiratory tract, resulting in excessive vaccine reaction if using a respiratory disease vaccine. Although there is some variability, Newcastle disease virus and infectious bronchitis virus vaccines are often delivered in 7 ml of distilled water per 100 chicks. Coccidiosis vaccines generally use more distilled water, approximately 20–25 ml per 100 chicks. Birds preening themselves and each other immediately following spray vaccination is thought to be important to the resulting vaccination response, although little data exists to support this concept.

Spray Vaccination on the Farm

With the increased acceptance and use of closed watering systems and the increased cost of labor required to effectively vaccinate through the drinking water, spray vaccination of respiratory vaccines, such as Newcastle disease virus and infectious bronchitis virus, has become increasingly popular. This method of vaccination frequently uses spray equipment adapted from insecticide and pesticide application technologies. As with the hatchery spray vaccination, the method is designed to mimic eye-drop vaccination but allows the vaccinator to avoid handling each bird in the poultry house.

mately two hours prior to the vaccination procedure. This time varies widely. Climatic conditions may necessitate longer or shorter time periods. Thirst is optimal when the time between the first and last access to vaccine is approximately two hours. Two hours generally allows all birds, even those lower in the social order, adequate time to get a drink of water containing vaccine. This technique requires constant adjustment as the climate changes.

Wing Web Stab

Wing web vaccination requires individual bird handling but can be done relatively rapidly. There are two commonly used wing web application tools. The first is the traditional small plastic handle approximately 3 cm long that has two solid stainless steel prongs, approximately 2 cm long, with a bevel on each prong toward the needle end. The second newer application tool is referred to as a Grant inoculator. This tool has a self-contained reservoir for vaccine, most often fowl pox or fowl cholera, in which a needle passes through loading a new dose of vaccine for each bird inoculated. Both tools are designed to deliver approximately 0.01 ml on the needles to the bird's wing web. The wing web is an area that has relatively few feathers, bone, or muscle. The vaccinator loads the applicator and sticks the needle(s) completely through the skin on both sides of the web, originating from the underside of the wing. There is little or no bleeding, and vaccine has been inoculated through the needle holes. Wing web vaccination technique can be checked by returning to the vaccinated flock 7–10 days after vaccination and palpating the wing web area for nodular scabs or granulomas. These areas created by the vaccine are commonly referred to as "takes." Proper vaccination technique frequently results in 95–100% take.

Subcutaneous or Intramuscular Injection on the Farm

Subcutaneous and intramuscular injections are frequently used in breeder pullets and commercial egg-laying pullets prior to egg production. These vaccines are generally recommended for use at least 4 weeks prior to the onset of egg production to minimize any adverse effect the handling or the vaccine may have on egg production performance. Subcutaneous vaccination is most frequently performed using a 1/2 inch, 18-gauge needle, in the neck. The area half way between the head and the shoulder is optimal and allows the vaccinator to lift the skin away from the neck muscle and insert the needle, pointed towards the body of the bird, into the subcutaneous area and deposit the vaccine. Intramuscular injection generally is performed using a 1/2 inch, 18-gauge needle to inject vaccine into the breast or leg muscle. Breast muscle injections are safest when the vaccine is deposited in the superficial pectoral muscle 2–3 cm lateral to the keel bone. If the needle is kept at a 45-degree angle to the bird, any accidental injections into the body cavity or liver can be avoided (35). Leg vaccination generally is done in the lateral gastrocnemius muscle. Both intramuscular injection sites may result in residual emulsion being present for an extended period of time (21). A residual deposit in muscle depends on many factors including the antigen and the adjuvant found in the vaccine. Care should be taken to determine the intended use of meat before injecting intramuscularly.

Vaccine Failure

Numerous factors can cause a vaccine failure. One of the most common causes of vaccine failure is the inappropriate administration of the vaccine. Certain live vaccines, such as Marek's disease vaccine, are easily killed, and failure to follow the manufacturer's recommended handling practices will result in the inactivation of the virus prior to administration. Viable vaccines administered in the drinking water can, likewise, be destroyed before they reach the bird if they are mishandled or if water sanitizers have not been removed from the water prior to the addition of the vaccine. Vaccines that are administered by intramuscular or subcutaneous injection can also fail if vaccinators do not deliver the vaccine to the appropriate vaccination site.

Although the most common cause of vaccine failure is an inadequacy or error in vaccine delivery, numerous instances of vaccines simply not providing adequate protection have occurred. In some cases, the field strain of an organism is of very high virulence, and the vaccine strain is highly attenuated. In this situation, the flock may be effectively vaccinated, but the immunity is insufficient to protect against disease completely. Many infectious agents have several different serotypes, and vaccine failure may be the result of the antigens in the vaccine serotype being different and not providing protection against the particular serotype of the agent causing the field challenge. It is not uncommon for a vaccine break to occur with infectious bronchitis virus when the field challenge is of a serotype different from that of the vaccine used (8).

Management conditions play an important role in the prevention of vaccine failures. If infectious disease agents are allowed to build up on a farm over successive flocks without clean-out and disinfection, it is possible that the challenge dose of a particular infectious agent will be so great, or so soon, that a normally effective vaccination program will be overwhelmed. The immune status of the breeder flock also can be involved in a vaccine failure. If the breeder flock provides progeny with high levels of maternal antibodies, vaccination during the first 2 weeks of life may result in the vaccine being neutralized. The timing of the vaccination of young poultry with viable vaccines must always take the presence or absence of maternal antibodies into consideration.

Certain infectious disease agents and mycotoxins are immunosuppressive and may result in vaccine failure. Infectious bursal disease virus (Chapter 7), infectious anemia (Chapter 8), and Marek's disease virus (Chapter 15) are examples of agents that may cause severe immunosuppression in chickens. One mycotoxin, aflatoxin, has been shown experimentally to be immunosuppressive and has been implicated in decreased resistance to disease (see Chapter 32).

Monitoring a Vaccination Program

Methods for evaluating the effectiveness of a vaccination program varies widely and generally involves evaluating and monitoring overall health. Frequently, absence of morbidity and mortality is used as a criteria for success. In areas of endemic challenge with very pathogenic organisms, such as viscerotropic velogenic Newcastle disease virus, an ineffective program is very

obvious due to clinically ill or dying birds. However, in most areas of the world, a suboptimal program is much less obvious. In this case, an effective program must minimize the risk associated with disease and maximize production efficiency as economically and practically as possible. Many aggressive vaccination programs aimed at high levels of protection are detrimental to growth efficiency and expensive. The goal of veterinarians and other health professionals is to balance these criteria as efficiently as possible.

Performance Parameters

Metrics generally used to judge overall health, which encompasses vaccine program efficacy, are culls at the hatchery, 7-day mortality, 14-day mortality, final flock livability, feed conversion efficiency, rate of gain, condemnation, egg production, and egg quality. Many of these metrics have standards or comparative histories established through each company's own historical data or, in the United States at least, national reporting services such a AgriStats (AgriStats, Fort Wayne, IN), or Agrimetrics (Agrimetrics Associates, Inc., Midlothian, VA), and government reporting services such as the poultry slaughter reports published monthly by the National Agricultural Statistics Service (NASS), Agricultural Statistics Board, U.S. Department of Agriculture. An additional metric that can be used over time is antimicrobial and antiparasitic drug usage. Although this is influenced by many things, including management changes and climatic shifts, monitoring usage is an essential piece of evaluating overall health and vaccination program efficacy.

Examination of Field Birds

Health surveys (6, 33) that include extensive gross and microscopic evaluation of necropsy specimens and controlled challenge studies (46) to measure a relative protection level are both useful in assessing vaccine program effectiveness. Perhaps the most frequent or routine controlled challenge work is done to measure passive protection of broiler chicks from hens hyperimmunized to infectious bursal disease (46). Trends in program efficiency may be identified over time if sufficient groups of chicks are sampled.

Serologic Monitoring

Serologic monitoring (60) is only useful in production medicine if adequate samples have been analyzed over time in order to establish a normal baseline for a specific program, in a specific location, in a specific bird, using specific and consistent application techniques, with samples run consistently by a specific laboratory. After a baseline is established, flocks can be identified, that have serologic profiles above or below the established baseline.

In broiler and turkey production flocks, an effective monitoring program can be the regular sampling and testing of blood as they are slaughtered at the processing plant. This serologic monitoring will establish a baseline of antibody titers that are the result of both vaccination and field challenge. Changes in the usually observed antibody titers may indicate a decrease in the efficacy of vaccine administration or an increased field challenge

by a particular pathogen. A regular serologic monitoring program is also helpful to determine whether a flock has been exposed to a new pathogen, not previously present in the region.

Serologic monitoring of layer flocks should be performed before the flock is placed in the layer building, with periodic serologic monitoring throughout the production cycle. This type of program will assess both the efficacy of vaccine administration and the disease challenge the flock experiences in the field. Breeder flocks should be monitored in the same way as layer flocks and, in certain instances, breeders can be revaccinated during production to boost the maternal antibody titers of their progeny if they are found to be low.

Interpretation of Serologic Data

It is usually impossible to differentiate between antibodies that are produced by vaccination versus those induced by field exposure to a given infectious agent. The only difference that may be observed is that the antibody titer following a field challenge may be higher than that observed following vaccination. A valid interpretation of serologic results requires a complete knowledge of the flock's vaccination history.

It usually takes poultry 1–3 weeks to produce detectable levels of antibodies in their serum. It is possible, therefore, to collect blood during the middle of a disease outbreak and not be able to detect any antibodies to the causative disease agent. If this same flock is tested 2 weeks later, however, serum-antibody levels will be high. A useful practice in establishing a disease diagnosis is to take acute and convalescent serum samples from the flock as it is undergoing an unknown disease challenge. Typically, the acute serum sample collected during the initial phase of the disease outbreak will be negative for antibodies to the suspected disease agent. The convalescent serum sample, taken shortly after the flock has recovered, if positive, will provide a definitive diagnosis when interpreted in conjunction with the clinical signs and lesions of the case. An important concept in the interpretation of serologic results is that a single positive serologic test only indicates that the flock was exposed to that disease agent during its life.

Different laboratories often conduct serologic tests using different reagents or techniques. Because of this, comparing antibody titers (a titer is a measure of the level or concentration of antibody in the serum) reported from different laboratories may be confusing. It is best to use one laboratory for a given test so that a familiar range for negative, low, or high titers is established. With experience and training, production managers can become skilled at the interpretation of serologic results.

Flock Profiling

Today's disease problems often represent the sum of various subclinical disorders occurring at different times throughout the life of a flock. Acquisition of the fullest understanding of this sequential collection of serologic and other data concerning multiple pathogens requires disciplined and careful organization. The systematic, graphic presentation of this data is commonly called a "flock profile." The establishment of such profiles is facilitated by enzyme-linked immunosorbent assay (ELISA) technology,

FLOCK : X

AGENT : IBD

1 DAY

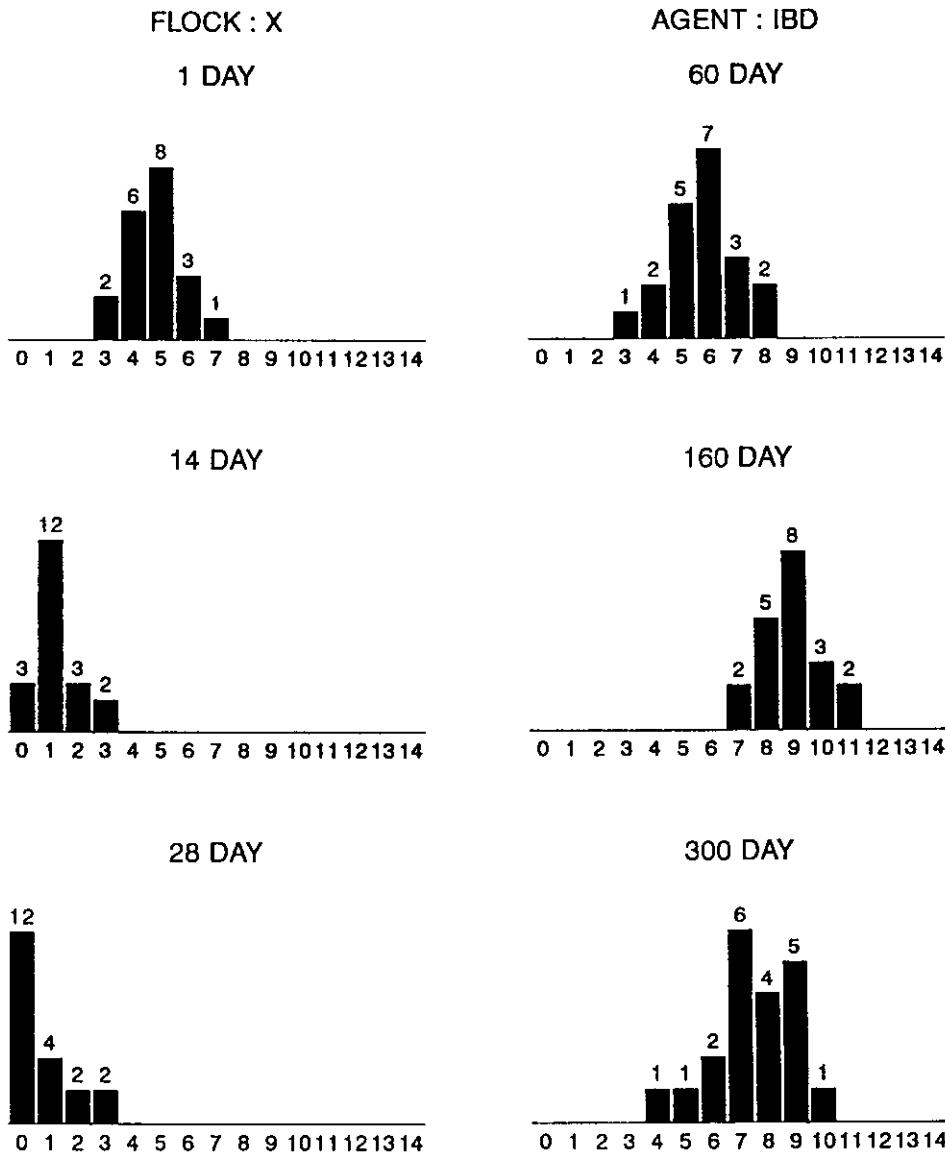
60 DAY


Fig. 1.9. Temporal graphic distribution of infectious bursal disease (IBD) enzyme-linked immunosorbent assay (ELISA) group titer levels at 1, 14, 28, 60, 160, and 300 days of age for an IBD-vaccinated broiler breeder flock. Numbers on the X-axis represent group titer levels obtained by ELISA. Titers of 0 are group 0; 1–350 are group 1; 351–1500 are group 2; 1501–2500 are group 3; 2501–3550 are group 4; etc., with titers of 12,500 comprising group 14. Numbers above each bar represent the number of samples reacting at each level on the indicated day of age.

because a single basic test system is used to monitor for a broad array of diseases (59).

Snyder *et al.* (61) demonstrated the value of correlating ELISA profiling data with flock performance. The further evolution and diagnostic advantages of the graphic presentation of ELISA-based flock profiling data in combination with gross and microscopic pathology data was described by Mallinson *et al.* (39). The method has broad applicability to epizootiologic investigations, field research, and quality control. Baseline profiles can be established both as targets for vaccination goals and as a base from which deviations from the norm may be demonstrated when a field problem is subsequently encountered. Several flock-profiling kits and systems are now commercially available. Their value is enhanced when good data retrieval and graphic presentation of data (Fig. 1.9) is combined with the diagnostician's vet-

erinary skills and experience in assimilating medical information and establishing a plausible diagnosis.

Sanitary Environments
Grounds around Buildings
Rodent Control

Piles of trash and unused equipment are good hiding and breeding places for rats, mice, and ground squirrels, which may serve as reservoirs of disease and contaminate troughs with their excrement. Rodents are reluctant to travel over open spaces that do not provide protective cover. A 20-m band of short-mowed grass or gravel tends to discourage the migration of rodents into a poultry building from surrounding areas. Feed spilled or left in stored troughs is an attractive food supply; when it is exhausted, rodents will find any avail-

able route into the building where they have intimate contact with poultry. Even if buildings are rodent-proof, excrement can be tracked in on footwear. It is more difficult to get rid of rodents once the premises are infested than to keep them out initially.

Insect Control

Many parasites and disease agents are harbored from one generation to another in resident insects (Marek's disease), require an insect for an intermediate stage of development (tapeworms), or are simply carried from bird to bird mechanically or by biting (fowl pox virus). Countermeasures against insects are part of the sanitary environment and cleanup.

Some methods used to keep insects away from buildings are an apron of treated soil to prevent growth of all vegetation, an apron of hard surface material, or a border of well-mowed green grass. Spraying the area around buildings with an insecticide also prevents insect buildup, but the other methods have the additional advantage of reducing fire hazards to the buildings.

A good practice during cleanup is to spray the grounds, litter, and buildings with an insecticide immediately after removing fowl and then allow a few days for effective insect kill before removing litter preparatory to cleaning and disinfection. This is especially important when there is a history of an insect-borne disease in the previous brood. After cleaning, the building should be sprayed again with an insecticide having a residual effect to prevent reinfestation. Professional, integrated rodent and insect control services are available in some locations. They may provide cost-effective convenience.

Dead-Bird Disposal

Foci of Infection

When birds die owing to disease agents, carcasses remain a source of infection for penmates and other poultry on the same or other farms. Also, hopelessly sick birds discharge infectious material into the environment and should be removed from the flock and killed in a manner that will not permit the discharge of blood or exudates (see "Diagnostic Procedures"). Whether the result of a serious clinical infection or just the usual expected mortality, all carcasses should be disposed of by one of the following methods to prevent dissemination of disease. Whatever method is used must be a practice that is allowed by state and federal environmental authorities.

Rendering

Freshly dead poultry, like livestock, can be rendered into fertilizer or other products. The rendering temperature should be sufficient for sterilization, and the truck bed used to transport the carcasses washed and disinfected. Cans used to haul the carcasses should be steam-cleaned and sterilized. Again, it should be remembered that commercial or contract haulers of dead carcasses may introduce another disease from some other outbreak unless strict precautionary measures are taken.

Incineration

Incineration is the most dependable way of destroying infectious material. Many smokeless, odorless incinerators for disposal of animal carcasses are available commercially. These devices are expensive to purchase and operate but are suitable in some instances.

Burying

For losses creating a serious disposal problem, where environmental regulations allow, a deep hole may be dug and the carcasses buried so animals cannot get at them. The best and easiest way is to use a backhoe and dig a deep narrow trench. Each day's collection of dead birds can be deposited and covered until the trench is filled.

Pit or Tank Disposal

For small losses and normal attrition, a decomposition pit can be used (Fig. 1.10A). A bigger and less elaborate one than that shown can be built, but precautions should be taken to ensure that it is not located where it will contaminate drinking water supplies, that the roof or walls will not cave in, that animals will not dig into it, that flies and other insects cannot get into it, and above all that children cannot fall into it. The pit cover should be sealed with tar paper or plastic and be strong enough to hold at least a foot of soil overlay. Where ground water levels are close to the surface (deltas, lowlands, and shorelines), underground pits may be undesirable.

Composting

Aerobic, thermophilic batch composting of poultry carcasses is a method of disposal developed at the University of Maryland (43). Compost mixtures of straw, whole poultry carcasses, manure, and water in the proportions of 1:1:1.5:0.5, respectively (1/3 of water added to each layer), decompose rapidly and odorlessly. Composts heat rapidly, attain temperatures of between 145–165° F, and reduce soft tissues completely within 14 days. Compost structures and management procedures are simple (Fig. 1.10B). Pathogen survival studies suggest the process is biologically "clean." Attempts to isolate coliform and *Salmonella*-like bacteria and IBD virus have yielded negative results. Composting may be an effective alternative to more traditional dead-bird disposal methods, especially where water tables are near the surface.

Buildings and Runs

Clean Buildings

A clean sanitized environment is good insurance against disease outbreaks from any cause. Stringent sanitary practices are frequently ineffective because disease is tracked in after the buildings and equipment are cleaned and disinfected, or because some step in the total program was omitted, and a focus of infection was preserved.

Litter Removal

When a house is depopulated, the litter or droppings should be removed preparatory to cleaning. With development of huge specialized poultry farms, proper and economical disposal of litter and poultry manure has become a serious problem. There is no clear-cut answer. A general recommendation is to remove it far enough from the buildings so that insects will not crawl or fly

A

back into the houses, and to dry it, compost it, or spread it onto fields and work it into the soil. If cleaning is done while chickens are still present (cages), remember that contracted personnel, trucks, and equipment may recently have been on another farm where a disease outbreak occurred.

In some cases, the nature of a disease may dictate that some extra precautions (wetting down or soaking with disinfectant, delaying removal, burying, burning) be taken with litter, even though expensive. Any treatment of manure or litter must consider residual effects of the applied compounds on plant life when treated manure is spread on the land. For most disease agents, composting of litter or droppings is sufficient. Whatever is done, one must be aware that wherever litter is spilled or piled, it remains as a disease reservoir for varying lengths of time.

Outside Runs

In the case of outside runs such as turkey and game bird ranges, the topsoil should be scraped off and hauled some distance from the poultry. Sunlight and soil activity combine over a long period to destroy most pathogens. Anything that can be done to aid the destruction process is helpful. Removal of organic residues, such as leaf beds and manure accumulations, helps to reduce the danger for future broods. It is best to rotate the ranges or dirt yards so that they stand idle for one complete flock cycle.

Washing and Disinfecting

After the litter or cage droppings have been removed, cleaning and transfer equipment, feeders, waterers, egg collecting equipment, walls, floors, roosts or cages, outside concrete or suspended runs, and entries to buildings should be washed thoroughly and disinfected. If the supply of water is limited and washing is not possible, dry cleaning may suffice if it is thorough and includes scraping and sweeping or vacuuming surfaces, corners, ledges, nests, and feeders. The amount of disinfectant used on dry-cleaned surfaces must be increased over that required for washed surfaces.

If possible to do so efficiently, it is preferable to clean the house without removing equipment. If not, all portable equipment should be removed, soaked with water, then thoroughly washed and dried. A high-pressure water hose is effective. Equipment that cannot be removed should be washed in place and then the entire inside building surface washed clean. If the building has been constructed to facilitate good cleaning, it can be done easily. If not, satisfactory cleaning may not be accomplished at all or only with great effort and expense. A large concrete apron equipped with racks and a high-pressure hose is a good place to clean and stack equipment.

After washing, disinfection is in order (see "Disinfectants"). Many effective disinfectants are sold under a variety of trade names; follow the manufacturers' recommendations. The impor-

tant thing is that the surfaces be clean before application. Disinfectants applied to dirt-encrusted surfaces are ineffective and wasted. Not only are they inactivated by organic material in the dirt, but they never reach the infectious agents beneath it. Thorough washing removes most infectious agents from the house and equipment and leaves a clean surface so the disinfectant can reach those that remain. Two to four weeks of idleness or "down time" before a new flock is moved in is additional insurance against carryover of disease; however, down time should be considered as an adjunct to, and not a substitute for, thorough cleaning, washing, and disinfection.

Built-up Litter and Uncleaned Buildings
Commercial producers demand chicks and poults that are free of pathogenic microbial agents acquired through egg transmission or from unsanitary hatchery or delivery environments. To maintain this status, it is preferable to place these healthy new flocks in cleaned and disinfected buildings with fresh clean litter. Providing these ideal conditions is expensive because of labor and litter costs. Also, suitable litter materials are becoming less plentiful. In keeping with the constant necessity to reduce production costs and cope with shortages, rearing of several successive flocks on the same (built-up) litter has become an economically acceptable practice with broilers, where the life span is very short and single ages of birds per farm permit complete depopulation at the end of each brood. The litter in turkey grow-out buildings is also frequently used for several successive flocks. This trend has become commonplace with the use of litter-processing machinery, which can break up caked litter and produce a litter with acceptable production characteristics. The continual reuse of such built-up litter will result in an increase of microbial pathogens and parasites within the litter. Commercial producers recognize, however, that cleaning and disinfecting a house or group of houses may become necessary any time excessive economic losses are attributable to a disease that may carry over to the next brood.

The practice of reusing litter is much less attractive for rearing egg-production flocks, where the life span usually exceeds 18 months; it is not acceptable for rearing breeding flocks that produce hatching eggs for new generations. In any case, those who reuse litter should be fully aware of the possible hazards involved and should follow other sound disease control practices to minimize the dangers.

When old litter must be reused, it is good insurance to remove any caked or excessively fouled litter, accumulated feathers, and decomposed carcasses. A layer of fresh clean litter then should be placed under the heating brooders and over the area to which the young will be confined or will spend most of their time the first weeks of life. One disadvantage of multiple brooding on the same litter is the excessive dust that accumulates. Inhalation of the dust provides an avenue of entry to the respiratory tract for bacteria and fungal spores.

Disinfectants

To disinfect is to free from pathogenic substances or organisms or to render them inert; a disinfectant is an agent or substance that disinfects chiefly by destroying infective agents (pathogenic microorganisms) or rendering them inactive; disinfection is the act or process of destroying pathogenic microorganisms. To sanitize is to reduce microbial populations and keep them from multiplying.

Properties
Among the properties of an ideal disinfectant are low cost per unit of disinfecting value, ready solubility in hard water, relative safety for humans and animals, ready availability, nondestructibility to utensils and fabrics, stability when exposed to air, absence of objectionable or lingering odor, no residual toxicity, effectiveness for a large variety of infectious agents, and no deleterious accumulation of any portion of the disinfectant in meat or eggs. For any disinfectant to be effective in economical quantities it must be applied to surfaces that have first been freed of debris and organic material by thorough scraping, scrubbing, brushing, and dusting and washing with soap or detergent solutions. Many disinfectants are highly efficient but only when these basic cleaning prerequisites have first been met.

Types
Many disinfectants of similar composition are sold under different trade names. Before buying a product with an unfamiliar name, compare types and values with a well-known product. Directions for dilutions given by the manufacturer should be closely followed. Complete discussions of various disinfectants and sterilization methods should be consulted (12, 52). Additional references on disinfectants and their use (28, 48) and textbooks on pharmacology and therapeutics should be consulted.

The virucidal activities of several commercial disinfectants against velogenic viscerotropic Newcastle disease have been determined (73). A list of 99 commercial disinfectants approved for use against avian influenza virus is available from the Environmental Protection Agency (USA). The list provides product names, basic formulations, and dilutions along with the names, addresses, and telephone numbers of appropriate distributors or formulators.

Phenol (Carbolic Acid)
Phenol is a chemical substance obtained from coal tar. In its pure form, it occurs as colorless crystals having a characteristic and familiar odor (lysol soap). It usually is sold in water solutions and is too expensive for general poultry house use. It is, however, the chemical used as a basis for determining the phenol coefficients of various disinfectants (relative ability to kill specific test organisms when compared with that of phenol). O'Connor and Rubino (45) present a complete discussion of the phenolic compounds. Commercial disinfectants containing phenolic compounds have been developed and marketed at cost values, which permits wider use in poultry operations. Some have residual activity persisting after they have dried, giving the advantage of continued suppression of bacterial and viral populations on sprayed surfaces.

Cresols
Cresol extracts of coal tar products are compounds closely related chemically to phenol and having similar bactericidal prop-

erties. They are thick yellow or brown liquids, miscible with water but only slightly soluble. They form the basis for a large number of commercial brands made by combining cresol with soap.

Bisphenols

Bisphenols are compounds composed of two phenol molecules modified and joined by various chemical linkages. Halogens, particularly chlorine, have been combined with bisphenols to increase their effectiveness; some of the chlorophenols have high antifungal activity. Bisphenols are frequently combined with other phenolic compounds in disinfectants. Additional information on these compounds is available (45).

Pine Oil

Pine oil has proved satisfactory as a disinfectant and has the advantage of being less injurious to the skin than cresol compounds. The odor is also less objectionable and in fact is rather pleasant, which enhances its desirability for use in offices and lavatory areas. Because it is insoluble in water, it is used in the emulsion form with soap or other emulsifying agent.

Hypochlorites and Chlorinated Lime

Chlorine is the basis of disinfectants known as hypochlorites, which contain about 70% available chlorine. Hypochlorites (22) are available as powders containing calcium hypochlorite and sodium hypochlorite (NaOCl) combined with hydrated trisodium phosphate and as liquids containing NaOCl. Chlorinated lime (bleaching powder), prepared by saturating slaked lime with chlorine gas, was one of the earliest recognized disinfectants. It has been largely supplanted by the more readily available hypochlorites.

Products containing NaOCl are essentially liquids ranging in concentrations from 1–15%. The 15% solutions are used to prepare 5% solutions with water for bleaches and sanitizing agents. Germicidal potency of hypochlorites is dependent upon concentration of available chlorine and the pH (acidity) of the solution or upon the amount of hypochlorous acid formed, which, in turn, is dependent upon both factors. The influence of pH, especially in dilute solutions, is even greater than the percentage of available chlorine. Increasing the pH decreases the biocidal activity of chlorine, and decreasing the pH increases the activity. Germicidal activity is speeded up by raising the temperature.

If used according to directions, hypochlorites are highly efficient. Their principal use in the poultry industry is for egg washing and sanitizing and for disinfecting limited areas such as incubators, incubator and hatcher trays, and other areas around the hatchery, egg breaking areas, small brooders, and water and feed containers. They can also be used on cement surfaces. All surfaces to be disinfected with hypochlorite solutions must first be thoroughly cleaned to ensure the greatest efficiency. Stock supplies should be kept in dark, cool places, and containers should be tightly sealed when not in use. Fresh solutions must be prepared daily and periodically tested to ensure that proper levels of available chlorine remain. A simple swimming pool test kit may prove helpful for such monitoring. Recently purchased or stored

hypochlorites have been found to have wide ranges of concentration values.

All products containing chlorine must be handled with care because free chlorine is destructive to fabrics, leather, and metal.

Organic Iodine Combinations

Iodine has long been recognized as an effective disinfectant. Many of the disadvantages of earlier products have been overcome by combining iodine in organic complexes, sometimes called tamed iodine. The term *iodophor* refers to a combination of iodine with a solubilizing agent that slowly liberates free iodine when diluted with water. The term most frequently refers to formulas consisting of iodine complexed with certain types of surfactants that have detergent properties. These complexes are said to enhance the bactericidal activity of iodine and render it nontoxic, nonirritating, and nonstaining when used as directed. The detergent also makes the products water soluble and stable under usual conditions of storage. No offensive odor exists, and the detergent properties impart cleansing activity. See Gottardi (30) for additional information on iodine compounds.

A group of commercial iodophors have been developed and marketed for a wide variety of disinfectant uses. Some of these products have a built-in indicator of germicidal activity; as the solution is used up, the normal amber color fades. When the solution is colorless, it is no longer effective. The products can be mixed in cold and hard water. Organic iodine products have a wide variety of uses in the industry. They can be applied without hazard to nearly all surfaces and are useful for disinfecting hatchery and incubator surfaces, incubator and hatcher trays, egg breaking areas, feeders and fountains, footwear, and poultry buildings. Like other disinfectants, these compounds are most effective on clean surfaces.

Quicklime (Unslaked Lime, Calcium Oxide)

The action of quicklime depends on liberation of heat and oxygen when the chemical comes in contact with water. On the poultry farm, its use is limited to small yard areas that are damp and cannot be exposed to the sun, disinfection of drains and fecal matter, and whitewashes. As quicklime has a caustic action, birds should be kept away from it until it has become thoroughly dry.

Formaldehyde

Formaldehyde (CH_2O) is a gas. It is sold commercially in a 40% solution (37% by weight) with water, under the name of formalin. It may also be purchased in the form of a powder known as paraformaldehyde (paraform, triformal, formaldegen). When heated, this powder liberates CH_2O. A suitable heating device is a thermostatically controlled electric pan with a timer that can be controlled from outside the fumigation chamber. Manufacturer's directions on amounts to use for each type of equipment and the means of liberating the gas must be carefully observed.

Formaldehyde is often generated by adding formalin to potassium permanganate ($KMnO_4$) in an earthenware crock or metal container. Because of the heat generated by the chemical reaction, glass containers should not be used. The container should be deep and have a volume several times that of the combined chem-

icals, because considerable bubbling and splattering takes place. The ratio in liquid measure of formalin is approximately twice the dry measure of $KMnO_4$ (1 g $KMnO_4$/2 mL formalin). If too much formalin is used, the excess will remain in the vessel. If too much $KMnO_4$ is used, the excess remains unchanged and is wasted. Potassium permanganate is poisonous. Both these compounds must be kept in accident-proof containers in a safe place away from work traffic.

A suitable fumigation cabinet must have a source of heat, a fan to circulate the warm humid air and fumigant, a source of humidifying moisture, and a method of generating formaldehyde gas. The box should be airtight and have an exhausting device from the fumigation box to the outside of the building. It is much safer to locate fumigation chambers outside of any building and away from human traffic.

Although it is a powerful disinfectant, CH_2O has many disadvantages, especially its volatility, pungent odor, caustic action, and tendency to harden human skin—properties that make it disagreeable to apply. It is extremely irritating to the conjunctiva and mucous membranes, and some people are very sensitive to it. Because of this and other toxic properties, precautions must be taken to prevent its escape into areas where people work. Its chief advantages are that it can be used as a gas or vapor for fumigation of hatching eggs. It is a good disinfectant in the presence of some organic matter, and it does not injure equipment with which it comes in contact. The maximum atmospheric concentration permitted in work areas by some Occupational Safety and Health Administration (OSHA) regulations is 2 ppm with a maximum 15 minute exposure time. Suitable gas masks should be readily available near fumigation boxes. Formaldehyde can be neutralized with ammonium hydroxide by using a solution of approximately 30% and a quantity not to exceed one-half of the quantity of formalin used in the fumigation. Ammonia may be released by sprinkling or spraying in the intake air during evacuation of the fumigation box after the surfaces have dried completely.

Formaldehyde gas is widely used in poultry enterprises for fumigation of hatching eggs to destroy potential pathogenic shell contaminants. It is also used at the end of cleanup to fumigate the inside of incubators and hatchers and their contents.

Fumigation of incubators and eggs has been an established practice in the industry and has varied little over the years. Various recommendations have been made for quantities, humidity, temperature, and time for adequate sterilization of shells of hatching eggs. Frequent recommendations specify the following: 60 g $KMnO_4$:120 mL formalin/100 ft^3 (2.8 m^3) cabinet space, 21.1°C, 70% humidity, and 20 minutes fumigation time. The higher the humidity and temperature, the more effective the fumigation. When fumigation is completed, exhaust ducts are opened and the gas thoroughly exhausted before anyone opens the door to the cabinet.

In modern enterprises, hatching eggs frequently are handled only once and are placed directly into plastic holders (flats), which then travel in stacks through the fumigation, transportation, and storage route and eventually into the incubators. Entire racks, dollies, or pallets of closely stacked flats of eggs are thus fumigated in large boxes. To generate adequate concentration of CH_2O and have it penetrate and disinfect the egg shells in the

centers of these stacks, there should be an increased quantity of chemicals (75 g $KMnO_4$:150 mL formalin/100 ft^3), higher humidity (up to 90%), higher temperature (up to 32.2°C), longer time (up to 30 minutes), and vigorous agitation of the gas during fumigation so that it will penetrate the spaces and effectively sanitize surfaces of eggs in the centers of such large stacks. Pressed paper egg flats tend to trap CH_2O and continue to release the gas during storage and processing; therefore, CH_2O fumigation should be confined to eggs in plastic flats or wire containers.

CH_2O fumigation is sometimes used to disinfect the inside and contents (including eggs at 18 days of incubation) of hatching machines. Because these machines are inside of the building, this should not be done unless provision is made for adequate ventilation of the gas to the outside of the building when fumigation is completed.

Certain precautions are necessary after fumigation of hatching eggs. The incoming air for exhaustion must be clean, otherwise the humid surface of the egg can become recontaminated. During extremely cold weather, outside air must be warmed before entering the fumigation chamber to avoid overchilling eggs. Although humidity is essential for disinfective activity of the CH_2O, the surface of eggs should not become visibly wet during fumigation and should be dry when the eggs leave the fumigator.

Fumigation should not be done in incubators because of the danger of injuring embryos. Also, it should not be done at such a high concentration after the hatch begins because of the danger of injuring chicks or poults. Formaldehyde may be generated in hatchers by using approximately 20 mL formalin solution/100 ft^3. The formalin is soaked into enough cheesecloth so that it does not drip, and the cloth is hung in the circulating currents in the box. Effectiveness of this method is limited because of the low concentration.

Antifungal Imidazoles
The use of formaldehyde may pose some health and safety concerns for hatchery personnel. An effective substitute for formaldehyde used to control *Aspergillus* spp. in the hatchery is imazalil or enilconazole (nonproprietary names for phytopharmaceutical and veterinary uses, respectively) (70). The imidazoles are fungistatic at low concentrations by inhibiting ergosterol synthesis and fungicidal at high concentrations by causing direct membrane damage (55). Imazalil is intended for use on clean hatchery surfaces or equipment and is delivered in an aqueous spray or by smoke propellant canisters. The antifungal properties of imazalil must be complemented with the use of antibacterial disinfectants for a complete hatchery sanitation program.

Copper Sulfate (Bluestone)
Although copper sulfate ($CuSO_4$) and other salts of copper have a marked toxic effect upon some of the lower forms of life, they are not considered good general disinfectants. Copper sulfate is toxic to algae and fungi and has been used in attempts to stop or prevent outbreaks of fungal diseases. It has been used in the feed at 0.5 lb/ton and sometimes 1 lb/ton for short periods without noticeable toxicity to chickens. Poultry usually will drink water containing $CuSO_4$ at no greater concentration than 1:2000, but a

concentration greater than 1:500 may be toxic when given in the only source of water. Turkeys do not like water containing $CuSO_4$ and will seek other supplies if available. A 0.5% solution may be of value for disinfecting feed hoppers, water fountains, and surrounding areas associated with outbreaks of fungal disease.

Quaternary Ammonium Surfactant Disinfectants

Quaternary ammonium products (quats) are considered to be good disinfectants when used according to directions. They are noncorrosive, water clear, odorless, cationic (+ charged ions), nonirritating to the skin, good deodorants, and have a marked detergent action. They contain no phenols, halogens, or heavy metals and are highly stable and relatively nontoxic. Most quats cannot be used in soapy solutions. All surfaces to be disinfected must be thoroughly rinsed with water to remove any residue of soap or anionic (– charged ions) detergent before using quats for sterilizing purposes. Some hard-water minerals may interfere with their action. See Merianos (42) for more information on these compounds.

Quats are used for washing eggs and disinfecting hatchery surfaces, incubator and hatcher trays, egg breaking equipment and areas, feeders and waterers, and footwear, among other uses.

Sunlight and Ultraviolet Radiation

Solar radiation has disinfecting properties; however, because the material to be treated must be in thin layers and exposed to direct rays, this method is limited to impervious surfaced yards, concrete and blacktop aprons, and equipment that can be thoroughly cleaned before being exposed. The construction of most poultry houses prevents efficient disinfection by the sun. A cement platform fully exposed to the sun makes a convenient place for treating movable equipment. If properly constructed with a drain, such a platform can be used as a washing and disinfection rack. A concrete apron before the poultry house entry will be washed by rains or can be washed by hose to take advantage of the disinfecting power of the sun's rays on the clean surface.

There are many types of germicidal (ultraviolet or UV) lamps, but not enough scientific evidence is available to warrant a recommendation for their general use in hatcheries or on poultry farms. A complete review of the use of UV radiation in microbiologic laboratories is available (47).

Hot Water

Hot water adds to the efficiency of most disinfectants, and if applied in the form of boiling water or live steam, is effective without the addition of any chemical. Detergents added to systems for generating and disseminating hot water and steam will increase cleaning and decontaminating efficiency. Live steam must be applied directly and at close range to the part to be disinfected.

Dry Heat

Dry heat in the form of a flame is effective if the flame comes in contact with the pathogen to be killed. All methods involving direct flame are fire hazards and not recommended except possibly on cement surfaces. In tightly controlled circumstances, flames might be used to eliminate hard-to-remove feathers and fluff accumulations.

Other commercial disinfectants, mostly organic compounds, are available under trade names. Many are combinations of several individual disinfectants with complementary properties. Some also have long residual activity. To choose disinfectants wisely, one must continually keep abreast of new product development through current scientific and lay publications.

Residues of disinfectants used to sanitize drinking fountains should be rinsed off with fresh water before water vaccines are given, because they can inactivate the vaccine virus.

Pesticides (Insecticides and Parasiticides)

Properties

The Environmental Protection Agency (EPA) defines a pesticide as any substance intended for the preventing, destroying, repelling, or mitigating of any pest. A pest can be any insect, animal, plant, or microorganism. Insecticides destroy animal parasites such as lice, mites, ticks, and fleas. They also destroy other undesirable insects (flies, beetles, ants, and sow bugs) in the environment. Some insecticides are highly toxic to humans and livestock. Their use (preferably by a licensed expert as part of a professional, integrated insect and rodent control service) is recommended only as an adjunct to a properly conducted total sanitary control program. Many disinfectants are also destructive to lice, mites, and other similar parasites but must come in contact with them. Most pesticides, however, are useless as disinfectants.

Suitable insecticides are those that can be used on or around poultry without causing toxic effects to humans or birds from contact or ingestion and that do not accumulate to harmful levels in edible tissues or eggs as a result of ingestion or absorption.

The list of available and permissible commercial insecticides has declined greatly and changes frequently. Two extension bulletins, *Livestock and Livestock Building Pest Management* and *Poultry Pest Management,* are available from the Ohio State University Extension. Many, widely used in the past, have been prohibited for use around food animals because of the deposition of insecticides in fatty tissues and eggs. Others have been abandoned because populations of insects became resistant to them. It is necessary, therefore, to keep informed on available effective insecticides through current government, university, and industry literature. In some situations, it may be cost effective to contract this complex changing activity through an agency providing professional insect and pest control services. Biosecurity measures for the agency employees and equipment must be considered when contemplating such contract services.

The limited number of available commercial parasiticides, their active chemical properties, limitations, tolerances, and various applications, are discussed in detail in Chapter 26. See also Chapter 32 for toxic effects of some insecticides.

Unlike flies, which travel to insecticide baits or over insecticide-treated surfaces, bird ectoparasites are best controlled by bringing the insecticide into contact with the parasite. A wide assortment of housing types and production systems are in use. One application method or system is seldom suitable for all types of housing. The type and form of parasiticide best suited for a

particular type of housing and management system should be determined and then used according to directions on the label. Fogging and misting can be effective only if the insecticide can be confined in the building and/or applied (blown) into cracks and crevices and on feathers where parasites are congregated. Otherwise, the effort and expense are largely wasted. Pyrethrum preparations containing synergists can be used in light- and temperature-controlled houses, but the automatic ventilation system must be bypassed and hand controlled during treatment. In high-rise houses, one must be sure to compensate for the large volume of space under the floors by using additional insecticide in a space-calculated application.

A common error is to assume that one application of insecticide will accomplish the objective. Parasite eggs are seldom destroyed; they remain to generate a new population, which must be attacked with a second application 2–3 weeks after the first. In addition, no system, application, or insecticide will result in a 100% parasite kill. After the parasite gains a foothold, it must be attacked repeatedly. Frequently, alternating insecticides and methods is necessary to effect control. Do not be misled by statements that the birds learn to live with their parasites. Such thinking encourages continuous poor bird performance and a host of problems.

Handling Precautions

Possible hazards to humans and animals from many of the modern pesticides must always be remembered when considering their use. It is best to wear a suitable mask, rubber gloves, and protective clothing when applying insecticides. The most important precaution in handling chemical insecticides is to read the directions, hazards, and antidotes on labels of containers before any use.

A basic rule in handling insecticides is to keep them properly labeled and stored in a locked building reserved for that purpose. Disposal of empty containers and discarded leftover insecticides is becoming more of a hazard and responsibility. Large drums should be returned to the supplier or heated to red heat for 5–10 minutes. Paper and plastic containers should be burned. Small glass and metal containers should be broken or punctured so that no one will use them for any purpose. In addition to the human hazard, discarded insecticides must not pollute lakes or streams nor become a hazard for honeybees. A safe policy is to check with the local Environmental Protection Agency (EPA) for recommendations.

Types

Crude Oil, Distillates, and Similar Compounds
Petroleum oils applied to clean buildings and equipment prior to introducing a new flock have been widely used to control lice, mites, and ticks. Oily residues get on the parasites and cause suffocation. They have been effective in getting at parasites in cracks and crevices of the building, but they cannot be applied to parasites on birds. Carbolinium, a wood preservative, also repels mites and other insects for long periods after it is applied. These products are quite messy and smelly and not as effective as many newer products.

Space Diffusion Insecticides
Pyrethrum products are released as a fog or mist, and the volatile compound permeates the room. Pyrethrum, an extract from plants, has low toxicity for higher forms of life but high toxicity for insects. It is relatively costly and may fail to penetrate adequately through feathers of birds and into insect hiding places. Synthetic forms of pyrethrum are now available commercially.

Vapona or DDVP, a preparation of dichlorvos, is sometimes impregnated into special materials from which it slowly vaporizes and diffuses through the air. This has greatest application in storage and other rooms that are closed and unventilated for long periods (overnight).

Systemic Inhibitors
Sulfaquinoxaline, used so extensively in feed and water to control coccidiosis and many bacterial infections, was found to rid birds of northern fowl mites (23). The product or its metabolites apparently create body conditions objectionable to the parasites (possibly odors), which drive them off the birds. The drug has since been banned from feed for hens laying eggs for human consumption, but other products have been reported to exert similar effects, and some may exert an unsuspected mite-repelling action. Drugs providing this type of mite control seem most effective when incorporated in feed prior to infestation and least effective as a treatment after infestation has become established.

Dusts and Sprays
Nearly all insecticides adaptable to control of parasites on fowl can be obtained as ready-to-use dusts or in the form of wettable powders, emulsifiable concentrates, or liquid suspensions, all of which can be prepared as sprays. Each has advantages, and suggested uses are supplied with the insecticide.

Chickens dust themselves instinctively. In litter-floor houses, insecticide dusts can be added to litter to control mites, according to specifications of the manufacturer. Special dust boxes with added insecticide can be placed in large cages and wire- or slat-floored houses to accomplish the same objective. Dusts can also be applied to birds in cages by using a dust applicator. The dust must be blown into the feathers to get at the parasites. Although laborious, dusting individual birds can be effective.

The most common method of applying insecticides is by spray. The mixture must be agitated during application to maintain a constant concentration and prevent separation. Sprays are mostly applied to floors and walls, but some can be sprayed on the birds.

None of the insecticides is perfect, and resistance is already known to have developed against some of them. New products are constantly being developed and tested for effectiveness. Poultry producers should be alert for products, preparations, and local vendors of professional pest-control services most suitable for their type of management system.

The best parasite control is to prevent the initial infestation through wise management practices. Once again, parasite infestations, like bacterial and viral diseases, can be most successfully controlled and eradicated from single-age farms or quarantinable units as part of a total, integrated system of "disease-prevention management."

Handling Disease Outbreaks

Observe the Normal

Good poultry producers watch feed and water consumption and egg production at all times, but more important, they observe normal sounds and actions of the flock. They sense immediately when any of these conditions are abnormal and interpret them as signs of abnormal health. When this happens, it should be assumed that an infectious disease has gained entry and may be tracked elsewhere during the investigation period. In a modern poultry production system, any disease creates serious disruption in the economical operation of the farm and the plants processing products from it. Serious infectious diseases can create havoc. The following steps should be followed when disease is suspected.

Look for Noninfectious Conditions

Take precautions against tracking an infectious disease that may be present, but investigate management errors immediately. A high percentage of so-called disease problems referred to laboratories for diagnosis are noninfectious conditions related to management: beak trimming errors; consumption of litter and trash; feed and water deprivation; chilling of chicks; injury from rough handling, automatic equipment, or drug injection; electrical failures; cannibalism; smothering; overcrowding; poor arrangement of feeders, waterers, and ventilators; inexpensive low-quality feed ingredients; ingredients causing feed refusal; improper particle size of feed ingredients; and rodent and predator attacks (1, 11). Zander observed a severe drop in egg production in a pathogen-free flock after a 48-hour failure of a mechanical feeder (77). Bell (10) observed marked reduction in lay from water deprivation related to a beak trimming system that resulted in long lower beaks, making it difficult to obtain water when the level was low. These are conditions that do not require services of a diagnostic laboratory. External parasites (mites, lice, and ticks) can be determined by producers if they examine affected birds.

Quarantine the Flock

In the event that no management factors can be found, the next step is to set up a quarantine of the pen, building, farm unit area, or entire farm, depending upon its design and programming. If this emergency was anticipated when the farm was laid out and programmed originally, the quarantine will be a minor problem. If the basic principle of "a single age in quarantinable units" was disregarded in original farm planning, a disease outbreak can be an economic disaster. Separate caretakers should be established for affected birds or at least sick ones should be visited last.

Submit Specimens or Call a Veterinarian

The owner or caretaker should submit typical specimens to a diagnostic laboratory or call a veterinarian to visit the farm and establish the diagnosis. Owners should seek professional diagnosis, rather than trying to hide some disease because of possible public recrimination. Veterinarians and caretakers can and should help dispel this apprehension by maintaining high ethical standards and refraining from discussing one producer's problems with others. Yet, there comes a time when all producers must be apprised of a problem. Service workers frequently are requested to examine the flock, select specimens for the laboratory, and initiate first-aid procedures until the veterinarian can be called or visited. If so, they should wear protective footwear and clothing when they enter the house. No other farm should be visited en route to the laboratory.

Diagnosis

It is important to get a diagnosis as soon as possible. The course of action will be determined by the nature of the disease. A producer should not procrastinate for any reason when a disease threatens, or it may get completely out of hand before a diagnosis is made. It is not always possible to treat a disease or check its deleterious effects, but to plan effectively for the future, it is important to identify any and all diseases that occur. A veterinarian should also be aware of the owner's economic plight at such times and render advice and assistance as quickly as information is available or a judgment can be made.

Special Precautions

In addition to causing serious losses in poultry, some diseases (chlamydiosis, erysipelas, and salmonellosis) are especially hazardous for humans. When these conditions are suspected or diagnosed, extra precautions must be taken to ensure against human infection. The proper government health authorities should be notified of chlamydiosis outbreaks, and all handling and processing personnel should be apprised of the disease, hazards, and necessary precautions.

In some states, certain diseases (*Mycoplasma* infections, avian chlamydiosis, and laryngotracheitis) must be reported immediately to the state animal disease control authorities so that proper investigation and action can be taken to protect the human population and the poultry industry. Common sense dictates that when a condition suggestive of an exotic disease, such as velogenic viscerotropic Newcastle disease, fowl typhoid, or avian influenza, is encountered, the proper state and federal regulatory authorities should be informed.

Nursing Care

Nursing care plays an important role in the outcome of a disease outbreak. Additional heat should be supplied to young chicks that begin huddling because of sickness. Clean and fresh (or medicated) water should be available at close range. Temporary, more accessibly located waterers are sometimes necessary during sickness. If water founts normally are located where chickens must jump onto some raised device or turkeys must cross through hot sunlight to reach them, the sick will not have the energy or initiative to seek water. They will soon become dehydrated, an early step on the road to death.

The same principles are true for feed. Sick birds can be encouraged to eat if the caretaker will proceed through the house, stirring feed and rattling feed hoppers or adding small quantities of fresh feed. Some antibiotics appear to stimulate feed consumption when included in the diet; however, any additive that proves distasteful to the bird should be removed immediately.

Sometimes birds become so depressed and moribund that the

caretaker must walk among them frequently to rouse them so that they will eat or drink.

Hopelessly sick and crippled birds should be killed in a manner to preclude or control the discharge of blood or exudates (see "Diagnostic Procedures"). Dead and destroyed birds should be disposed of immediately (see "Dead-Bird Disposal").

Drugs

No drugs should be given until a diagnosis is obtained or a veterinarian consulted. If the wrong drug is given, it can be a waste of money, or it may be harmful or even disastrous. If an infectious disease is found and corrective drugs are indicated, they should be used very carefully according to directions.

Strict regulations govern the use of drugs in mixed feeds for food-producing animals. For information, write to the U.S. Food and Drug Administration (FDA), 5600 Fishers Lane, Rockville, MD 20857. A handy reference is the annually updated *Feed Additive Compendium* published by Miller Publishing Co., Minnetonka, MN. Feed manufacturers must have FDA clearance to include drugs in mixed feeds. When treated flocks are to be marketed, a specified period (depending on the drug used) must follow cessation of treatment to allow dissipation of drug residues from tissues before slaughter. If the flock is producing table eggs when treated, the drug must be one permitted for use in laying flocks, or eggs must be discarded during, and for varying lengths of time after, treatment, which is a costly alternative.

If the flock is producing hatching eggs when it becomes infected and there is danger that egg transmission of the infectious agent from dams to offspring may occur (salmonellosis, mycoplasmosis, and avian encephalomyelitis), eggs should not be used for hatching until the danger has passed. It should also be kept in mind that in fertile eggs, residues of drugs used to treat breeders occasionally may cause abnormalities in some embryos.

Disposition of the Flock

The flock should not be moved or handled until it has recovered, unless the move is to a more favorable environment as part of the therapy. After treatment, if any, has been completed and the flock appears to be completely healthy, it may be marketed or moved to permanent quarters if such a move is part of the management program. Some healthy carriers may remain. If the flock is moved to another depopulated farm, this will present no problem except that occasionally a disease may flare up from stress of handling and moving. If the recovered flock is moved to a multiple-age farm, carriers can introduce the disease into susceptible flocks already there. If the recovered flock is already in permanent quarters having multiple ages, newly introduced flocks may be exposed and contract the disease, a common occurrence especially with respiratory and litter-borne diseases.

Diagnostic Procedures

Many satisfactory diagnostic and necropsy methods exist. The techniques and instruments used by one pathologist may vary considerably from those used by another. Some suggestions are offered here to guide the student and beginner. The goal of the necropsy is to determine the cause of impaired performance, signs, or mortality by examining tissues and organs, and to obtain the best specimens possible to carry out microbiologic, serologic, histopathologic, or animal inoculation tests. It is important that in the process, infectious materials do not endanger the health of humans, livestock, or other poultry. By proceeding in an orderly fashion, possible clues are less apt to be overlooked, and tissues will not be grossly contaminated prior to examination. Remember that a blood sample or tissue specimen determined later to be superfluous can always be discarded. It's better to save tissues and then discard them if they are later determined to be unnecessary or unimportant to the diagnosis.

A key to good poultry diagnosis is the art of "seeing the forest as well as the trees." Try to identify the most significant flock problem(s), rather than becoming engrossed in individual bird disorders. Watch for telltale patterns of pathology as presented by the total diagnostic consignment.

The techniques and procedures necessary to make an accurate diagnosis and identify specific disease agents are found in the technical information contained in succeeding chapters of this book and in the following excellent reference manuals: *A Laboratory Manual for Isolation and Identification of Avian Pathogens* (64), *Avian Disease Manual* (17), *Avian Histopathology* (53), and *Color Atlas of Diseases and Disorders of the Domestic Fowl and Turkey* (51). *Avian Hematology and Cytology* (15) should be consulted for detailed information on avian blood elements and methods for preparation and study. New information is continually being presented in the following journals, *Avian Diseases, Avian Pathology,* and *Poultry Science,* in the proceedings of several regional poultry disease conferences, and in other avian pathology and science journals.

Case History

The pathologist who has not seen the farm or the flock before attempting to diagnose the problem and recommend corrective measures is at a disadvantage. This can be partially overcome by getting a complete history of the disease and all pertinent events leading to the outbreak. The more information pathologists have about the history and environment, the more directly they can proceed to determining solutions for the problems. Unfortunately, the history includes only the situations, events, and signs that the caretaker, owner, service worker, or neighbor has observed and remembered. Knowledge of management factors such as ventilation; feeding and watering systems; accurate records of egg production, feed consumption, feed formulation, and body weight; lighting program; beak trimming practices; brooding and rearing procedures; routine medication and vaccination used; age; previous history of disease; farm location; and unusual weather or farm events may make the difference between diagnosis of the flock problem and the finding of a few miscellaneous conditions in a sample that may or may not be representative. Duration of the signs, the number of sick and dead, and when and where they were found dead can be important clues.

Poultry producers have developed a high degree of knowledge about poultry diseases and usually recognize those resulting in

dramatic or clear-cut signs and lesions. The veterinarian, therefore, is often confronted with obscure, undramatic, and complicated disease cases requiring extensive investigation. Even if all indications are that reduced performance is most likely due to a management factor, the veterinarian must check all reasonable disease possibilities. This requires a systematic approach to be sure that nothing is overlooked.

External Examination

Look for external parasites. Lice and northern fowl mites (*Ornithonyssus silviarum*) can be found on the affected chicken. If red mites (*Dermanyssus gallinae*) or blue bugs (*Argas persicus*) are suspected, examination of roosting areas and cracks and crevices in the houses and around the yards must be made, because these species do not stay on birds. See Chapter 26 for diagnosis and identification of external parasites.

The general attitude of live birds and all abnormal conditions should be noted carefully. It is very important to observe evidence of incoordination, tremors, paralytic conditions, abnormal gait and leg weakness, depression, blindness, and respiratory signs before the specimens are killed. It is very helpful to place birds in a cage where they can be observed after they have become accustomed to the surroundings and perform at their best. It is sometimes advisable to save some of the affected birds to observe possible recovery from a transitory condition (transient paralysis), respiratory infection, chemical toxicity, feed or water deprivation on the farm, or overheating during transport to the laboratory.

Examination should be made for tumors, abscesses, skin changes, beak condition, evidence of cannibalism, injuries, diarrhea, nasal and respiratory discharges, conjunctival exudates, feather and comb conditions, dehydration, and body condition. These are all useful clues.

Blood Samples

Blood specimens may be taken at this time (or immediately after the bird is euthanized). Frequently, it is desirable to have two (paired) blood samples several days apart to determine a rising or falling titer of antibodies to some disease (Newcastle disease) in the serum. In this case, a blood specimen may be taken from the main (brachial) wing vein or jugular vein or by heart puncture, and the bird then is saved for a second sample.

Venipuncture of the brachial vein is usually the simplest and best method for obtaining blood from turkeys, chickens, and most fowl under field conditions, especially when the bird is to be returned to the flock. Ducks are bled from the saphenous vein near the hock. Expose the vein to view by plucking a few feathers from the ventral surface of the humeral region of the wing. The vein will be seen lying in the depression between the biceps brachialis and triceps humeralis muscles. It is more easily seen if the skin is first dampened with 70% alcohol or other colorless disinfectant. To facilitate venipuncture, extend both wings dorsally by gripping them firmly together in the area of the wing web with the left hand. Insert the needle into the vein of the right wing holding the syringe in the right hand (Fig. 1.11). The needle should be inserted opposite to the direction of blood flow.

Fig. 1.11. Obtaining a blood sample from the wing vein.

Heart puncture can be made anteromedially between the sternum and metasternum (31), laterally through the rib cage, or anteroposteriorly through the thoracic inlet. Only through experience can one learn exactly where and at what angle to insert the needle. It is best to practice these techniques on freshly killed specimens before attempting to bleed live birds. A general rule for the lateral puncture is to form an imaginary vertical line at the anterior end of, and at a right angle with, the keel, and then palpate along that line. The heartbeat can be felt, and the needle inserted to the proper depth.

For heart puncture through the thoracic inlet, the bird should be held on its back with the keel up. The crop and contents are then pressed out of the way with a finger while the needle is guided along the ventral angle of the inlet. After penetrating the inlet, the needle is directed horizontally and posteriorly along the midline until reaching the heart.

The site for heart puncture between the sternum and metasternum is (in a mature chicken) about an inch above and posterior to the anterior point of the keel. The needle is directed at approximately a 45-degree angle in the anteromedial direction toward the opposite shoulder joint. The needle should pass through the angle formed by the sternum and metasternum and directly into the heart. For further details and illustrations, see Hofstad (31).

The size and length of the needle required for heart and venipuncture will depend on the size of the bird: for young chicks and poults, a 1/2-in. 20-gauge needle; for mature chick-

ens, a 2-in. 20-gauge needle. Mature turkeys may require larger needles. For quick and accurate bleeding, it is essential that the needle be sharp. A very slight vacuum should be developed intermittently to determine when vein or heart puncture has occurred. After vein puncture, a steady slight vacuum should be continuous to withdraw blood. If the vacuum is too great, the vessel wall may be drawn into the needle and plug the beveled opening. It is sometimes necessary to rotate the needle and syringe to be sure the beveled opening is free in the lumen of the vessel.

For most serologic studies, the serum from 2 mL blood is adequate. The blood should be removed aseptically and placed in a clean vial, which then is laid horizontally, or nearly so, until the blood clots. An occasional sample may require a long time to clot. This is especially true of turkey blood. Clotting can be hastened by adding a drop of tissue extract, made by killing and pooling a number of 10–12-day-old chicken embryos, grinding in a Waring blender, and freezing for future use. After the clot is firm, the vial may be returned to the vertical position to permit serum to collect in a pool at the bottom. Plastic vials are also available for blood collection. The clot does not adhere to the vial, and special positioning during clotting is unnecessary. Frequently, the serum from fat hens will appear milky due to lipids. Placing vials in an incubator will hasten the separation of the blood clot and serum. A fresh blood sample should never be refrigerated immediately after collection, as this will hinder the clotting process. Sera should not be frozen if agglutination tests are to be performed as this frequently causes false-positive reactions.

If an unclotted blood sample is required, it should be drawn into sodium citrate solution at the rate of 1.5 mL 2% solution/10 mL fresh blood, or deposited in a vial containing sodium citrate powder at the rate of 3 mg/1 mL whole blood, and the mixture should be gently shaken. One way to prepare tubes for collecting sterile citrated blood is to add the proper amount of 2% sodium citrate solution to the collecting tubes ahead of time and then sterilize the solution and evaporate the moisture in an oven.

Blood-collecting vials containing the anticoagulants heparin or EDTA can also be obtained commercially from laboratory supply companies. For certain types of serologic tests, fresh blood can be absorbed on the tips of filter paper strips, dried, and sent to the diagnostic laboratory, where antibodies can be recovered for testing by placing pieces of the treated paper into saline solution.

If a blood parasite or blood dyscrasia is suspected, smears of whole blood should be made on clean glass slides previously warmed to promote rapid drying. For staining techniques, see Campbell (15).

A drop of blood for a wet mount or smear may be obtained from very small chicks by pricking the vein on the posteromedial side of the leg or by pricking or cutting the immature comb.

Killing Birds for Necropsy
Cervical Dislocation
Several methods can be used to kill fowl, and each has certain advantages. The objective is to kill the bird instantaneously so it will not suffer in the process. Cervical dislocation, as described, is considered a humane method of poultry euthanasia by the American Veterinary Medical Association (AVMA) (5).

Bovine Burdizzo castration forceps can be used for killing large chickens and turkeys. It is difficult for one person to perform this operation and hold the bird at the same time, but it is quite easily done with the aid of an assistant. This technique also prevents agonal regurgitation and aspiration of crop contents into the respiratory passages if the forceps are left clamped until reflex muscle spasms cease. The neck of a young chick can also be broken easily by pressing it firmly against a sharp table edge, or by pinching between thumb and index finger, or by using the inside, noncutting angles of a surgical scissor such as a small Burdizzo.

Electrocution
Electrocution is a satisfactory method also. Clamps fixed to the end of electrical wires are fastened to the cloaca and mouth (this will assure moist contacts). The wires are then attached by means of a standard plug directly to 110-V alternating house current. A switch is thrown to feed the electric current through the wires. With this system, the bird rarely struggles and, thus, does not stir up dust or regurgitate crop contents. There is also less danger of agonal hemorrhages occurring or loss of blood when tissue specimens are desired. Obvious hazards to personnel and of short circuits on metal table tops should be recognized.

Other
Specimens selected for diagnosis may also be killed by intravenous injection of euthanasia solutions. Another method that would be satisfactory is euthanasia by placing the bird in a chamber filled with carbon dioxide (CO_2). Local availability of a CO_2 source may limit utilization of this technique.

Other methods of euthanasia can be found in a report of the AVMA (5). The method selected will depend upon the existing situation: species, size, and number of birds to be necropsied or sacrificed; tissues, fluids, and cultures to be taken; etc.

Necropsy Precautions
If there is reason to suspect that birds to be necropsied are infected with disease that may be contagious for humans (chlamydiosis, erysipelas, or equine encephalitis), stringent health precautions are essential. The carcass and the necropsy table surface should be wet thoroughly with a disinfectant. Good rubber gloves should be worn, and care should be taken that neither the pathologist nor assistants puncture the skin of their hands or inhale dust or aerosols from tissues or feces. It is advisable to wear a fine-particle respiratory mask to prevent inhalation of contaminated dust. All laboratory personnel who may come in contact with carcasses, tissues, or cultures should be informed of their possible infectious nature and precautions to be taken.

With some notable exceptions (see sections on the specific diseases), most commonly encountered poultry disease agents are not considered pathogenic for humans. Nevertheless, it is wise to wear rubber gloves at all times while performing necropsies. For a review of poultry diseases in public health, see Galton and Arnstein (25). Adequate instruments for routine work are necropsy shears to cut bones, enterotome scissors to incise the gut, a necropsy knife to cut skin and muscle, and a scalpel for

fine examination of tissues. These should be supplemented with forceps, sterile syringes, needles, vials, and petri dishes for collecting blood samples and tissue specimens as the situation dictates.

Necropsy Technique

Internal Organs

The specimen is laid on its back and each leg in turn drawn outward away from the body while the skin is incised between the leg and abdomen. Each leg is then grasped firmly in the area of the femur and bent forward, downward, and outward until the head of the femur is broken free of the acetabular attachment so that the leg will lie flat on the table (Fig. 1.12A).

The skin is cut between the two previous incisions at a point midway between keel and vent. The cut edge is then forcibly reflected forward, cutting as necessary, until the entire ventral aspect of the body, including the neck, is exposed (Fig. 1.12B). Hemorrhages of the musculature, if present, can be detected at this stage.

Either of two procedures is now used to expose the viscera. The poultry shears are used to cut through the abdominal wall transversely midway between keel and vent and then through breast muscles on each side (Fig. 1.12C). Bone shears are used to cut the rib cage and then the coracoid and clavicle on both sides (Fig. 1.12D). With some care, this can be done without severing the large blood vessels. The process may also be done equally well in reverse order, cutting through the clavicle and coracoid and then through the rib cage and abdominal wall on each side. The sternum and attached structures can now be removed from the body and laid aside. The organs are now in full view and may be removed as they are examined (Fig. 1.12E,F).

If a blood sample has not previously been taken and the bird was killed just prior to necropsy, a sample can be promptly taken by heart puncture before clotting occurs. Large veins leading into the leg may be incised, allowing blood to pool in the inguinal region for subsequent collection.

Laboratory Procedures

Bacterial Cultures

If gross lesions indicate bacterial cultures are needed, they can be made from unexposed surfaces of the viscera without searing the surface. If contamination has occurred, the surface of the organs should be seared with a hot spatula or other iron designed for that purpose before inserting a sterile culture loop. Care must be taken not to sear and heat the tissue excessively. It is often desirable to transfer large tissue samples aseptically to a sterile petri dish and take them to the microbiology laboratory for initial culture in cleaner surroundings.

Respiratory Virus Isolation

If a respiratory disease is suspected and virus culture or bird passage is desirable, an intact section of lower trachea, the bronchi, and upper portions of the lungs is removed aseptically with sterile scissors and forceps and transferred to a sterile container. Other tissues (air sac tissue) can be added aseptically to the sample or transferred to other sterile containers for separate study.

The trachea can now be incised; if exudate is present, it can be added to the preceding collection or saved in separate vials. Similar procedures can be followed for initial virus isolation from various parenchymatous organs.

Salmonella Cultures

All other visceral organs should be examined for abnormalities (microabscesses, discoloration, swelling, and friability). If abnormalities are observed, inoculum from the affected tissues should be transferred to suitable solid or liquid media for culture before the intestinal tract is opened. Once opened, gross contamination of other organs with gut contents is almost certain to occur. If *Salmonella* infection is suspected, selected sections of the gut are removed with sterile forceps and scissors and placed directly into a sterile petri dish for later culture. For routine examination, a single section comprising the lower ileum, proximal portions of the ceca and cecal "tonsils," and proximal portion of the large intestine may be used. All are minced or ground aseptically to produce an inoculum. Additional areas of the intestinal tract or tissues of other visceral organs may be added to the gut collection or cultured separately. Alternatively, sterile swabs may be used to obtain samples from the exposed gut lining for *Salmonella* cultures. See Chapter 2 of *A Laboratory Manual for Isolation and Identification of Avian Pathogens* (64) for detailed culture technique.

Gross Necropsy

After necessary cultures have been collected, a thorough gross examination of all tissues should be performed. Enlargement of the liver, spleen, and kidney should be evaluated. A clear indication of hepatomegaly is rounded liver margins. The intestine may be examined for inflammation, exudates, parasites, foreign bodies, malfunctions, tumors, and abscesses. The various nerves, bone structure, marrow condition, and joints can now be examined. The sciatic nerve can be examined by dissecting away the musculature on the medial side of the thigh. Inside the body cavity, the sciatic plexus is obscured by kidney tissue. These nerves can best be exposed by scraping away the tissue with the blunt end of a scalpel. Nerves of the brachial plexuses are easily found on either side near the thoracic inlet and should be examined for enlargement. Examination of vagus nerves in their entirety should be made; otherwise, short enlargements may be missed.

The ease or difficulty with which bones can be cut with the bone shears is indicative of their condition. The costochondral junctions should be palpated and examined for enlargement ("beading") and the long bones cut longitudinally through the epiphysis to examine for abnormal calcification. Rigidity of the tibiotarsus or metatarsus should be tested by bending and breaking to check for nutritional deficiency. A healthy bone will make an audible snap when it breaks. Bones from a chicken deficient in vitamin D or minerals may be so lacking in mineral elements that they can be bent at any angle without breaking.

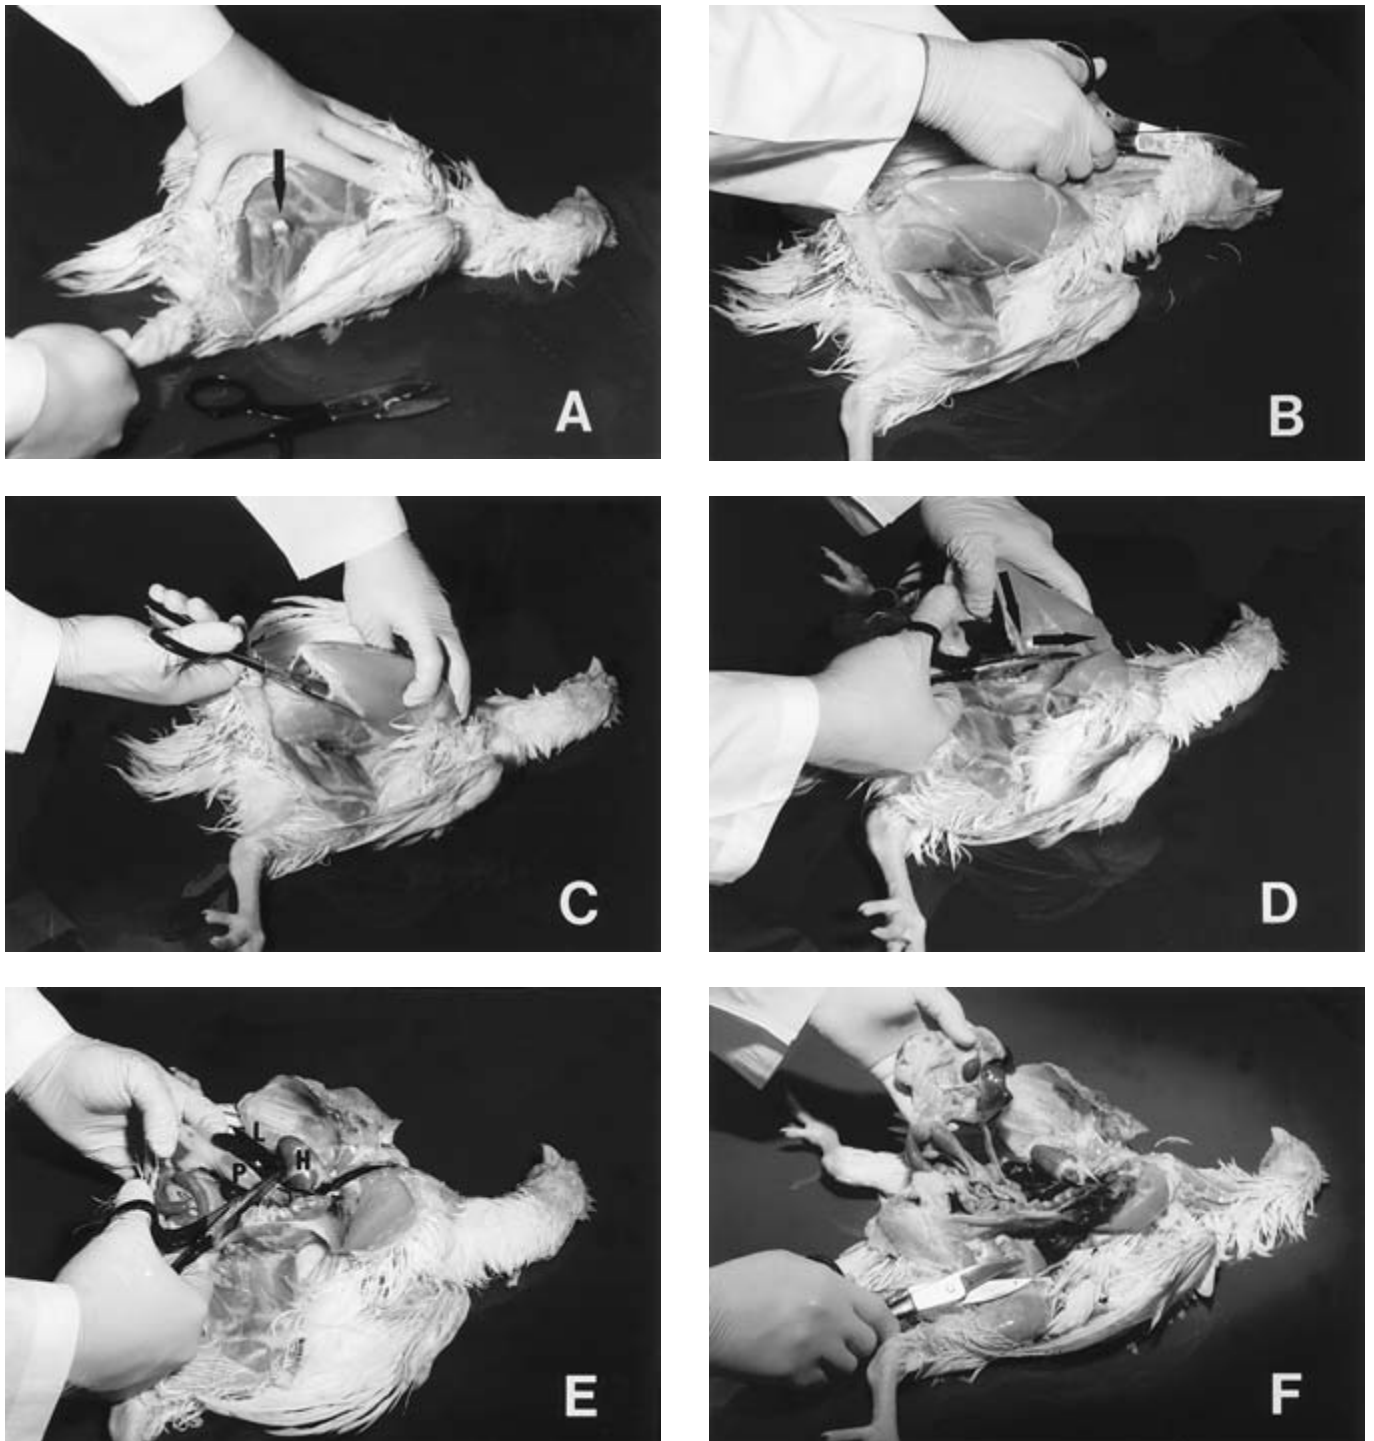
Joint exudate, if present, can be removed after first plucking the feathers and searing the overlying skin with a hot iron. After searing, the skin may be incised with a sterile scalpel and exudate removed with a sterile inoculating loop or swab. Paranasal sinus exudates can be removed and examined in a similar manner.


Fig. 1.12. Each pathologist will develop his/her own systematic technique for conducting a necropsy. A sturdy pair of poultry shears is usually sufficient to conduct a necropsy. Other instruments such as scissors, forceps, and scalpel may be helpful in collecting small or delicate samples. A knife may be needed to cut through joints and bone. The illustrated technique will aid the beginner. A. The skin and fascia between the leg and abdomen are cut, and the legs are pulled and twisted to disarticulate the head of the femur (arrow) from the hip. B. The skin from the vent to the beak is incised and reflected. C. The body cavity is entered at the ventral tip of the sternum. The incision is made at the margin of the pectoral muscle and continues through 2–3 ribs. A similar incision is made on the opposite side of the breast. D. The shears are reoriented (arrows), and the incision is continued through bone and muscle to the thoracic inlet. The breast is broken over to the opposite side (or removed) exposing the viscera. At this point of the necropsy, microbiological samples are collected. E. The intestinal viscera are freed by cutting through the esophagus and vessels of the liver just anterior to the proventriculus and liver. Heart (H), liver (L), and proventriculus (P) are indicated. F. The intestines can be removed by gentle traction, which tears mesenteric and air sac attachments. The lungs, heart, and kidneys remain in the body cavity for later examination.

Exposure and Removal of Brain

Removing the intact brain is not easy, since meningeal layers are attached firmly to bony structures in some places. The following technique can be performed quickly and is satisfactory for examination and removal of the brain in most instances.

Remove the head at the atlanto-occipital junction and remove the lower mandible. Sear the cut surface and trim away excess loose tissue. Reflect the skin forward over the skull and upper mandible and hold it firmly in that position with one hand. Sterile instruments should be used for the succeeding steps if a portion of the brain is desired for animal inoculation, virus isolation, or fungal or bacterial culture.

With the sterilized tips of heavy-jawed bone shears or strong surgical scissors, nip just through the bone to the cranial cavity on both sides of the head, beginning at the occipital foramen and proceeding forward laterally to the midpoint at the anterior edge of the cranial cavity (Fig. 1.13A). Lift off the cut portion of bone and expose the entire brain (Fig. 1.13B).

If a portion is needed for culture or animal inoculation (e.g., avian encephalomyelitis virus suspect) and also one for histopathologic examination (e.g., vitamin E deficiency), cut the brain medially from anterior to posterior along the midline with a sharp, sterile scalpel blade. With sterile, sharp curved scissors, cut the nerves and attachments carefully from one of the brain halves while the head is tipped upside down, so that the loosened portion falls into a jar of formalin as it is freed (Fig. 1.13C). The second half can now be removed aseptically (but without concern for preservation of tissue structure) to a sterile petri dish or sterile mortar and pestle. Be careful not to contaminate brain tissue intended for virus isolation with instruments that have been in contact with formalin. The separate halves may also be removed in reverse order (Fig. 1.13D). If all of the brain is required for either purpose, proceed with proper precautions for the purpose intended. If the brain is destined only for sectioning, it may be fixed *in situ* and then removed. Large brain portions should be incised longitudinally to permit good penetration of fixative.

Tissues for Histopathologic Examination

Frequently, stained tissue sections are needed. The quality of the slide is no better than the quality of the specimen and the care taken to preserve it. For good preservation, the tissue pieces from killed birds should be saved immediately after death, especially brain and kidney tissues, which deteriorate rapidly. Specimens should be small to allow quick penetration of fixative, gently incised with a sharp scalpel or razor blade to preserve tissue structure, and preserved in 10 times their own volume of 10% formalin or other fixative. Bone pieces should be sawed with a sharp bone saw unless thin or soft enough to cut with scissors or scalpel. After proper labeling and dating, they should be sent immediately to the processing laboratory.

Lung tissue usually floats on the surface of the fixing solution because of trapped air. Satisfactory fixation can be accomplished by placing absorbent cotton over the tissue, which serves to keep it immersed. Methods to exhaust air from air spaces in lung tissue by creating a vacuum over the fixative can be used but are less satisfactory and may result in artifacts.

After fixing, bone tissue must be decalcified by immersion in a decalcification solution made by mixing equal parts of aqueous 8% hydrochloric acid and aqueous 8% formic acid (50). Decalcification typically takes 1–3 days, the length of time depending on the size and density of the bone sample.

If eye tissue is to be saved for sectioning, the whole eye should be removed and all ocular muscles trimmed off the globe to allow for rapid penetration by the fixative.

Any tissue held too long in formalin fixative becomes excessively hard. If processing is to be delayed, tissues should be transferred to 70% alcohol after 48 hours in fixative. Textbooks on histologic techniques (49, 50, 65) should be consulted for detailed procedures.

Progressive Examination Hints

The following procedures during the course of necropsy may be helpful to the beginner in checking for some commonly encountered diseases. They are not intended as definitive diagnostic methods. To arrive at a diagnosis, the student and beginning diagnostician must refer to the characteristic signs and lesions, diagnostic procedures, and characteristics of the infectious agent discussed under the specific diseases in succeeding chapters, and also to the manual, *Isolation and Identification of Avian Pathogens* (64).

Coccidia. Observe and note the subserosa before incising the intestine. Make wet mount smears of mucosal scrapings from various segments of the intestine and cecal contents and examine directly under the microscope for suspended oocysts and merozoites and stages undergoing development in epithelial cells (tissue stages).

Other Protozoa. Make wet mounts of affected areas, adding a little warm physiologic saline solution if necessary to provide fluid, and examine under a microscope for hexamita, histomonads, and trichomonads.

Capillarids and Ascarid Larvae. Collect mucous exudate and deep mucosal scrapings and press into a thin layer between two thick pieces of plate glass. Examine before a strong light or under low-power magnification for the presence of parasites. Under magnification, look for bi-polar, lemon-shaped eggs in the female capillarids.

Fungi. Make wet mount smears of scrapings of affected areas and add 20% sodium or potassium hydroxide. Digest with frequent warming for 15 minutes or more and examine under high-power magnification for mold hyphae.

Campylobacter. Examine fresh bile wet mounts under dark-field or phase illumination. Only positive findings may have significance.

Bacteremia and Blood Parasites. Make fresh mounts, preferably with citrated blood, and examine under light- and dark-field illumination for viable organisms. Make fresh blood smears
Fig. 1.13.   With a little practice, the brain can be removed with a minimum of trauma. A. Incise bone all the way around the periphery of the cranial cavity with heavy bone shears. B. Remove loosened portion of the bony skull. C. Incise brain longitudinally with sterile, sharp scalpel and remove one-half for sterile culture technique. D. Remove second half by dropping it into 10% formalin for histologic techniques.

and air dry for staining by Giemsa's, Gram's, Wright's, or other method.

Exudates. If infectious coryza is suspected, make thin smears of clear nasal or sinus exudate for staining by Giemsa's, Gram's, methylene blue, or other method. Inoculate appropriate media or susceptible chickens for isolation of the organism.

Abscesses. Select appropriate culture media suitable for the growth of a variety of infectious organisms that may be suspected of causing the abscess. Sear and incise the surface of the abscess and inoculate culture media with the extracted material, using a sterile inoculating loop or swab. Make smears from the abscess on clean glass slides, diluting with a drop of water if the material is too thick. Air dry and flame slides and make Gram's, acid-fast, or any other stain as desired.

Embryo Inoculation for Virus Isolation. For routine virus isolation, centrifuged and/or filtered fine-ground suspensions of sus-

pect tissues (trachea, bronchi, lung, liver, spleen, kidney, brain, bone marrow) or body fluids and exudates may be inoculated into the chorioallantoic cavity and yolk sac and onto the chorioallantoic membrane (CAM) of embryos at various stages of incubation. See discussions of the specific diseases for virus culture techniques. Also see *A Laboratory Manual for the Isolation and Identification of Avian Pathogens* (64) for selection of the proper age of embryo and route of inoculation for various disease agents as well as detailed inoculation procedures. Embryos from specific-pathogen-free dams should be used for culture to be sure that any agent recovered originated in the inoculum and not in the dams that produced the eggs. Equally important is assurance that negative cultures are due to absence of infectious agents in inoculum, rather than to interference of passive antibodies in eggs. Because the purpose of virus isolation is to determine which may be present, it is advisable to inoculate various ages of embryo by the various routes. Several blind passages may be necessary before the culture attempt can reasonably be considered negative. A simple technique that does not require dropping the CAM has been described (29).

The CAM may be drawn away from the shell (dropped) to facilitate inoculation. First, drill or punch a small hole in the shell over the air cell and then slowly drill or punch a second hole through the shell at a point on the side over the embryo. Applying mild suction through a rubber tube over the hole into the air cell causes the CAM to drop away from the inner shell membrane under the second drilled hole. A bright candling light should be used while suction is applied to determine when the CAM has dropped.

For yolk sac inoculation, the needle can be directed through the air cell and directly to the center of the egg. Some yolk may be withdrawn into the syringe to verify the location of the needle.

For chorioallantoic cavity inoculation, a hole is drilled over the edge of the air cell at a spot previously marked with the aid of a candling light. The cavity lies adjacent to the shell and can be easily penetrated from that point. All holes should be sealed with suitable sterile material before reincubating.

Cell culture procedures are becoming more common in diagnostic laboratories. Technicians with this capability may inoculate the cell cultures directly with tissue extracts or body fluids, or they may use embryos for primary screening and transfer embryo fluids or extracts to cell culture for further study and identification.

Disposing of the Specimen

If a disease infectious for humans is suspected, the carcass should be autoclaved, incinerated, or otherwise rendered incapable of causing infection to laboratory or other personnel. Similar precautions should be followed during disposal of carcasses infected with a virulent poultry pathogen that presents a health hazard to the industry. The necropsy area, instruments, and gloves should then be cleaned, washed, and disinfected.

Communication

Flock owners are not always interested in technical data. They want to know what the problem is and what should be done to correct it and/or how to prevent reoccurrences. Sometimes technical data are necessary to clarify the diagnosis, but the report should be in language and terms that they will understand. A minimum of complicated scientific and medical technology words should be used. When medical terms are apt to be confusing, they should always be explained in lay terms.

The report should include the necropsy findings, results of laboratory studies, (histopathologic, serologic, and cultural), diagnosis (temporary or final), and conclusions and recommendations. The owner is seeking professional advice. The veterinarian should give his/her best conclusions and recommendations based on the facts available. A verbal report or telephone call to the flock owner, manager, or service worker soon after completion of the necropsy and initial tests is highly advisable. A tentative diagnosis can be offered pending further confirmation.

Antimicrobial Therapy

Dennis P. Wages

Introduction

Even though the trend in the poultry industry is toward preventative disease programs and improved management practices, the occurrence of bacterial diseases is not uncommon. Medicating poultry has been performed by the industry for many years and will continue to play a role in successful commercial production. Because of a limited spectrum of antibiotics available in the United States, we must ensure that when we do treat, we use information and procedures that best place us in a position to be as successful as possible. When initiating medication use, we must consider all aspects of therapy to ensure the best possible outcome.

The key to antibiotic treatment success is related to many principles and includes identification of the pathogen; basing antibiotic selection on sensitivity results; effective antibiotic concentrations present at the infection site; proper dosing and route of administration; and responding to management needs. Antibiotic therapy should be used as a tool to manage disease outbreaks and not to be used as a crutch for deficiencies in management or nutrition. Because many of the diseases that occur in poultry are secondary to other primary infections and conditions, identifying the primary cause of infection is paramount in modern poultry production to minimize any overuse of antibiotics.

Overall, specifics regarding antibiotic therapy in poultry in the literature are lacking. Much of the discussion in this chapter is based on the clinical experience of the author. In this chapter, routes of medication, properties of antibiotics, and general antibiotic use considerations are discussed. General principles established and supported by the American Veterinary Medical Association regarding judicious therapeutic antimicrobial use are also listed for reference in antibiotic use protocols.

Routes of Medication

Three routes exist for administering antibiotics in poultry: injection, water, and feed. By far, the most common treatment route is by water. It provides rapid blood levels in diseased birds and is administered easily for mass application. Water therapeutic intervention can be performed for a minimum of 3 and up to 7 days. Premature withdrawal or change in therapeutic water medication should be done based on only clinical assessment, diagnostic sampling results, and/or a 2–3 fold rise in mortality. Feed grade antibiotics are used therapeutically on a limited basis. Feed grade antibiotic therapy provides excellent follow-up therapy after an initial water treatment and can be used for long-term therapy. Problems related to feed grade antibiotic use include delayed therapeutic blood levels, and diseased birds may have decreased feed consumption. In the United States, feed grade antibiotics can be used only in accordance with the Feed Additive Compendium, published in cooperation with the Animal Health Institute (2). Extra label antibiotic use in feed is prohibited under the Animal Medicinal Drug Use Clarification Act of 1996 (AMDUCA)(1). Feed grade antibiotics are more commonly used in poultry for disease prevention, such as necrotic enteritis control. Injectable antibiotics occasionally are used in breeders in an extra label manner, but more commonly are used either *in ovo* or injected at one day of age for bacterial omphalitis control. Any extra label use of injectable antibiotics is defined and covered under AMDUCA (1).

Antibiotic Considerations

Historically, poultry have been treated through the water based on a volumetric approach (i.e., based on a known concentration of antibiotic in the drinking water, ppm or mg/gal). This volumetric

dosing is generally described on product labeling. Volumetric dosing is performed by mixing a stock solution of concentrated antibiotic at the manufacturer's recommended instruction and delivering the antibiotic through a proportioner at the rate of 1 ounce of the antibiotic stock solution per gallon of drinking water. This dosing regimen has been in place throughout the world for years. However, any increase in water consumption will, increase the cost of medication and potentially result in residues and/or toxicity. Likewise, decreased water consumption and subsequent decrease in antibiotic uptake usually are interpreted as lack of antibiotic efficacy. Most other animals, including those used for food, are treated based on body weight. No present evidence suggests that this method of treatment would not be successful in poultry. Except for the tetracycline class of antibiotics (dosed at 55mg/kg), mg/kg dosing is not well documented with antibiotics for poultry. The inconsistency in water consumption makes it imperative that we look at more scientific approaches to antibiotic treatment in poultry. We must realize, however, with current regulatory issues in place, most dosing based on body weight is considered extra label and requires a veterinary prescription in the United States (1). Also, antibiotic withdrawal times are based on labeled indications, which may not be based on mg/kg of body weight. Therefore, if dosages other than labeled recommendations are used, an extended withdrawal time may be necessary.

Water consumption is affected by water quality, which includes mineral content, pH, and nitrate content. Increased combinations of magnesium, sulfates, and chlorides in water can produce laxative effects and increase water consumption. It is well recognized in the poultry industry that high sodium/salt levels will increase water consumption (5). When the pH of water falls below 4, water consumption tends to decrease. Poor weight gain associated with high nitrate levels above 50 ppm has been associated with decreased water consumption and overall poor performance (5).

Feed ingredients such as protein sources, sodium/salt content, and energy density also affect water consumption. Fish meals, bakery by-product meals, and certain phosphorous sources can tend to increase water consumption based on sodium and/or salt content or the presence of biogenic ammines. Different protein sources and shipments can be inconsistent in their nutritional analysis and result in variations in water consumption. Water consumption is also impacted by environmental temperature. Most water consumption charts are based on an environmental temperature of 70°F. For every 1° increase in environmental temperature, a corresponding increase occurs in water consumption of approximately 4%. Therefore, for every 5-degree increase in temperature, a corresponding 20% increase in water consumption can be anticipated. However, when environmental temperatures are elevated above 90°F, overall activity of the birds tends to decrease and water consumption may be impacted.

All of the preceding information supports the conclusion that birds might best be treated based on body weight and not on water consumption alone.

Antibiotics and Antibiotic Properties
Each antibiotic possesses properties that allow it to have advantages and/or disadvantages compared to other antibiotics. These properties include their spectrum of activity and mechanism of activity. A bactericidal drug kills the bacteria; whereas a bacteriostatic drug inhibits the replication of the bacteria and requires a functional immune system (defense mechanism) to eliminate the bacteria from the body. Hence, a bacteriostatic antibiotic may have limited value in a chronic infection because of the duration of the illness and impairment of the body's defense mechanisms. A bactericidal product can be used in acute and/or chronic infections. Antibiotics are either broad in their spectrum of activity or narrow. That is, they may have an antibacterial spectrum against either gram-positive bacteria, Gram-negative bacteria, or bacteria in both classes. As a rule of thumb, most broad-spectrum antibiotics are bacteriostatic, and many of the narrow spectrum antibiotics are usually bactericidal. Exceptions to this rule include high doses of erythromycin and the tetracyclines, which are broad in spectrum and bactericidal in their action.

A limited number of antibiotics are cleared for use in poultry. Any antibiotic not specifically labeled for use in the species for the disease in question (indication) should be used by prescription only and be recognized as an extra label drug use. In the United States, this extra label drug use is also defined under the AMDUCA (1). Extra label drug use is permitted only when prescribing antibiotics in water and as injections. It does not allow the addition of antibiotics, with or without a prescription, in feed if not approved as listed in the *Feed Additive Compendium* (2). Likewise, illegal drugs (chloramphenicol, nitrofurazone, nitroimidazoles, etc.) cannot be used in an extra label manner. The following drugs are approved for use in poultry the United States. Action, spectrum, and approved route of administration are presented in Table 1.4.

Mixing Antibiotics (Compounding)
Many times, when faced with an acute disease outbreak, the combination of antibiotics is considered to broaden the scope of antibacterial activity. Mixing antibiotics, which are not approved for use in combination, constitutes a new animal drug in which noninterference, safety, and residue studies have not been performed and/or approved by the Food and Drug Administration. At this time, this policy deals only with antibacterial agents and does not apply to vitamins, minerals, and electrolytes. Mixing antibiotics not demonstrated to be safe and effective could potentially change the amount of individual drug absorbed and, thus, alter the excretion rate of the drug from the body (6). This excretion rate change may result in toxicity or potential illegal drug residues. Likewise, mixing drugs may affect the absorption to the extent that efficacy is negatively impacted.

Antibiotics that are weak acids should not be mixed with weak bases. Weak acids include the sulfonamides and penicillin. Weak bases include erythromycin, streptomycin, gentamicin, neomycin, tetracyclines, and lincomycin. Antibiotics shown to be more effective in basic solutions (>pH 7) include the sulfonamides and penicillin (6). Erythromycin and tetracyclines are more effective in acidic solutions (pH 6–7) (6). Specific interactions of antibiotics used in poultry have been reported (6). The addition of vitamins and electrolytes may affect the pH of antibiotic stock solutions. Penicillin should not be mixed with vitamin preparations.

Table 1.4. Action, spectrum, and approved route of antimicrobial administration in poultry[A].

Antibiotic	Action	Spectrum	Route of Administration
Bacitracin	Cidal	Gram +	Feed/water
Ceftiofur	Cidal	Gram + & –	Injection
Chlortetracycline	Static	Gram + & –	Feed/water
Oxytetracycline	Static	Gram + & –	Feed/water
Tetracycline	Static	Gram + & –	Water
Erythromycin	Static	Gram + & –	Feed/water
Gentamicin	Cidal	Gram + & –	Injection
Lincomycin	Static	Gram + & –	Feed/water
Lincomycin/spectinomycin	Static	Gram + & –	Water
Neomycin	Cidal	Gram –	Feed/water
Neomycin/oxytetracycline	Cidal	Gram + & –	Feed
Novobiocin	Cidal	Gram +	Feed
Penicillin	Cidal	Gram +	Feed/water
Spectinomycin	Static	Gram + & –	Water/injection
Streptomycin	Cidal	Gram –	Water
Sulfadimethoxine	Static	Gram + & –	Water
Sulfadimethoxine/ormetoprim 5:1	Static	Gram + & –	Feed
Sulfaquinoxaline	Static	Gram + & –	Water
Tylosin	Static	Gram + & –	Feed/water
Virginiamycin	Static	Gram +	Feed
Bambermycin[B]	N/A	N/A	Feed

[A]Data included is an accurate reflection of approved antimicrobials in the United States at the time of publication.
[B]Bambermycin is a feed additive having no specific antibacterial action.

Chlortetracycline and penicillin have been shown to be antagonistic in combination.

Treatment Records

With any treatment regimen, accurate records should be maintained. An important part of this record system is to collect bacterial cultures and conduct antimicrobial susceptibility testing. This data will ensure that therapy decisions are correctly directed and will provide a baseline for the recognition of the development of antimicrobial resistance in the future. Furthermore, a record of all antibiotic successes and failures will help to guide future antibiotic therapy decisions.

Antibiotic Resistance

Interest and concern have increased regarding the administration of antibiotics in food-producing animals and its emergence of populations of bacteria that are resistant to currently available antibiotics. From the poultry health perspective, the concern is that poultry pathogens will develop resistance to currently approved antibiotics. From the human health perspective, there is concern that food-borne bacteria that cause illness in humans will be resistant to antibiotic treatment or that food-borne bacteria will transfer resistance to human commensal or pathogenic bacteria and that these organisms will likewise be refractory to treatment. Both concerns are real and should not be minimized as classes of antibiotics that are used in poultry are also used in humans. Research is needed in this area to determine whether the use of antibiotics in poultry has played a role in the development of an-

tibiotic resistance in humans. All parties involved in using antibiotics should be aware of this concern and use antibiotics as judiciously as possible. The bacteria of concern from a human health standpoint are *Campylobacter* spp., *Salmonella* spp., and *Enterococcus* spp. None of the previously named bacteria are of significant clinical concern in poultry flocks (i.e., very few clinical diseases are caused by them). However, we must be aware that any time antibiotic treatment is performed, these organisms are exposed to the antibiotic, and resistance can develop as a consequence of this exposure.

Antibiotic resistance is a natural phenomenon that occurs when bacteria are exposed to antibiotics but also occurs without antibiotic exposure in the case of inherent resistance (4). The use of antibiotics in animals and humans has accelerated the rate of resistance development by increasing selection pressure placed against both pathogenic and nonpathogenic bacteria. We must remember that when poultry are treated with antibiotics, it affects both target and nontarget bacteria, and resistance in both classes of bacteria may develop. Resistance development occurs by the exchange of extra-chromosomal DNA called plasmids and through genetic or chromosomal changes within the bacteria. Plasmid-mediated resistance can occur within or between the same or different populations of bacteria (4).

Two basic methods are used in determining the susceptibility of bacteria to antimicrobials: disk diffusion and dilution (7). The disk diffusion method is most commonly used in diagnostic laboratories. The dilution method commonly is used so that the antimicrobial concentration can be diluted serially to provide mini-

mum inhibitory concentrations (MIC) for individual organisms against antimicrobials tested. Both disk diffusion and dilution methods are *in vitro* procedures performed in the laboratory. Host interactions, drug pharmacokinetics, and other practical aspects of antimicrobial therapy must be considered for the veterinarian to predict the *in vivo* or animal response to a particular disease antimicrobial therapy. Both methods should be standardized for reproducibility and confidence in the results (7).

Because antibiotic resistance is one consequence of antibiotic use, we must ensure the judicious use of antibiotics in poultry. National and international organizations such as the American Veterinary Medical Association (AVMA) and World Health Organization (WHO) have supported judicious therapeutic antimicrobial (antibiotic) principles for use in all animals, including food animals such as poultry. These principles, presented in the following section, are approved by the AVMA and have been applied to poultry to be used as guidelines to optimize therapeutic efficacy while minimizing the development of resistance to protect both animal and public health. After each principle is listed, a discussion of its importance in poultry follows.

Judicious Use Principles for Poultry

The principles enumerated here should be incorporated into the thought process when the decision is made to use therapeutic antimicrobials in our poultry flocks (3).

1. Preventive strategies, such as appropriate husbandry and hygiene, routine health monitoring, and immunization, should be emphasized.

    Minimizing antimicrobial use through disease prevention is the fundamental principle that has historically led to the success of poultry companies. Farms using all-in-all-out production minimize the presence of multiple ages of flocks on farms to help in disease prevention. Biosecurity programs in place on poultry farms prevent the introduction of diseases. The use of coveralls, boots, and head coverings can prevent the introduction and spread of disease within and between farms. Preventative disease programs based on vaccination strategies reduce disease outbreaks in poultry. The poultry industry is the leader in novel vaccination procedures for vaccination of large numbers of animals. Breeder and meat production flocks are monitored for protective response to vaccinations. Serological monitoring of disease exposure forms the basis of our strategic vaccination programs.

2. Other therapeutic options should be considered prior to antimicrobial therapy.

    The poultry industry approaches the treatment of diseases with antimicrobial agents very seriously. Because of the cost of disease treatment with antimicrobials, therapeutic antimicrobial intervention should be used only as a tool to treat active disease. Management adjustments should be made when disease outbreaks occur by reacting to environmental temperature, ventilation, and litter moisture to minimize the impact of any disease condition in flocks. Supportive therapy with vitamins and electrolytes can be used in some cases of disease outbreaks. All of the preceding strategies should help in preventing the use of antimicrobials for treatment.

3. Judicious use of antimicrobials, when under the direction of a veterinarian, should meet all requirements of a valid veterinarian-client-patient relationship.

    Poultry veterinarians, in integrated companies, should closely monitor antimicrobial use in their poultry flocks. They should maintain close contact with service technicians and managers related to the use of antimicrobials. Veterinarians are involved in the training of all individuals who will ultimately be following veterinary directions for antimicrobial use. Antimicrobials should be used always under the direction and knowledge of the company veterinarian or veterinary consultant.

4. Prescription, Veterinary Feed Directive, and extra label use of antimicrobials must meet all the requirements of a valid veterinarian-client-patient relationship.

    At the present time, no feed additives are approved for prescription or by feed directive in poultry. If these products are approved in the future, strict compliance with regulations will be done with the same policies set for other antimicrobial use and under the guidelines of AMDUCA (1).

5. Extra label antimicrobial therapy must be prescribed only in accordance with the Animal Medicinal Drug Use Clarification Act amendments to the Food, Drug, and Cosmetic Act and its regulations.(1)

    Veterinarians in integrated poultry companies should strive to use antimicrobials at labeled indications and dosage. When prescribing extra label use of antimicrobials, it must always be performed in compliance with AMDUCA (1).

6. Veterinarians should work with those responsible for the care of animals to use antimicrobials judiciously, regardless of the distribution system through which the antimicrobial was obtained.

    Veterinarians in the poultry industry are responsible for the production of poultry at the breeder and meat bird level involving multiple complexes in different geographic locations. Veterinarians work closely with service technicians, service persons, and production managers and are in close contact with all individuals responsible for the use of therapeutic antimicrobials. These individuals are trained in disease recognition and medication strategies. The veterinarian, however, will always be responsible for the initiation and evaluation of antimicrobial therapy.

7. Regimens for therapeutic antimicrobial use should be optimized using current pharmacological information and principles.

    Continuing education programs by the American Veterinary Medical Association, the American Association of Avian Pathologists, and technical updates from pharmaceutical technical service veterinarians keep poultry veterinarians and managers up to date on current information regarding antimicrobial use.

8. Antimicrobials considered important in treating refractory infections in human or veterinary medicine should be used

in animals only after careful review and reasonable justification. Consider using other antimicrobials for initial therapy.

Poultry veterinarians recognize the importance of antimicrobial resistance in both human and veterinary medicine. Important antimicrobials used in both poultry and humans are held in reserve to minimize the rate of resistance development.

9. Use narrow spectrum antimicrobials whenever appropriate.

Narrow spectrum, bactericidal antimicrobials are chosen when culture and sensitivity results suggest therapeutic success.

10. Use culture and susceptibility results to aid in the selection of antimicrobials when clinically relevant.

Before antimicrobial therapy is initiated, based on mortality and morbidity, typically affected birds are euthanized and samples taken for bacterial culture and sensitivity. This is common practice in the poultry industry today. The poultry veterinarian uses this information to make informed decisions regarding the appropriate antimicrobial therapy to be initiated. This information is kept as part of the flock and farm history to determine changes in antimicrobial susceptibility patterns on farms.

11. Therapeutic antimicrobial use should be confined to appropriate clinical indications. Inappropriate uses such as for uncomplicated viral infections should be avoided.

Viral, fungal, and other nonbacterial infections are not treated in poultry with antimicrobials. Veterinarians pay special attention to disease outbreaks to determine whether and when antimicrobial therapy is warranted. Every effort is made to address disease outbreaks with other disease management strategies prior to the initiation of antimicrobial therapy. Mortality and morbidity are monitored closely; diagnostic evaluations are performed to confirm bacterial involvement prior to antimicrobial therapy.

12. Therapeutic exposure to antimicrobials should be minimized by treating only for as long as needed for the desired clinical response.

Due to the cost of antimicrobial use in poultry, veterinarians and service technicians closely monitor antimicrobial treatments to minimize antimicrobial therapeutic exposure in flocks. Flocks are treated for the desired clinical response avoiding prolonged use of antimicrobials. Morbidity and mortality are used to base clinical judgments as to duration of therapy.

13. Limit therapeutic antimicrobial treatment to ill or at-risk animals, treating the fewest animals indicated.

In population medicine involving flocks in a disease outbreak, all birds are not infected at the same time with the disease to which antimicrobial therapy is warranted. However, birds in the same house are at risk to the same primary disease. Only birds within the same house, ill, or at risk are treated. Adjacent houses, not clinically affected with disease, are not treated. Cost figures for medication usually are maintained to the one-hundredth of a cent per pound of live weight. If therapeutic antimicrobial intervention is not cost effective, and a low number of birds are infected per house, the cost of treatment usually will dictate that no antibiotics be used at all.

14. Minimize environmental contamination with antimicrobials whenever possible.

Every effort is made to avoid environmental contamination with antimicrobials. The cost of antibiotics generally ensures that the antimicrobial is used specifically in the diseased flock and not introduced into the environment unnecessarily.

15. Accurate records of treatment and outcome should be used to evaluate therapeutic regimens.

Record keeping is an integral part of the integrated poultry industry. Production records including medication costs, evaluation, and outcome are kept and placed in the history of the farm for future reference in determining any changing antimicrobial susceptibility patterns.

Summary

Judicious antibiotic therapy includes proper diagnosis, knowledge of antibiotic properties, dosage, spectrum, interactions, and early initiation of treatment. It is not as simple as offering the drug to a poultry flock. The limited arsenal of drugs available for poultry makes it imperative that we combine an accurate diagnosis with antibiotic knowledge to result in the most cost effective approach to disease treatment.

Chapter 2
Host Factors for Disease Resistance

Introduction

J. M. Sharma

Domesticated and wild birds are vulnerable to many microorganisms that contaminate the environment in which they live. The microorganisms include viruses, bacteria, fungi, and parasites. In confined houses, such as the ones used for intensive rearing of commercial poultry, the concentrations of microorganisms can reach very high levels. Often, these microorganisms are pathogenic and invasive and can cause severe clinical disease or death. The birds manage to survive the microbial challenge primarily because their immune systems provide protection against infection and unrestricted replication of microorganisms. Without effective immunity, the life span of birds would indeed be very short, and commercial poultry production would come to a halt. Because of the importance of immunity in health, the study of the mechanisms of immunity has received much attention within the last few decades, and many pioneering observations have been made that have lead to effective disease-control strategies. One of the most important contributions of immunity to human and animal health has been the development of vaccines that have dramatically reduced the incidence of infectious diseases. Although the avian immune system has not been studied as extensively as that of mammals, important advances have been made. In the first subchapter, a broad outline of the basic elements of the avian immune system is presented. Although great similarities exist between immune mechanisms of the birds and mammals, there are also interesting differences. These differences are identified and briefly described.

In the second subchapter, the role of genetics in regulating immune-mediated resistance to disease is covered. Genetic background of a host determines how the immune response to a given microorganism will evolve, and, ultimately, whether protective immunity will be generated. This is well demonstrated by the great variation that is often observed among individuals within a population in their response to a common disease agent. Some individuals may succumb to infection and die, whereas others may show no phenotypic signs of infection. This wide variation in response to the same agent is attributed to an intrinsic polymorphism of genes that regulate the expression and interaction of various components of the immune system.

Although genetic resistance to a disease is a multigenic trait, in commercial chicken populations, resistance or susceptibility to disease is often attributed to the genes that regulate the major histocompatibility complex (MHC). The MHC encodes a set of cell surface proteins that are necessary for antigen recognition by T cells and, consequently, the capability of T cells to generate specific immunity. The MHC proteins are genetically diverse and polymorphic. Association of specific MHC haplotypes with disease resistance has been exploited by designing breeding programs that select for resistance. Recently, the entire chicken genome has been sequenced, which has provided new opportunities to identify and manipulate genes that control immunity and resistance to disease. The second subchapter provides information on how recent advances in molecular technology have facilitated the study of genetic linkages to disease resistance. This new information is likely to have a significant impact on commercial poultry production.

Avian Immune System

J. M. Sharma

Introduction

The immune system plays a critical role in defending birds against environmental pathogens. The overall organization and mechanisms of immunity in birds are quite similar to those in mammals. Early studies on the bursa and the thymus of chickens provided some of the basic information that led to the identification of the dichotomy of the immune system into B and T cell compartments. The recognition of this dichotomy initiated an era of extensive research on the mechanisms of immunity in mammalian, avian, and amphibian species. This influx of research activity that began about five decades ago continues unabated and is responsible for making immunology one of the fastest

growing branches of biology. Emerging concepts of immune mechanisms are constantly being revised by new information.

The immune system of birds, as of mammals, is complex and includes a number of cells and soluble factors that must work in concert to produce a protective immune response. A properly functioning immune system is of special importance to birds because commercial poultry flocks are raised under intensive rearing conditions. Under such conditions, the flocks are vulnerable to the rapid spread of infectious agents and disease outbreaks. A variety of vaccines must be used, often repeatedly, to protect the flocks against environmental exposure to virulent organisms. The protective efficacy of a vaccine is dependent upon a vigorous immune response against the organism(s) present in the vaccine. If animals are immunosuppressed and respond poorly to a vaccine, the flock health is placed in jeopardy. The understanding of how the immune response is generated is of interest, as is the knowledge of how to protect flocks from stresses that may induce immunosuppression.

This subchapter is not a comprehensive review and is intended to provide a broad overview of selected aspects of the avian immune system. For more detailed information, the reader should consult several books and reviews (17, 18, 28, 35, 81, 85, 87, 101).

Anatomy of the Immune System

The immune cells reside in primary lymphoid organs (PLO) or secondary lymphoid organs (SLO). The thymus and the bursa of Fabricius, respectively, are the PLO where T and B cell precursors differentiate and undergo maturation. The thymus is an elongated, multilobular structure located along the length of both sides of the trachea with some lobes extending into the anterior thoracic cavity (Fig. 2.1A). Thymic lobes are divided into lobules; each lobule has a peripheral cortical area in which lymphocytes are densely packed and a central medullary area in which the lymphocytes are less densely packed (Fig. 2.1B). Bursa of Fabricius is a sac-like extension of the hindgut and is located above the cloaca (Fig. 2.1C). Bursa of Fabricius is organized into follicles, each follicle is filled with lymphocytes. As in the thymus, the lymphocytes are arranged into a peripheral cortex and a central medulla (Fig. 2.1D).

Functional immune cells leave the PLO and populate SLO, the principal sites of antigen-induced immune response. SLO, characterized by aggregates of lymphocytes and antigen-presenting cells, are scattered through the body (Fig. 2.2). Examples of SLO include spleen, bone marrow, gland of Harder (located ventral and posteriomedial to the eyeball), conjunctival-associated (CALT), bronchial-associated (BALT), and gut-associated lymphoid tissue (GALT). Bursa may also serve as SLO. Chickens lack the mammalian equivalent of lymph nodes but have lymphoid nodules along the course of lymphatics.

General Features of the Avian Immune System

An outline of the mechanisms birds use to defend against pathogens is presented in Figure 2.3. Birds have well-developed innate defense mechanisms. Physical barriers such as skin or nor-

mal mucosal microflora prevent pathogens from entering the body. For the pathogens that enter the body, the first line of defense is provided by innate immune mechanisms such as phagocytic cells that include heterophils and macrophages (71), complement (47), and natural killer (NK) cells (25, 89).

Innate Immunity

Macrophages that are scattered extensively in the tissues of the host are the first line of defense against pathogens that cross the physical barriers. These cells phagocytize and destroy the invading pathogens and prevent active infection. Macrophages and dendritic cells, another phagocytic cell present in the tissues, respond to the encounter with the pathogen by secreting cytokines and chemokines that initiate a local inflammatory process. Heterophils and serum proteins accumulate at the site of inflammation in an attempt to localize and destroy the pathogen. The recognition of pathogens by the cells of the innate immune system, such as macrophages, neutrophils, and dendritic cells, is facilitated by the presence of toll-like receptors (TLRs) on their surface (23, 33, 54). TLRs are membrane proteins that recognize common antigenic patterns expressed by many pathogens. The interactions of TLRs on macrophages and dendritic cells induce these cells to produce cytokines and chemokines.

Complement is a heat-labile component present in the normal plasma of birds. The complement system is an important and essential part of defense against bacterial pathogens. The activation of the complement system results in the production of a series of proteins. Some of these proteins bind covalently to bacteria. This binding results in bacterial death or enhanced bacterial phagocytosis and destruction. The complement system can be activated by a number of different pathways. The most commonly known are the classical complement pathway (CCP) and the alternate complement pathway (ACP). In the CCP, the complement system is activated by antibodies bound to the surface of the pathogen. In the ACP, a spontaneously activated complement protein destroys bacteria by attaching to bacterial surface. The knowledge of the avian complement system is far behind that of the mammalian complement system. Some of the important biological and molecular characteristics of the avian complement are listed in Tables 2.1 and 2.2.

NK cells are non-T, non-B lymphoid cells that are cytotoxic for virus-infected and tumor cells. These cells are present in normal animals and do not need to be induced by immunization. Avian NK cells express surface CD8$\alpha\alpha$ homodimer and are large granular lymphocytes, morphologically similar to their mammalian counterparts. The NK cytotoxic activity is not restricted by the MHC. In chickens, intestinal epithelial cells are particularly rich in NK cells, although these cells are also present in spleen and peripheral circulation (25). A monoclonal antibody that reacts specifically with intestinal NK cells has been described (25). Studies on the distribution of NK cells suggest that precursors of these cells originate in the bone marrow and migrate to spleen and intestinal epithelium where they acquire functional maturation. The *in vivo* NK cell expression in chickens varies with the age, genetic background, exposure to infectious agents, or presence of tumors (89).
Fig. 2.3.   Physical and immunological mechanisms of defense against pathogens in birds.

NK cells and certain other effector cells may also induce target cell lysis if the target cells are coated with antibody. The antibody molecules present on the surface of target cells interact with Fc receptors present on NK cells, and this interaction triggers the cytotoxic attack against the target. The destruction of an antibody-coated target cell is called *antibody-dependent cellular cytotoxicity* (ADCC). The ADCC activity contributes to host defense and has been detected in several avian species (90).

Pathogens that cannot be denied entry by physical barriers or controlled by innate immune defense mechanisms initiate a specific immune response (adaptive immunity). *Adaptive immunity* is highly specific to the agent that stimulates its development whereas nonadaptive or innate immunity is nonspecific. Cells mediating specific immunity retain "memory" of their encounter

with the pathogen even after the pathogen has been cleared from the body and detectable immune response has subsided. Memory cells respond to the subsequent exposure to the same pathogen by initiating a rapid and highly effective immune response. Booster vaccinations, used routinely in poultry, take advantage of this memory response.

Adaptive immunity is mediated by a variety of cells, the most important of which are T cells, B cells, and macrophages. T cells, the principal cells of cell-mediated immunity (CMI), recognize foreign antigens after the antigens (such as microorganisms) have been processed by antigen-presenting cells (APC). Macrophages, dendritic cells, and B cells are among the most important APC. The APC generally break down complex antigens and present to T cells small fragments of the antigen in conjunction with the

MHC molecules. T cells and the APC must share the same MHC before T cells can recognize and react to the antigen being presented.

The MHC molecules are glycoprotein receptors coded by the genes within the MHC. The chicken MHC, also referred to as the B locus, is much smaller than the mammalian MHC and contains only 19 genes in comparison with the human MHC that contains more than 200. The organization of the chicken MHC is also quite different from that of the mammalian MHC (40). The B locus consists of at least 3 loci: BF that encodes class I antigens, BL that encodes class II antigens, and BG that encodes class IV antigens. Class I and class II molecules are highly polymorphic and are critical for antigen presentation by the APC. The BF molecules (class I antigens) are present on a wide variety of nucleated cells including erythrocytes. The expression of the BL molecules (class II antigens) is much more restricted. These molecules are expressed on macrophages, dendritic cells, monocytes, B cells, and activated T cells.

Whereas T cells require that the antigen be processed before it can be recognized, the recognition of an antigen by B cells is not dependent on prior processing. B cells can recognize the antigen as it interacts with immunoglubulins that project from the cell surface. B cells are responsible for humoral immunity and produce antibodies against the antigen.

Most microorganisms stimulate both CMI and humoral immunity although the type of immunity most critical for defense may vary with the microorganism. Some of the important features of the CMI and humoral immunity are discussed in the following section.

Adaptive Immunity

Cell-mediated Immunity (CMI)

T cells are the most important cells of CMI. Many subpopulations of T cells with diverse functions have been identified in chickens. These subpopulations express unique surface antigens that can be detected with monoclonal antibodies. Table 2.3 shows a list of monoclonal antibodies that can recognize some of the surface markers of chicken T cells. This table will undoubtedly undergo periodic revisions as new antibodies are developed.

As in mammals, avian T cells have two surface receptors that bind antigens: T cell receptor (TCR)αβ or TCRγδ. Chickens have a higher proportion of γδ T cells than mice or humans and may reach 30–50% of circulating lymphocytes (93). Both types of TCRs (αβ and γδ) are closely associated with another molecule called CD3, which is present on all T cells. Only the TCR portion of the TCR-CD3 complex interacts with the antigen. The CD3 molecule, which is composed of a complex set of proteins, transmits to the cell the signal of antigen/TCR interaction. The TCR molecules are diversified by rearrangement of single V, D, and J segments derived from multiple polymorphic copies of genes. The chicken TCRαβ locus is different from that of mammals and contains two Vβ families: $V_{\beta1}$ and $V_{\beta2}$ (9).

Surface molecules CD4 and CD8 differentiate two important functional subsets of T cells. CD4 is expressed on the surface of helper T (T_H) lymphocytes, whereas CD8 is expressed on the sur-

face of cytotoxic T lymphocytes (CTL). Great interspecies variation exists in the relative proportions of circulating CD4 and CD8 cells.

Helper T (T_H) Cells
T_H cells (CD4+ cells) recognize processed exogenous antigens in conjunction with MHC II and other costimulatory molecules. When the TCR on the surface of T cells comes in contact with the specific antigenic fragment on the surface of the APC, T cells become activated and proliferate and initiate an immune response directed against the antigen.

Studies in mammals have shown that antigen-induced activation stimulates T_H cells to differentiate into two types of effector populations: T_H1 and T_H2. Differentiation of T_H cells into T_H1 or T_H2 populations is determined by the nature of the stimulating antigen and is mediated by soluble proteins called *cytokines* (see below). Intracellular antigens such as those accumulating within macrophages, dendritic, and other cells stimulate the differentiation of T_H1 cells, whereas extracellular antigens stimulate the differentiation of T_H2 cells. T_H1 effector cells promote proliferation of CD8+ CTL, activate macrophages, enhance their microbicidal activity, and facilitate B cells to produce antigen-specific antibodies with strong opsonizing properties. The principal function

of T_H2 effector cells is to help B cells to produce antigen-specific immunoglobulins of various isotypes. Although definitive data are lacking, strong indications show that a similar dichotomy of activated T_H effector cells into T_H1 and T_H2 may also occur in the chicken (19).

Cytotoxic T Cells (CTL)
Most CTL express CD8 surface molecules. A small proportion of mammalian CD4 T cells may also have cytotoxic activity, although the presence of avian CD4 T cells with cytotoxic ability has not been documented. CD8+ CTL recognize endogenous antigens in conjunction with MHC I (59). Internalized antigens such as viruses are degraded into small peptides by a large proteolytic complex called a proteasome. Small antigen peptides, usually 7–13 amino acids long, are then transported to the endoplasmic reticulum where the peptides become attached to MHC I. The peptide-MHC I complex is then transported to the cell surface for possible recognition by antigen-specific CTL.

One of the most important functions of CTL is the elimination of virus-infected cells. Because most nucleated cells express surface MHC I, virus infection of almost any cell can lead to potential recognition and lysis by CTL. *In vitro* assays to quantitate

CTL in chickens have been difficult to establish because of MHC restriction of effector and target cells. Despite this difficulty, CTL activity has been shown to regulate pathogenesis of avian viral and neoplastic diseases (15, 35, 79).

Avian Cytokines

Cytokines are small, biologically active proteins secreted by a number of cells, most notably immune cells. Cytokines bind to specific receptors on the surface of target cells and regulate immune response by signaling between cells. Receptor-bound cytokines and other membrane-associated molecules often act together to stimulate the effector function in a target cell. T cells, B cells, macrophages, and dendritic cells all secrete cytokines. Cytokines produced by T_H cells in particular play a key role in modulating an immune response. T_H1 cells, which promote a CMI response, produce predominantly IFN-γ, which activates macrophages and enhances destruction of cell-associated pathogens. Other major cytokines produced by T_H1 cells include IL-2 and tumor necrosis factor-α (TNF-α). IL-2 is critical for the proliferation of a number of immune cells including T_H, T_H1, and T_H2 cells, CTL, NK cells, and B cells. The T_H1 cell activity and cytokine secretion is stimulated by IL-12 and IL-18, both produced by macrophages, dendritic cells, and B cells.

Cytokines produced by T_H2 cells, which promote B cell activation and antibody production, include IL-4, IL-5, and IL-10. IL-1, a product of a number of cell types, most notably macrophages, stimulates the T_H2 cell activity.

Within the last few years, a number of avian cytokines have been isolated and characterized. Genes coding for avian cytokines and their receptors have been cloned and sequenced (Table 2.4). The biological activity of avian cytokines is generally quite similar to their mammalian counterparts, although avian cytokines show little cross-species biological reactivity.

Humoral Immunity

Immunoglobulins (Ig) or antibodies secreted by B cells constitute the principal component of humoral immunity. Antibodies may be present in many body fluids but are most readily detected in the serum or the plasma fraction of blood. Exposure of birds to microorganisms stimulates the production of specific antibodies, which, in turn, react with microorganisms and hasten their destruction. The three mechanisms by which antibodies contribute to defense against pathogens are as follows: *Neutralization*, in which antibodies bind to and neutralize specific pathogens, particularly viruses. Neutralized viruses are unable to attach to surface receptors of target cells and are thus prevented from replication. *Opsonization* which includes bacterial pathogens that can replicate extracellularly, and are more readily internalized and destroyed by phagocytes if the pathogens are coated with antibodies. *Complement activation,* in which antibodies bound to the surface of pathogens, can activate complement and produce new complement proteins. The complement proteins attach to receptors on phagocytes, which facilitate the phagocytosis and destruction of pathogens.

Chickens have three main classes of immunoglobulins: IgM, IgG, and IgA (Table 2.5). Figure 2.4 shows the typical structure of an Ig molecule. All Ig molecules have two distinct types of polypeptide chains. The smaller polypeptide chain, called the "light chain," is common to all classes of Ig, whereas the larger chain, called the "heavy chain," is structurally distinct for each class or subclass of Ig. Covalent and noncovalent forces connect the two chains. The structure of the heavy chain determines the biological function of each class of Ig. Genes encoding all three classes of avian Ig have been cloned and sequenced, which has facilitated the generation of recombinant avian and chimeric antibodies *in vitro* and the expression of recombinant avian Ig in plants (16, 26, 60, 68, 77, 106).

IgM is found on the surface of most B cells and is the first antibody produced following primary immunization. As the immune response progresses, the IgM-producing cells stop IgM production and start the production of IgG or IgA. This phenomenon is called "class switch." The antigen-binding ability of the antibodies does not alter during or after the switch. The "class switch" occurs because the antibody-producing B cell begins to splice the variable (V) region genes (V genes) to the constant (C) region genes (C genes) of the heavy chain of a different class of Ig. Cytokines including IL-4, TGF-β and IFN-γ stimulate the B cell to undergo class switch (21).

A typical immune response of a chicken begins with IgM production. After some time, IgM production switches over to IgG production. IgG is also the principal antibody produced after secondary immunization and is the predominant Ig class in chicken blood. Because avian (and also amphibian, reptile, and piscine) IgG is larger than its mammalian counterpart, the chicken IgG is often called IgY (104). Figure 2.4 compares the relative structure of mammalian and avian IgG. Molecular cloning data suggest that IgY may be the ancestral precursor of mammalian IgG and IgE (104).

IgA is the most important Ig involved in mucosal immunity. Chicken secretory IgA (sIgA) exists as a dimer in mucosal secretions, whereas circulating IgA is polymeric or monomeric. IgA complexes with a secretory component present on the surface of mucosal epithelial cells to form sIgA (107). The acquisition of the secretory component protects IgA from proteolytic digestion in the gut. IgA is most concentrated on mucosal surfaces, although small quantities may be found in the circulation. Bile is also a rich reservoir of IgA in birds. IgA protects mucosal surfaces against pathogens, particularly viruses, by neutralizing and preventing their attachment to receptors on target cells.

As noted earlier, B cells use surface Ig to bind to antigens. Each B cell produces only one type of heavy and light chain and is committed to one kind of antigenic determinant. Thus, for an antigen to initiate antibody production and clonal expansion, the antigen must interact with a B cell that expresses the homologous Ig receptor. Potentially thousands of antigens and millions of antigenic shapes are in the environment. How does the immune system maintain an inventory of B cells with such a wide variety of antigenic specificities? This is accomplished by a number of genetic mechanisms during the development and maturation of B cells. In mammals, Ig gene rearrangement leads to extensive Ig diversity. In the chicken, because of a relatively small numbers of Ig genes, the rearranged genes must undergo a process called *gene conversion* to attain needed diversity (21). In gene conver-

Table 2.5 Properties of chicken immunoglobulin isotypes.

Isotype	Heavy chain (kDa)	#H chain Ig domains	Homology to mammalian	Serum concentration	Sources	Structure and comments
IgM	70 kDa	5	About 30%	1–2 mg/ml	Serum	900 kDa, consistent with heavily glycosylated (μ_2L_2)$_5$ plus a J chain
			78% for TM*		Cell surface	μ_2L_2 monomer of membrane IgM, no J chain
IgG	67 kDa	4	30–35%	5–10mg/ml	Serum	175 kDa, γ_2L_2 monomeric form
					Egg Yolk	γ_2L_2, high concentrations (10 mg/ml) of IgG are found in egg yolk(low concentrations in egg white)
IgA	65 kDa	4	32–41%	$\cong$3 mg/ml	Serum	170 kDa, α_2L_2-monomeric form without J-chain
					Bile	350 kDa, consistent with (α_2L_2)$_2$ plus a J-chain
					Mucosa (tears, saliva)	600–700 kDa, consistent with (α_2L_2)$_4$ plus a J-chain

*TM refers to the transmembrane and cytoplasmic domains of chicken sIgM.

sion, the rearranged light and heavy chain gene complexes acquire clusters of chromosomal pseudogenes. Large segments of highly homologous pseudogenes are present in the vicinity of light and heavy chain genes in the chicken chromosome (73, 74).

Maternal Transfer of Immunity

Transmission of immunity from the hen to the newly hatched chick is critical for protecting the chick against infections during early life. In chickens, Ig are the principal mode of transfer of immunity. There is little evidence that the mother's immune cells are passed on to the embryo. Ig from hen's circulation are deposited in the superficial epithelial and glandular cells of the oviduct (45). From the oviduct, IgG is transferred into the maturing oocyst in the ovarian follicle and accumulates in the yolk sac. Ig produced locally in the oviduct likely constitutes an insignifi-

cant proportion of the transferred Ig. The developing chick acquires maternal IgG from the yolk sac. IgA and IgM are transferred via the amniotic fluid. The developing embryo swallows IgA- and IgM-containing amniotic fluid.

Assays to Measure Immunity
NK Cells

NK cell assays are based on *in vitro* cytotoxicity against susceptible target cells (24, 49, 89). The most commonly used targets are the cells of the line LSCC-RP9 (88). These cells were derived from a retrovirus-induced tumor in a B^2B^{15} male chicken (65). The target cells are labeled with ^{51}Cr and incubated *in vitro* with varying concentrations of cell suspension being tested for NK cell activity (effector cells). Two controls are important: a) adding "neutral" cells such as thymocytes to target cells at the same effector:target ratios as used for the effector cells, and b) the use of NK-resistant target cells. After 4 hours of incubation at 37°C, the radioactivity released into the medium is quantitated. Specific cytotoxicity, a measure of NK cell lysis, is calculated by the following formula:

% cytotoxicity = counts per minute (cpm) in target cells mixed with effector cells – cpm in target cells mixed with normal thymus cells / total cpm incorporated in target cells – cpm in target cells mixed with normal thymus cells × 100.

Macrophages

Macrophages, a phenotypically diverse population of cells, are present in almost all tissues. Because most macrophages adhere to substrates, they can be readily isolated from short-term *in vitro* cultures of peripheral blood cells (PBL) or single cell suspensions of spleen (42). Peritoneal macrophages may also be induced in birds by intraperitoneal injections of inflammatory

stimulants such as Sephadex beads. Some of the assays used to assess macrophage functions include a) phagocytosis, b) cytokine production upon stimulation with mitogens (lipopolysaccharide), c) ability to lyse tumor cells, and d) production of nitric oxide (NO) upon activation by T cell-produced cytokines, most notably IFN-γ. Some of the functional characteristics of avian macrophages have been described (41, 42, 62, 66, 71, 86).

T Cells

Most T_H cell assays are based on *in vitro* stimulation of cells with mitogens or specific antigens (43, 44, 99). Stimulated cells proliferate and secrete cytokines. Mitogen-induced proliferation is a common assay of T-cell competence. Concanavalin A (Con A) and phytohemagglutinin (PHA) are the mitogens of choice. These mitogens bind to cell surface glycoproteins on T cells and stimulate the cells to proliferate. In the typical assays, spleen cells, PBL, or diluted whole blood are cultured *in vitro* in medium containing Con A or PHA. After 40 hours of incubation at 37–41°C, the cells are pulse labeled with radioactive thymidine. The incorporation of the label in cellular DNA is quantitated. Actively proliferating cultures incorporate higher levels of radioactivity than non-proliferating cultures. If the proliferative response of the test group of chickens is lower than the response in age-matched healthy controls, the test group is viewed as being deficient in functional T cells. This general conclusion should be viewed with caution because the mitogen-induced proliferation is not antigen-specific, and response to mitogen is an *in vitro* function of T cells. The *in vivo* relevance of this function to other *in vitro* or *in vivo* functions of T cells is not known, and functional T cells may be prevented from proliferating by non-T suppressor cells or suppressor products present in the culture (43, 69).

T cells recovered from immunized animals may proliferate *in vitro* when co-cultured with the antigen used for immunization (44, 99). This antigen-specific proliferation has been shown with several avian viruses, although the ideal assay conditions are not well established, and the test is not widely used.

Mitogen- or antigen-induced stimulation of T cells *in vitro* also results in the secretion of cytokines. Quantitation of cytokines in the culture medium gives an indication of the functional capability of T cells. A nitric oxide inducing factor (NOIF) test has been described in which macrophage-stimulating cytokines such as IFN-γ can be quantitated. Macrophage line cells are exposed to the test supernatants, and NO concentration in the supernatants is calculated (39).

CTL activity can be measured *in vitro* by co-culturing effector cells with ^{51}Cr-labeled target cells (59). The protocols are quite similar to those described previously for NK cell cytotoxicity assays. The cytotoxic activity of CTL is MHC I-restricted. Therefore, both effector and target cells must come from the same or a genetically compatible bird. Because of this limitation, CTL assay is difficult to perform in outbred populations of birds and remains a research tool.

Certain *in vivo* assays may also be used to assess T-cell functions. The delayed type hypersensitivity assay measures antigen specific response. In this test, an animal immunized against an antigen is intradermally injected with the same antigen. Swelling at the site of the injection comprises a positive response. Local swelling at the site of an intradermal injection of mitogens such as PHA has also been attributed to a non-specific T cell response.

Antibody Levels

Birds exposed to pathogens develop circulating antibodies that generally persist for several weeks after the antigen has been cleared. Detection of these antibodies is much more convenient than detecting cellular immunity, and a number of serologic assays are available to quantitate antibodies. Some of the commonly used serologic tests include agar gel precipitation test, virus neutralization test, immunofluorescence test, hemagglutination inhibition test, and enzyme-linked immunosorbent assay (ELISA). Protocols for conducting these tests have been described (98).

ELISA is by far the most common serologic assay used under commercial settings. Automated technology allows rapid processing of large numbers of serum samples. Computerized data transmission facilitates flock profiling and provides useful information on environmental exposure to pathogens and response to vaccination. ELISA kits that can be used to detect antibodies against most of the common viral and bacterial pathogens of poultry are available commercially.

The transfer of IgG from the yolk sac to the embryo or the hatchling occurs by absorption into the recipient's circulation. Yolk sac is highly vascularized, and IgG is transferred by receptor-mediated endocytosis across the yolk sac epithelium (56). The transfer of IgG begins during the first week of embryonation but occurs most predominantly during the last three days before hatching (48). The transfer from the yolk continues after hatch. Peak levels of maternal IgG in the circulation of the newly hatched chick reach around 2–3 days of age. Maternally derived antibodies decline linearly in the recipient and become undetectable after 2–5 weeks.

Although maternal antibodies are important for the well being of the newly hatched chick, the antibodies may interfere with active immunization with live vaccines. Neonatal or *in ovo* vaccination is often necessary in flocks being raised in heavily contaminated environment. Besides neutralizing the antigen present in the vaccine, pre-existing antibodies may also interfere with the development of active immunity by providing negative feedback to the immune system.

Genetics of Disease Resistance
Hans H. Cheng and Susan J. Lamont

Introduction

Genetic resistance is alluring from both the industrial and academic viewpoints. With respect to poultry companies, losses due to diseases induced by infectious pathogens continue to be a significant issue and can be the key factor in determining economic viability. This is because pathogens lead to loss or condemnation of birds; inhibit the immune response, making birds susceptible to other pathogens and diseases; divert critical resources from growth and production; add expenses for vaccination programs; and force changes in husbandry practices, all of which increase the cost of production. Furthermore, certain pathogens may cause a disruption in trade between countries or produce a loss of public confidence in food product safety. Consequently, genetic resistance can be a powerful approach in combination with other management practices to eliminate or manage infectious diseases of agronomic interest, especially as a long-term solution in light of the emergence of new and more virulent pathogens and increasing restrictions on the use of antibiotics.

From the academic side, modern molecular genetics has provided an arsenal of new tools for identifying genes and alleles that confer resistance to disease. Some of the complexity of biology, and in particular the immune response, may finally become fully elucidated. It is reasonable to expect that genetics will identify genes, or at least genomic regions containing these genes (known as QTL or quantitative trait loci) that influence complex traits like disease resistance. It is also expected that information will be forthcoming on how these genes function and interact as well as respond to changing environments to control disease. Ultimately, this information will be transferred to poultry companies to generate elite lines with superior disease resistance or better vaccinal response. On the other hand, it is clear that the field is in its formative years, and our ability to predict and model complex traits is limited. And while advancements in biotechnology will continue, technology cannot speed up the maturation rate, generation intervals, the number of progeny produced per day or per bird, and other biologically-limited traits and resources that are required for experimental studies. Consequently, it is anticipated with the rapidly changing landscape of biological knowledge that long-held assumptions will be shattered, requiring revised models and paradigms. Fortunately, the momentum for continued progress in genomics remains high along with the seemingly unending string of technological advancements.

Besides these interests, studies on genetic resistance and genetics in general are the forerunners of change that will undoubtedly occur in all areas of biology including veterinary medicine and diagnostics. With the advent of molecular genetic maps, the genome sequence, and genomics, "discovery-driven research" emerged as the preeminent method for dissecting and understanding complex traits like disease resistance. Consequently, while genetics has always been a field that used a holistic approach to examine the entire organism, with the ability to measure and record millions of data points at the DNA, RNA, and protein levels quickly and economically, the power of the existing and upcoming technologies has and will continue to shift the field toward large-scale unbiased screens using molecular and computational biology and their integration. This does not mean that scientists and clinicians need to become facile in genomic technologies, rather it indicates that knowledge and information can be more readily transferred to other fields.

In this section, we focus on recent advancements in genetic resistance to disease, namely, molecular and quantitative genetics; for reviews on classical genetics or specific genes for disease resistance, see 16, 27, 37, 55, 56, 75, 96. The targeted audience is animal health professionals and others that may not be familiar with molecular or quantitative genetics. We hope to convey the high level of excitement (as well as limitations) in these areas, which has been brought about with the recent release of the chicken genome sequence and other related technologies. To achieve these goals, sections are presented on (1) a review of genetic concepts necessary for a basic understanding, (2) molecular genetic approaches to identify disease-resistance genes, (3) complementary functional genomic approaches that provide insights on the biochemical mechanisms and pathways of disease resistance, (4) brief summaries of genetic resistance and experimental studies for specific diseases, and (5) thoughts on how this information may be applied in poultry breeding to improve host resistance to infectious disease. The emphasis throughout these sections is on basic concepts as given the short history and dynamics of the field, knowledge, and state-of-the art methods will change rapidly. Finally, some topics of general interest (e.g., the chicken genome assembly, use of molecular genetic tools for veterinary diagnostics) are briefly discussed as general interest or tools that could be transferred to veterinary diagnostics.

Review of Quantitative and Molecular Genetics

Classical or Mendelian genetics trains us to think about biology in mathematical (quantifiable) terms by using discrete phenotypes (measurable traits) that are explained by one or a few genetic loci. Certainly, there are "simple" or qualitative traits as evidenced by the large number of loci and alleles, often with interesting and descriptive names that account for plumage color and patterns—e.g., dominant white, slow feathering, naked neck. However, for the majority of traits (phenotypes), there is natural variation with continuous (or quantitative) rather than discrete (or qualitative) phenotypic classes within a population. This phenotypic variation can arise from the segregation of a single gene with multiple alleles (forms of genetic variants), or numerous genes, combined with modulating effects due to interactions with

the environment. The critical difference is that for a quantitative trait, the phenotypic variation among individuals of a specific genotype, is relatively larger than the average phenotypic difference between genotypes.

Genetics strives to understand how the phenotypes of organisms are influenced by their genotypes (genetic makeup). More specifically with modern molecular genetics, we wish to know the relationship between genetic variation and phenotypic variation. In other words, the goal is to determine how variation within a population can be accounted for at the genetic level, which should facilitate selection of the trait in a breeding program. This does not mean to say that a gene with no discernable allelic variation does not contribute to the trait but rather that there is no variation within this population for genetic improvement. At the simplest level, given a genetic component, we wish to know whether different alleles for a given gene or locus give statistically significant differences in a particular trait. With the advent of molecular genetic maps, we can extend this same question to the entire genome. In short, the goal of genetics is to predict what kinds of offspring are produced by a specific cross. More specifically, the major goal of molecular and quantitative genetics is to identify the genes and alleles that account for the observed phenotypic variation within a population. This result is achieved by mapping the traits genetically and by understanding the mechanistic basis of the genetic contributions to phenotype.

The basic genetics concepts, which are described in the following discussion, have been established for many years and utilized well as evidenced by the great progress made by poultry breeding companies. What has changed is the emergence of molecular genetic maps and high-throughput screening of genotypes, which has had a dramatic and positive impact. It is now possible to identify the underlying genetic basis for complex traits such as disease resistance. It is anticipated that many genes and gene products discussed in the prior subchapter will contribute to genetic resistance to disease.

Phenotypic Distributions

Even within individuals with identical genotypes, there is a range of phenotypes. In other words, while an individual's genotype certainly influences its phenotypes, it does not mean that genotype equals phenotype. This can be seen where field crops with the same genetic makeup are very uniform but upon closer inspection, subtle variations in height or other measurable traits are found. This range is due to the fact that traits are not the outcome of the contributing genes only, but normal biological variation, response to the environment, and other factors. For simple and qualitative traits, the phenotypic distributions of unique genotypes may be very tight and not overlap with others to give discrete classes. This is often not the situation when dealing with complex and quantitative traits where a continuum is found. This also implies that individuals with different genotypes may have the same phenotype.

Disease presents unique issues with analysis of quantitative traits, as the definition often varies according to the pathogen. Disease is the unfavorable outcome of the interactions between the host, pathogen, and environments whereby conditions exist to favor pathogen growth and spread. Disease resistance could

mean absolute resistance to infection. For example, chickens that are resistant to certain subgroups of avian leukosis viruses (ALV) lack the corresponding cellular receptor for ALV attachment and entry. Alternatively, disease resistance could mean tolerance—e.g., all birds are considered to harbor intestinal parasites—but the resistant birds do not go on to show debilitating symptoms. In other words, the resistant birds did not pass a certain threshold to be classified as diseased. Regardless of the situation, it is necessary to define what disease means for that pathogen.

Disease can also be considered as simply a binary or two-state trait, as a bird is classified as either resistant or susceptible. It would be advantageous for disease to be broken down into continuously variable, quantifiable, and/or measurable components. Using Marek's disease (MD) as an example, besides asking whether a bird gets tumors or enlarged nerves (i.e., diseased), one could monitor the amount of virus after infection, the days until death, and a whole variety of other measurable MD-associated traits. Besides providing additional statistical power, it has the potential advantage that disease resistance can be ascribed to one or more components. It is in the ability to define and quantify disease traits that veterinarian pathologists and immunologists may significantly help studies on genetic resistance.

Heritability

A prerequisite of genetics and breeding (genetic improvement) is that the trait of interest is heritable. This can be determined somewhat by observing whether related birds are more similar to each other than unrelated ones. This assumes that the environmental conditions are the same for all birds. A more direct test would be to take individuals at the two extreme ends of the phenotypic distributions, mate them to birds of similar phenotype, and then determine whether the measurable differences between the two groups of offspring are maintained, thus, inherited. For example, let's say in a population of broilers grown in the same environment under the same feed regiment that birds vary in the percent abdominal fat. To determine whether there is a genetic basis for this variation in abdominal fat, one would mate sires and dams with high abdominal fat and sires and dams with low abdominal fat to produce two sets of chicks. Following the rearing of these chicks in the same environment, if abdominal fat is heritable, then the phenotypic distribution of abdominal fat should differ between the two groups with the chicks resembling their parents in the percent abdominal fat.

This extent of similarity from parent to offspring, or heritability, can be quantified. Variation in a trait within a population results from variation in the genotypes (genetic effect) and variation due to mainly the environment. The genetic variation can be further broken down into what are called the additive and dominance variance components. Suffice it to say that the additive genetic variance accounts for the average effect of each allele of a gene, while the dominance variance component measures deviation from the predicted average of the two alleles. What is normally reported for the heritability of a trait is the amount of phenotypic variation that can be accounted for by the additive genetic variation and is represented as h^2. Values range from 0 (no heritability) to 1, where the trait measures of the parents
Fig. 2.5. Linkage between a hypothetical virus receptor with defective (R) and functional receptor (r) alleles, and a molecular marker with alleles M and m. In this example, parental (P) chickens that are susceptible (R/r) and resistant (R/R) to the virus are intermated to produce backcross (BC) progeny. If the loci encoding the viral receptor and the molecular marker are completely linked at the genetic level, then the molecular marker will absolutely predict the virus resistance status of the bird as all resistant birds will have the M/M genotype while all susceptible birds will be M/m. However, if loci are linked but can be separated at the genetic level during meiosis, if the distance between the loci is 10 cM, then the molecular marker will again be predicted but only 90% of the time.

would exactly predict the value of the offspring. By knowing the heritability estimate of a trait, breeders can predict the response to selection. Using percent abdominal fat as an example, if the population average was 4%, and we choose parents with 2% abdominal fat, then if the heritability of abdominal fat was 0 (no genetic influence), 0.5 (moderate genetic influence), or 1.0 (absolute genetic influence), the offspring would be expected to have an average of 4%, 3%, and 2% abdominal fat, respectively.

For disease resistance, in general, heritability estimates for specific diseases are reported to be low to moderate (37). However, it is important to note that heritability estimates are for a particular population (set of birds and genetic composition) under a single environment. This may be one of the main reasons why there is a range of reported h^2 for the same traits as the populations and environments are not constant between experiments and estimates. This also shows that heritability is not fixed for any one population and may change following selection (genotypes are altered) or in a different environment.

Linkage

Linkage, or the nonrandom association (co-inheritance) of alleles, is the main weapon in the molecular geneticist's toolbox. It is this ability that can determine whether a disease-resistance gene is nearby or linked to a specific molecular marker. To illustrate this point, let's start with the simplest example of a single gene trait. We'll assume that there is a gene that encodes the cellular receptor to a nasty virus, and virus binding to this receptor is required for cellular infection. The R allele makes a defective receptor, thus, confers resistance to infection and disease while the other allele r makes the normal protein, which confers virus entry and susceptibility. Because the bird needs only one r allele for disease susceptibility, disease resistance is a recessive trait, as a bird would need two R alleles to prevent virus-induced disease. If you mated a susceptible bird with the R/r genotype (chickens are diploid, thus, have 2 alleles for each locus) with a resistant bird (R/R), about half of the progeny should be susceptible with the R/r genotype while the other half should be resistant with the R/R genotype.

To locate the disease-resistance gene, one can test for co-segregation using molecular markers. In Figure 2.5, for 100 backcross (BC) progeny, if we find that all 50 resistant and 50 susceptible birds always have the genotypes of M/M and M/m, respectively, for a marker, then the marker is completely linked with and cannot be separated from the disease-resistance gene. This is not to say that marker M is the disease-resistance gene, but only that the two loci were not separated genetically when the gametes were formed during meiosis.

This also demonstrates that alleles M and R, and alleles m and r, are in linkage disequilibrium (LD). If the marker locus and disease resistance gene were unlinked, then the alleles should randomly segregate. But this is not the case as M occurs more frequently than is expected, and in this case, the marker allele is predictive of the disease resistance gene allele.

But what if the two loci are not absolutely linked? Imagine that of the 50 disease resistant birds, 45 had the M/M genotype and 5 had the M/m genotype. Likewise, of the 50 susceptible birds, 45 had the M/m genotype while 5 had the M/M genotype. Having the M allele is still a very good indicator of disease resistance (or vice versa with the m allele), but it is not 100% accurate. In this case, we can determine the linkage of the two loci by quantifying the percentage of recombinant alleles (non-parental ones—e.g., R and m or r and M). In this example, there are 10 recombinant progeny out of 100, which means that the disease resistance gene and the marker are 10 centiMorgan (cM) away. The genetic term cM reflects the number of recombination events between two loci detected in 100 progeny. In other words, the extent of linkage between these two loci is determined by the amount of genetic recombination that occurs during meiosis, which can be determined by measuring how often particular alleles within each locus are inherited together.

To make the situation even more difficult and to put into perspective the challenge of finding genes for complex disease resistance, imagine now that each disease resistance gene accounts for only a small percent (2–10%) of the total observed variation in the segregating population, as is typical for most diseases. Furthermore, not all R/r birds are susceptible as the r allele may not always be expressed at sufficient levels to allow virus entry. Or not all the birds get challenged with nasty virus as natural exposure is being used. While daunting, these challenges can be overcome with proper and controlled experiments, the use of molecular markers that encompass the entire chicken genome, many progeny to give more statistical power, accurate phenotypes, and biometrical analyses.

Experimental Approaches for Molecular Genetics

The development of genetic maps based on molecular markers defined the birth of genomics. No longer were scientists limited to assaying for genetic effects using markers at undefined locations. Now it was possible to systematically query the entire genome. This ability also changed the way experiments were primarily conducted. Rather than using the reductionist approach of formulating a hypothesis about a specific gene and then testing it, genomics is a discovery-driven field where the end results allow definition of the next series of experiments. The genomics approach is growing in influence and is being reinforced and strengthened with whole genome sequences and high-throughput technologies that deliver quick, accurate, and low-cost data points.

Candidate Genes

In the preceding subchapter, a number of genes and genes products have been identified that modulate the immune response. Many of these immune function genes have or may be good candidates for conferring disease resistance. Consequently, prior knowledge to identify candidate genes for specific disease resistance is a valid method and often the best first choice for testing for a genetic effect. This approach requires a population that is segregating for disease or disease-associated traits, and an informative DNA polymorphism within or close to the gene of interest.

Although a gene and its gene product may be a critical component of the immune response and disease resistance, it is possible that there is no variation or genetic effect attributable to the gene in a specific population. Consequently, the first requirement is to identify polymorphisms (structural variations in the DNA) and alleles of the gene that are segregating within the population. Furthermore, evidence for a genetic effect does not prove causation by that gene but may be a result of linkage between the causal gene and the analyzed gene. Finally, only that specific gene and genomic region is being screened for genetic effects, and no information is generated about other genomic regions that may also influence resistance to the disease.

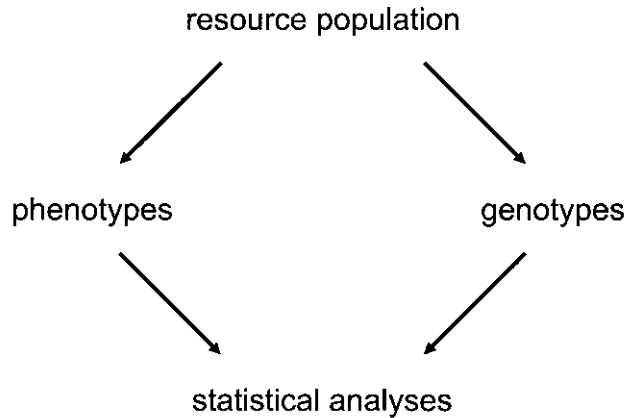
The MHC represents a unique situation and opportunity. Due to its importance in many diseases, chicken lines have been developed that vary only in the MHC or B locus (1, 5, 40). Thus, these lines have the identical genetic background and carry different and unique MHC haplotypes. So, rather than using a genetic marker to the MHC and asking whether it is associated with disease resistance, these "B congenic" strains can be used to quickly screen for MHC influences on disease resistance by challenging each line with the pathogen of interest and monitoring disease and disease traits. Furthermore, due to the inbred nature of each line, there is less genetic variation that has to be accounted for, which translates into fewer chickens needing to be measured to detect genetic associations with traits.

Whole Genome Scans

With availability of the chicken molecular genetic map, it is possible to screen the entire chicken genome for disease-resistance genes. The general approach is shown in Figure 2.6. In brief, what is called a resource population is identified or produced where birds segregate for disease resistance. Some or all of the animals are measured for disease or disease-associated traits. Likewise, the same animals are genotyped for molecular markers spaced evenly throughout the entire chicken genome. Statistical analyses are performed to see whether certain genomic regions (genotypes) are associated with disease resistance (phenotypes) and, if yes, then how much does each region account for. The regions that contain one or more disease resistance gene are known as a quantitative trait loci or QTL.

Two approaches can be used in genome-wide QTL scans. The difference between the two lies in how the resource populations are produced, which also influences the density and, consequently, number of genetic markers required.

Linkage Analysis

In this approach, for each marker, one tests whether the inheritance of alleles influences disease resistance in a defined population. This type of linkage is known as identity by descent (IBD).


resource population

phenotypes   genotypes

statistical analyses

Fig. 2.6. General scheme for identifying genes or genomic regions associated with phenotypes. Using a resource population that is segregating for measurable traits, statistical analyses are used to associate genetic variation with the observed phenotypic variation.

Parents that differ markedly in disease resistance are selected and mated to produce progeny, which favors the use of inbred or divergently selected experimental lines due to their genetic simplicity and defined disease status. In initial QTL scans, the mating structures are often backcross (BC) or F_2 populations. Due to the limited number of generations and recombination events that can erode the amount of LD, marker spacing can be relatively high at 20–40 cM apart, which reduces the number and cost of markers that need to be genotyped.

To validate and fine-map a QTL, additional generations are required to reduce LD and break apart distant marker-disease gene linkages through recombination, leaving only markers that are tightly linked to the disease resistance gene. A popular approach, known as advanced intercross lines (AILs), is to intermate progeny to get F_3, F_4, F_5, etc. (28). With each passing generation, the extent of LD grows smaller, which increases QTL resolving power.

Although simple in concept, the actual execution of the experiment entails a number of factors. Probably the biggest factor that one can control is the number of progeny. The ability to detect QTL with smaller effects increases with more progeny. From a practical standpoint, this means at least 200 birds, if not 1000 or more. Normally, the generation and measurements of resource populations is the rate-limiting step.

A typical result is that a few to 15 QTL are revealed. These are classified as suggestive or significant based on statistical analyses that are corrected for the large number of multiple tests. The reason for including suggestive QTL at this point is that subsequent studies are usually designed to validate potential QTL detected in the first-phase studies. Furthermore, it allows for comparisons across related studies conducted under varied conditions.

How robust is this experimental approach? No one really knows as the true architecture of any one complex trait has not been completely deciphered. In the most advanced study to date (86), after examining 101 traits in 1904 F_{50} mice with 13,549 genetic markers, there was a surprising consistency in genetic architecture across all traits. For most traits, a relatively large num-

ber of QTL that explained 1 to 5% of the total phenotypic variation for each trait were identified. And the QTL in total explained around 75% of the genetic variance of each trait. This indicates that it should be possible to achieve a great understanding of disease resistance in the chicken, given powerful enough populations (and funds to perform these tasks). Thus said, even in the powerful mouse study, each QTL was only resolved to a 2 cM interval, which still encompasses 25–50 genes, illustrating the great challenge in going from a QTL region down to a verification of a single gene's effect.

Association Mapping

In association or LD mapping, a pedigreed population is not required, which makes it attractive for use in the commercial environment as existing populations can be tested. The power of this approach is that it relies on historical recombination events to greatly minimize the extent of LD. And rather than following the inheritance of specific alleles (identify by descent), association mapping analyzes genetic marker allele frequency or identity by state (IBS). Thus, resistance birds should be highly enriched for a specific marker allele while the other allele(s) is found in the susceptible birds. This method has both advantages and disadvantages. On the positive side, given the tight linkage required to detect a disease-resistance gene, any genetic marker with a significant association will be relatively close, which means that it is almost immediately amenable to further verification and implementation in a breeding program. On the other hand, since LD is small, one requires a much larger number of genetic markers so that each region is screened.

Association mapping has not been attempted in poultry mainly due to the lack of genetic markers, cost of genotyping, and not having estimates on LD in commercial populations. This situation though has and will continue to change. The identification of nearly 3 million single nucleotide polymorphisms (SNPs) (91) and high-throughput genotyping platforms makes this approach much more feasible.

Genomic Tools

The field of genetics and genomics is heavily influenced by technological advances. Key among these developments are molecular markers, which allow for the generation of high-density genetic maps and the chicken genome sequence. In short, comprehensive genetic maps and the genome sequence allow for the genetic dissection of simplex and complex traits.

Molecular Markers. The beginning of genomics was marked with the development of genetic maps composed of molecular markers. Unlike classical markers, molecular markers are typically based on DNA. Using an assay to type DNA variation, alleles can be determined for each individual, which allows for the development of linkage maps and association studies.

The most commonly used molecular markers are called microsatellites and SNPs. Both of these types of markers rely on specific and unique sequences and can be anchored to a sequence tagged site (STS). Consequently, both genetic and physical distance can be determined for any pair of these molecular markers.

Microsatellites are sequence stretches that contain repeat units of 1 to 6 bases, e.g., CACACACACACACACA or $(CA)_8$. The number of repeat units often varies among individuals. Consequently, PCR primers that amplify this region will produce products that differ in size. The use of automatic DNA sequencers and fluorescently labeled PCR primers allows for the rapid identification of each allele. On average, there is one microsatellite for every 75 kb in the chicken genome. In the chicken genome, 1 cM of genetic distance equates to ~250 kb of physical distance, although this varies substantially across chromosomes. Therefore, there could be several informative and multi-allele microsatellites for every cM in the chicken genome.

SNPs, or single nucleotide polymorphisms, are sequence variants at a specific base in the DNA sequence. In theory, SNPs should have 4 alleles as there are 4 bases (A, C, G, and T). However, most SNPs have only 2 alleles and are often referred to as bi-allelic markers. SNPs are much more frequent than other molecular markers with ~5 found for every kb of chicken sequence. The presence of only 2 alleles greatly simplifies genetic analyses, which makes platforms based on this type of marker the current method of choice for large-scale studies. On the other hand, SNPs are not as informative as microsatellites as they are limited to 2 alleles while microsatellites can have several.

Chicken Genome Assembly. The chicken genome contains 38 autosomes and the Z and W sex chromosomes. In 2002, the NIH funded the sequencing of the entire chicken genome, which was released in 2004. To generate the draft genome sequence assembly, a framework was built using the genetic map as its foundation. Layered on this was a physical map derived from 180,000 BAC (large insert) clones ordered through restriction enzyme analyses. Connections between the genetic and physical maps were made through genetic markers located on individual BAC clones. Finally, the whole-genome shotgun sequence was assembled into contigs and located onto the framework through common sequences; the BAC clones had their ends sequenced. As a result, the initial assembly contained 1.05 Gb of assembled sequence of which 933 Mb were localized to specific chromosomes; the haploid content of the chicken genome is ~1.2 Gb. Each base was sequenced ~6.6 times on average, which is an indicator of genome coverage.

Like all other sequences including the human, there were gaps and assembly errors. In 2006, a second build that incorporated more genetic markers and sequence was generated. Additional sequencing of targeted regions is still under way.

Functional Genomics

As described previously, genetics relies on statistical association of genotypic variation with phenotypic variation to identify genomic regions and determine how much variation each region contributes. Consequently, the ability to identify a disease resistance gene relies on statistical power and probabilities. Currently, this ability translates into QTL being localized to 5 or 20 cM intervals, at best. Even the best mapping studies in mice, with very large populations and dense marker placement, can only place a QTL of moderate effect to a 2 cM interval. This means that it will be extremely difficult to resolve the location of a QTL down to the single gene level. As the chicken genome contains 400 kb per cM and 5 or more genes, on average for the larger chromosomes (43), even a 2 cM interval contains a lot of DNA sequence and candidate genes.

To complement this genetic approach, there are a number of tools that query at the RNA, protein, or metabolite level. These functional genomic tools strive to identify components that vary between two or more states, for example, gene transcripts that are differentially expressed between disease resistant and susceptible chickens. The hope is that by identifying these molecules, gene function and biological pathways can be ascribed to every gene.

Functional genomic assays identify gene transcripts, proteins, or other molecules, which combined with genome-wide QTL scans can reveal positional candidate genes. This integrative approach will be described in more detail for Marek's disease resistance. Below are a few enabling technologies, which can also be applied in a number of ways beyond genetics.

DNA Microarrays

During the generation of whole genome sequences, it became obvious to scientists that there was a huge challenge to study all the genes and gene products that would be identified. Furthermore, it was clear that the reductionist approach of studying one gene or protein at a time would not be sufficient to meet this requirement.

In one of the key technological developments, Pat Brown and colleagues developed DNA microarrays (80). For many years, scientists had used hybridization, which detects complementary sequences for DNA and RNA analysis of specific sequences using labeled probes. In an elegant extension of this concept, all the probe sequences instead of being individually labeled were arrayed onto a microscope slide and the total mRNA population of the tested individual was labeled. As a consequence, the relative expression of thousands of genes in a single sample could be simultaneously measured in one step.

Within a relatively short period of time, this technology was adapted for all species that had substantial RNA and DNA sequence information or resources. With respect to chicken, Affymetrix presently makes the most comprehensive microarray with coverage extending to all the ~28,000 genes predicted in the first genome assembly. In addition, there are probes sets for genes to 17 different avian viruses including Marek's disease virus, Newcastle disease virus, and avian influenza, which allows this tool to be used for veterinary diagnostics in the detection of these viruses.

DNA microarray experiments generate a list of genes that are expressed more or less between two or more samples. For example, genes A, B, and C may be expressed more and genes X, Y, and Z less in the thymus of 5 day old resistant birds compared to age-matched susceptible birds. It is important to note that because

gene expression (RNA) is being measured, unlike DNA, it can vary depending on the bird, tissue, time point, and other influences. Because of this natural biological variation, even for a given set of conditions, it is critical that several replicates are conducted. Unfortunately, at the moment, this is a relatively expensive procedure as each sample can cost $500 or more to process, which when combined with more variables (e.g., several tissues, more time points) inflates the total experiment cost quickly.

The list of genes can be further analyzed to provide a higher order understanding. For example, if all the genes belonging to a specific biological or functional class are elevated in the resistant bird compared to the susceptible bird, then most likely this pathway is involved in disease resistance. Tools to better analyze and extend the biological meaning of array results is an area of intense study.

With the success of this highly parallel process, it was quickly adopted to many other molecules or situations. There are now protein arrays, tissue arrays, metabolite arrays, with the list going on and on. Undoubtedly, many of these techniques will become viable and implemented in poultry in the near future. For reviews on diagnostic applications in animals, see references 33, 81, 89.

Proteomics

Moderate to large scale global screening at the protein level is also available today. For identification of proteins in a complex mixture, mass spectrometry is the technique of choice (29). Typically, protein samples are fractioned to reduce the complexity; then peptides are analyzed by the mass spectrometer; and finally the data sets are analyzed to deduce the identity of proteins. Although simple in concept, analysis of proteins is much more challenging than either DNA or RNA because for each gene, there are many proteins with varying post-translational modifications, and the concentration of proteins encompasses many orders of magnitude. Consequently, it is fairly simple to identify the abundant proteins but difficult for the ones in low quantity. And like DNA microarrays, cost can be a serious issue, which partially explains the minimal usage of this technique thus far in poultry research, though the situation is gradually changing (20).

Besides identifying individual proteins, it is possible to screen for protein-protein interactions. The classic method, known as the two-hybrid screen (34, 35), takes advantage of the ability to reconstitute the activity of a transcription factor that is in two parts. By fusing a cDNA (prey) library to the activation domain (AD) of a transcriptional activator, it is possible to identify proteins that interact with bait (protein of interest) that is fused with the DNA-binding domain (BD). As the AD and BD do not need to be physically connected to promote transcription, if two proteins interact, a reporter gene is expressed if AD and BD are brought into close proximity of each other. Due to the nature of the assay, all interactions must be independently confirmed to eliminate false positives.

Higher order interactions can be revealed with gentle cell lysis and immunoprecipitation of a protein complex using antibodies directed against one member. The identity of the other interacting proteins can be quickly revealed through mass spectrometry.

Genetic Resistance to Specific Diseases

As discussed previously, one generally needs to first demonstrate heritability of resistance to disease to demonstrate a genetic component. Although differences for disease resistance between chicken genetic lines may suggest a genetic basis, they are insufficient to prove it. Combined with the need in molecular genetics for controlled disease challenges and marker associations, the number of studies conducted to date is limited, especially for genome-wide scans. There is, however, evidence for genetic control of poultry diseases caused by a wide range of pathogens, including viruses, bacteria and parasites.

Avian Leukosis

As described in Chapter 15, avian leukosis viruses (ALV) are a group of retroviruses that can induce tumors. ALVs are classified into various subgroups based on virus-specific cellular receptors and virus envelope glycoproteins. The subgroups that infect chicken are A–E and J with all but subgroup J being exogenous ALVs.

Genetic resistance to ALVs subgroups A–E is well defined and based on specific cellular receptors. Since a single functioning receptor allele is all that is required for virus entry, susceptibility is dominant and the genetics is simple with only one locus involved. Molecular studies taking advantage of this fact have revealed not only the encoding gene but the basis for differences between resistant and susceptible lines. Interestingly, although the ALV subgroups are related and thought to have arisen from a common ancestor, all the cellular receptors show no obvious sequence or structural similarity.

Resistance to ALV subgroup A is determined by the tva locus found on chromosome 28, and encodes a protein a member of the low-density lipoprotein receptor (LDLR) family of unknown function (10, 30). There have been two alleles identified that confer resistance. The tva^r allele contains a single nucleotide mutation that results in a protein with very low binding affinity to the ALV subgroup A envelop while the other resistance allele, tva^{r2}, has a 4-nucleotide insertion near the beginning of the coding sequencing, which results in an altered protein.

The tvc locus, which confers resistance to ALV subgroup C, is ~1 cM from tva (31). This receptor shows homology to butyrophilins, a member of the immunoglobulin superfamily. The resistant allele contains a premature stop codon and, thus, would not produce a complete and functioning receptor (32).

Resistance to ALV subgroups B, D, and E (endogenous) are all controlled by the tvb locus (2), which is located on chromosome 22 (82). There are several reported alleles for this receptor, which is related to the tumor necrosis factor receptor (TNFR) family. A single nucleotide change that generates a premature stop codon, results in a non-functioning receptor and resistance to all three subgroups. The tvb^{s1} or wild-type allele is susceptible to all three subgroups while the tvb^{s3} allele confers resistance to subgroup E as the result of a different single nucleotide mutation (53). Molecular tests that can determine the tvb genotype have been reported (97).

Although the receptor for ALV subgroup J has been identified and shown to be Na+/H+ exchanger 1 (NHE1) (22), no cellular resistance has been observed, which suggests that variants that do not allow for virus binding are lethal. Field reports showing differences between lines suggest a genetic basis for differences in resistance to the myeloid leukosis.

Marek's Disease

Chickens resistant to Marek's disease (MD) are those that fail to develop characteristic symptoms upon exposure to MDV (see Chapter 15). Genetic differences in resistance to fowl paralysis, assumed to be MD, have been reported for 60 years (3). Resistance to MD is complex and controlled by multiple genes or QTLs (6).

The best understood mechanism for the involvement of genetic resistance to MD involves the major histocompatibility complex (MHC) or, as it is known in the chicken, the *B* complex. The MHC contains three tightly linked regions known as *B–F* (class I), *B-G* (class II), and *B-L* (class IV), which control cell surface antigens. The *B-G* locus is expressed in erythrocytes, which enables convenient typing of blood groups. By measuring the allelic frequency of specific blood groups, it has been observed that certain B alleles are associated with resistance or susceptibility. Chickens with the B^{21} allele have been found to be more resistant than those with other *B* haplotypes (4, 8). (Haplotype refers to a set of alleles that is frequently co-inherited.) Other studies have allowed for the relative ranking of the other B alleles: moderate resistance, B^2, B^6, B^{14}; susceptibility, B^1, B^3, B^5, B^{13}, B^{15}, B^{19}, B^{27} (67) The MHC also influences vaccinal immunity as some haplotypes develop better protection with vaccines of one serotype than of a different serotype (7, 9).

In addition to the MHC, chromosome 16 contains another set of class I and class II MHC genes that is called the *Rfp-Y* locus (73). Work by Wakenell (90) using data obtained from commercial chickens challenged with MDV suggests an association with MD resistance. However, results from matings with experimental lines indicate that the *Rfp-Y* genes do not influence any MD associated trait in these genetic backgrounds (88). These conflicting results further demonstrate the complexity of genetic resistance to MD, and the probable influence of genetic background.

Besides the MHC, other genetic factors have a major influence on resistance to MD. For example, lines 6 and 7 chickens share the same *B* haplotype, B^2, yet are MD resistant and susceptible, respectively. Due to the availability of these characterized lines and their genetic simplicity, genome-wide QTL scans have been conducted. In one study, unvaccinated F_2 progeny were challenged with MDV and measured for MD as well as a variety of MD-associated traits such as viral titer, number of tumors, and length of survival (87, 92). Using genetic markers spaced throughout the chicken genome, 14 QTL (7 significant and 7 suggestive) were discovered that explain one or more MD-associated traits. The QTL were of small to moderate effect as they explained 2 to 10% of the variance, with additive gene substitution effects from 0.01 to 1.05 phenotypic standard deviations. Collectively, the QTL explained up to 75% of the genetic variance. Interestingly, 10 of the 14 QTL displayed non-additive

gene action; 3 with overdominance (individuals that are heterozygous have a phenotype better adapted than either class of homozygous individual) and 7 were recessive. With multiple traits being measured, the QTL could be grouped. In the first set, 3 of the QTL were associated almost exclusively with viremia levels while the remaining QTL could account for disease, survival, tumors, nerve enlargement, and other disease associated traits. This suggests that disease resistance occurs at least at two levels: initial viral replication and cellular transformation, which occurs later. It also highlights the added value of measuring several components as it may functionally separate a complex trait as well as provide clues on positional candidate genes.

In the second study, Bumstead (17) used a (6 x 7) x 7 back-cross population and measured MDV replication by quantitative polymerase chain reaction (qPCR). A single large effect QTL on chromosome 1 was identified, which accounted for approximately half of the viral replication differences between the two parental lines. This result also supports the relationship between virus titers and disease resistance.

As described previously, going from a QTL to identification of the underlying causative genes is a tremendous challenge, even in model organisms. Consequently, additional functional genomic approaches have been incorporated to give further screens. The first approach utilizes DNA microarrays to profile transcripts that are differentially expressed between MD resistant or susceptible lines. Gene profiling has been conducted to identify differentially expressed genes between lines 6 and 7 after MDV challenge (61), among *B* (MHC) congenic lines of chicken following inoculation with different MD vaccines, and in chicken embryo fibroblasts (CEF) infected with MDV (74). Analyses of these experiments have identified a number of genes and pathways that are consistently associated with either MD resistance or MDV infection. More importantly, the results suggest that chickens with immune systems that are more stimulated by MDV infection are more susceptible. Initially, this seems counterintuitive but upon further reflection, MDV is thought to only infect activated lymphocytes and, thus, chickens with immune systems that are more responsive may present more targets for MDV to infect and later transform.

The second approach uses the two-hybrid assay to identify host proteins that interact with specific MDV proteins. Thus far, 9 MDV-chicken protein-protein interactions have been confirmed by an in vitro binding assay, which demonstrates that the interactions are direct and specific, and do not require other intermediary factors (e.g., yeast proteins) to be involved (76).

In both approaches, a finite number of candidate genes are obtained, which can be further evaluated for a genetic influence. For example, having confirmed the MDV SORF2-chicken growth hormone (GH) interaction, the GH gene (*GH1*) was evaluated as a candidate gene for MD resistance. *GH1* variation was significantly associated (P<0.01) with a number of MD-associated traits in MHC B^2/B^{15} chicks from commercial White Leghorn lines (62). Furthermore, DNA microarray results indicate that GH is differentially expressed between MD resistant (line 6) and susceptible (line 7) chicks following MDV challenge (61). Thus, the combined results of a specific MDV-chicken protein interaction, differential expression of GH between MD resistant and

susceptible chickens, and association of *GH1* with MD disease-related traits and selected lines for MD resistance, all strongly suggest that *GH1* is a MD resistance gene (62). Using the same strategy, *LY6E* [lymphocyte complex 6, locus E, aka, stem cell antigen 2 (*SCA2*) and thymic shared antigen 1 (*TSA1*)] (63) and *BLB*, the gene for MHC class II β chain (76), meet the same criteria.

Salmonellosis

Control of salmonellosis presents special challenges to the poultry industry. As reviewed in detail elsewhere in this book (Chapter 16), some species of *Salmonella* bacteria are highly pathogenic and contagious in chickens, while other species cause little response in the host birds, which can then become asymptomatic carriers. Because they are maintained in the production flocks, birds with subclinical salmonellosis can transmit zoonotic bacteria into the human food chain. Chicks infected with *Salmonella* immediately after hatch can be persistently colonized to maturity, when the bacteria are shed vertically to infect table or hatching eggs, or horizontally to infect other hens (36).

Heritability estimates of various parameters of *Salmonella* response indicate that genetic selection to improve resistance to salmonellosis is feasible. The heritability of chick mortality after *Salmonella* challenge was estimated at 0.14 and 0.62 for sire and dam components, respectively (11). Estimated heritability of resistance to cecal carrier state, measured by enrichment culture, in laying hens was 0.20 (13). Heritabilities of number of bacteria persisting in internal organs ranged from 0.02 to 0.29 (39). Estimated heritability of antibody response to *Salmonella* ranged widely, from 0.03 to 0.26 (11, 52). Measuring antibody response is less expensive and laborious than measuring bacterial colonization and because vaccine antibody has a negative genetic correlation with cecal colonization, vaccine antibody is a useful biomarker to improve resistance to colonization (50).

Many genes are associated with genetic control of response to *Salmonella* species. The individual effect of most genes on the disease phenotypic variation is relatively small, often only 3 to 5% of the total variation, which is consistent with complex control of the disease by many genes. Important factors, such as chicken genetic line, population structure, definition of response (antibody, mortality, systemic or enteric colonization), and serovar of *Salmonella* differed among studies, resulting in some variation in results. However, a generally consistent picture of genetic control has emerged.

The strategy of comparative genomics was very effectively used to identify genes controlling salmonellosis resistance in chickens because response to *Salmonella* was previously studied in detail in the mouse, a model organism. Chicken homologs of major loci controlling natural resistance of mice to infection with *S. typhimurium* were examined as candidate genes. Together, *NRAMP1* (natural resistance-associated macrophage protein 1, now called SLC11A1 for solute carrier family 11 member 1) and *TNC* (a locus closely linked to *LPS*, now known as *TLR4*, which binds lipopolysaccharide, a major component of Gram-negative bacteria membranes) accounted for 33% of the differential resistance in *Salmonella*-induced mortality in a backcross population of inbred lines (44). Subsequently, the *NRAMP1* association was confirmed for several parameters of host response to *Salmonella* in other chicken populations (12, 54, 64), as was the *TLR4* association (12, 57, 68).

The success of the comparative genomics approach provided a starting point to select additional candidate genes to test. Some genes were positional candidates based upon genomic position, such as *CD28* and *VIL1* in the *NRAMP1* region (38). The *CD28* gene was associated with enteric *Salmonella* infection (68), and *VIL1* with visceral infection (39).

Other candidate genes were selected based upon involvement in pathways that are hypothesized to be important in host response to *Salmonella*. The product of the *MD2* gene interacts with the *TLR4* receptor on the cell surface, and SNPs in *MD2* are associated with persistence of *Salmonella* colonization in the cecum (68). The MHC, because of its crucial role in antigen processing and presentation, was investigated. In a series of 12 B-complex congenic lines, line differences occurred in morbidity and mortality after *Salmonella* challenge (26). The MHC class I was associated with resistance to *Salmonella* colonization in the spleen in an experimental cross (66). Genes in apoptotic pathways include *CASP1* and *IAP1*. A *CASP1* SNP was associated with *Salmonella* persistence in the spleen and cecum in an experimental cross (65) and in the liver and cecum in commercial broilers (54). The *IAP1* gene was associated with spleen (65) and cecum bacterial load (54). The genomic region containing genes encoding a newly identified family of antimicrobial peptides, the gallinacins, was associated with *Salmonella* vaccine antibody response (41).

Although the design of most candidate gene experiments does not preclude that the causal gene could be a nearby gene rather than the specific one studied, having supporting lines of evidence such as confirmation in independent populations, with QTL scans, by gene expression data, or from comparative genomics, helps to add confidence in the detected gene-resistance associations. Studies on gene expression in *Salmonella* challenged versus unchallenged, or resistant versus susceptible animals, are revealing differential expression in genes that may be active in pathways controlling resistance (23, 49, 98).

Genome-scan studies have identified QTL regions controlling *Salmonella* resistance. In analysis of a backcross population of resistant and susceptible parental inbred lines (lines 6_1 and 15I, respectively), genotyping of animals with extreme bacterial counts in spleen showed significant linkage between markers on chromosome 5 and the resistance trait (70). Fine-mapping of the chromosomal location of the QTL found a very strong effect, accounting for 50% of the parental variation difference, in the region near the *CKB* and *DNCH1* genes. The specific gene associated with resistance is not positively identified, however, and the *Salmonella* resistance QTL in this region is considered a novel locus named *SAL1*. The distance of almost 50 cM between *SAL1* and the *Salmonella* resistance QTL linked to marker ADL0298 (51) makes them unlikely to represent the same locus although both influenced bacterial colonization in the spleen.

Another genome scan for *Salmonella* resistance QTL used F_2 and BC populations formed from line N and 6_1, and assessment

of cloacal and cecal carrier state (84). This study confirmed an association of the *SAL1* region with enteric carrier state. Additionally, new QTL regions were identified at significant or suggestive levels on chromosomes 1, 2, 5, and 16, with some having effects as large as 37.5% of the phenotypic variance (84). The QTL on chromosome 16 lies in the MHC, although the two inbred lines are considered to have the same MHC haplotype. The QTL on chromosome 5 maps near *TGFB3*, which was shown in independent populations to be associated with spleen (54) and cecal colonization (69).

Colibacillosis

Escherichia coli is an important pathogen of poultry, both as a cause of colibacillosis in production flocks and as a potential food-safety pathogen (Chapter 18). Elucidation of the genetic control of resistance to *E. coli* has primarily been approached through analysis of lines that were divergently selected for circulating antibody level to *E. coli* vaccine in young birds. The principle underlying this approach is that if vaccine antibody is related to resistance and if resistance is under genetic control, then the genetic selection for antibody response will generate lines that differ in resistance genetics. These lines are then a resource to identify the specific genetic differences controlling resistance.

Divergent selection for *E. coli* vaccine antibody response successfully modulated mortality rate, and the immune response to pathogenic *E. coli* and several other antigens (42). Genetic control of *E. coli* response was studied in an F_2 population generated from crossing the divergently selected lines. Molecular probes were used for three candidate genes in the MHC region: *B-F, B-G* and *TAP2* (94). Each probe revealed genetic variation in the population (assessed by RFLP bands), and each gene had multiple bands associated with antibody traits. Also, analyzing the effect of all probes simultaneously revealed more significant effects than analyzing each separately.

Genome scans of resource populations produced from the same divergently selected lines revealed QTL for antibody response and mortality. The initial low-density scan with 25 markers found three markers associated with antibody response to *E. coli*, Newcastle disease virus, and/or SRBC and one with mortality (93). In a more extensive study, F_1 males derived from a cross of the divergently selected lines were mated with females of four genetic backgrounds (the F_1, the two divergent lines, and a commercial line) to produce 1700 progeny that were immunized with *E. coli* and *Salmonella enteritidis* vaccine (95). Individuals with the highest or lowest average antibody were selectively genotyped within each mating type and sire family. About 125 markers were heterozygous in each sire. Twelve markers were associated with QTL for *E. coli* antibody, and six of these were also associated with *S. enteritidis* antibody, with two markers suggesting a QTL on chromosome 2. The experimental design, with sires mated to dams of multiple lines, also demonstrated that the effect of markers was modulated by the genetic background.

Coccidiosis

Coccidiosis is caused by several species of parasites of the genus *Eimeria*, each of which has tropism for a different area of the gastrointestinal tract (Chapter 7). The cost of control of coccidiosis by pharmaceutical means, continual emergence of drug-resistant strains, and profit loss due to reduced growth efficiency all mandate the need for other approaches, such as genetic resistance, to control this disease. Population differences, and the ability to genetically select lines for divergent resistance/susceptibility, illustrate the feasibility of improvement in genetic resistance to coccidiosis (15, 46, 77).

Blood group antigens comprise the major category of genes associated with coccidiosis resistance, with the well-characterized B locus, or MHC, representing most of the reported associations. Several studies compared MHC (or B)-congenic lines, which share background genes but differ for the B locus region (21, 58, 79), or populations in which MHC haplotypes segregate within line or differ among lines (14, 24, 72, 85). Collectively, these studies provide strong support for the MHC being a coccidiosis resistance locus. However, effects of specific MHC haplotypes greatly vary, dependent upon factors such as *Eimeria* challenge strain and the specific trait used to characterize resistance (for example, antibody, oocyst shedding, weight gain, severity of intestinal lesions). A study of birds that were recombinants between the B–F and B–G (class I and II, respectively) regions of the MHC suggested that the MHC class I region had the greater role in resistance (25). Although studies of MHC-congenic lines reveal a clear picture regarding the role of the specific MHC haplotypes studied, they do not shed light on what impact genomic variation at other regions might have on resistance. Experiments that included variation in both the MHC haplotypes and the genetic background determined that both MHC and non-MHC genes control resistance to coccidiosis (59, 60). Erythrocyte loci (identified serologically) in addition to the B locus have been associated with resistance to coccidiosis, including *Ea-A, Ea-E* (46), *Ea-C* (47), and *Ea-I* (71).

An F_2 cross of commercial broiler lines was used to conduct a genome scan for QTL associated with resistance to coccidiosis caused by *Eimeria maxima* (99). Using 119 markers that gave about 80% genome coverage, a strong QTL for oocyst shedding was located on chromosome 1.

Infectious Bursal Disease

Infectious bursal disease virus (IBDV) causes acute infection and depletion of B cells in the bursa and other organs, often resulting in severe and permanent immunosuppression of the host (Chapter 4). Mating of resistant and susceptible lines to form F_1, F_2 and BC populations demonstrated IBDV-induced mortality to be under the control of a fully or partially dominant autosomal resistance gene (18, 19). Multiple studies have examined the MHC for association with IBDV resistance and detected no effect (18, 19, 45). In one study, however, an MHC effect was detected on resistance parameters of specific antibody to IBDV and bursal histopathology (48). The differences among studies are likely to be a result of examination of different MHC haplotypes in varied genetic backgrounds. Collectively, studies on genetics of IBDV resistance suggest involvement of the MHC and at least one other, currently unidentified, autosomal gene. Global transcriptional profiling has revealed numerous genes that are differentially regulated between

IBDV resistant and susceptible lines, and suggests that resistance may be mediated by more rapid inflammatory response and more extensive p53-related apoptosis of target B cells, thus limiting viral replication in resistant birds (78).

Future Perspectives

Genetic resistance to disease for any one individual or line of chickens is the overall outcome of a very complex set of signals and responses with which the chicken and pathogen interact. The ability for molecular genetics to unravel this biological complexity has been very impressive. Despite the rapid pace of advancements, there is a long way to go before scientists develop a detailed understanding of the molecular pathways, and poultry breeders are able to transfer this information to improve their commercial products.

Poultry breeding companies have achieved enhanced disease resistance in their flocks to many pathogens using traditional methods. However, this is a laborious process that requires the intentional exposure of individuals from elite lines to pathogens, and progresses rather slowly due to indirect selection on overall livability. With the emergence of molecular genetics and the field of genomics, there is a optimism that studies will be able to identify genes and alleles that confer superior disease resistance. When applied to breeding, the information will provide for the rapid and accurate improvement of commercial lines. In application, the poultry breeders do not necessarily rely on the identification of the disease resistance gene itself, but may use markers in linkage disequilibrium to increase the frequency of favorable alleles. But as science has shown many times, increasing knowledge gives increasing power that can often be applied in novel ways. So the ultimate goal should be to identify disease resistance genes and their pathways to reveal biological function and pathways.

So what will hasten the advancement of knowledge? With high-throughput platforms to determine genotypes, the rate-limiting step is in producing and measuring resource populations. With respect to animal production, one solution would be to increase the partnerships between poultry breeding companies and molecular geneticists, which allows for the leveraging of expertise and resources. This partnership also allows for scientists to work at the population level with all the diverse set of genes and allele combinations. Beyond this, trait measurements will be critical. As DNA microarrays and proteomics have already shown, breaking down a trait into specific components provides critical information on biological processes that cannot be or are difficult to obtain by traditional phenotypic measurements. Thus, veterinary medicine can make key contributions by refining trait measurements associated with disease and disease progression.

Viral Diseases

Chapter 3

Newcastle Disease, Other Avian Paramyxoviruses, and Pneumovirus Infections

Introduction

D. J. Alexander and D. A. Senne

The virus families *Paramyxoviridae, Filoviridae,* and *Rhabdoviridae* form the virus order *Mononegavirales* (i.e., the single-stranded, nonsegmented, negative-sense RNA viruses showing helical capsid symmetry). The family *Paramyxoviridae* is divided into two subfamilies *Paramyxovirinae* and *Pneumovirinae* (4).

The subfamily *Paramyxovirinae* has five genera: *Rubulavirus,* which includes the mumps virus, mammalian parainfluenzas 2 and 4; *Respirovirus* containing mammalian parainfluenza viruses 1 and 3; *Morbillivirus,* which includes measles, distemper, and rinderpest; *Henipavirus* formed from the Nipah and Hendra viruses; and the *Avulavirus* genus formed from Newcastle disease virus (NDV), and other avian paramyxoviruses (4).

Nine serogroups of avian paramyxoviruses have been recognized: APMV-1 to APMV-9 (1). Of these, Newcastle disease virus (APMV-1) remains the most important pathogen for poultry, but APMV-2, APMV-3, APMV-6, and APMV-7 are known to cause disease in poultry. The prototype viruses and the recognized natural hosts for each serogroup are shown in Table 3.1. Detailed descriptions of serotypes not shown to affect poultry and serotypes usually infecting feral waterfowl have been reviewed by Alexander (1–3).

The subfamily *Pneumovirinae* has two genera: *Pneumovirus,* consisting of mammalian pneumoviruses, and *Metapneumovirus.*

Avian viruses of this genus are correctly referred to as "avian metapneumoviruses" and disease in turkeys is referred to as "avian metapneumovirus infection of turkeys." However, avian pneumovirus[es] and turkey rhinotracheitis virus [TRTV] are still widely used.

Newcastle Disease

D. J. Alexander and D. A. Senne

Introduction

Newcastle disease virus varies widely in the type and severity of the disease it produces. This variety has often caused some problems in recognizing the disease as Newcastle disease (ND) when it is introduced into a country or area and consequently with nomenclature. ND is particularly complicated in that different isolates and strains of the virus may induce enormous variation in the severity of disease, even in a given host such as the chicken. To simplify matters, division into forms or pathotypes of disease based on clinical signs in chickens has been made as

summarized by Beard and Hanson (38): 1) Doyle's form (77), which is an acute, lethal infection of all ages of chickens. Hemorrhagic lesions of the digestive tract are frequently present, and this form of disease has been termed viscerotropic velogenic Newcastle disease (VVND). 2) Beach's form (34), which is an acute, often lethal infection of chickens of all ages. Characteristically, respiratory and neurological signs are seen, hence the term neurotropic velogenic (NVND). 3) Beaudette's form (41) that appears to be a less pathogenic form of NVND in which deaths usually are seen only in young birds. Viruses causing this type of infection are of the mesogenic pathotype and

Table 3.1.   Prototype viruses and host range of avian paramyxoviruses.

Prototype virus strain	Usual natural hosts	Other hosts	Disease produced in poultry
APMV-1—Newcastle disease virus	Numerous	See text	Varies from extremely pathogenic to inapparent, depending on strain and host infected
APMV-2/chicken/California/Yucaipa/56	Turkeys, passerines	Chickens, psittacines, rails	Mild respiratory disease or egg production problems, severe if exacerbation occurs
(1) APMV-3*/turkey/Wisconsin/68	Turkeys	None	Mild respiratory disease but severe egg production problems worsened by exacerbating organisms or environment
(2) APMV3*/parakeet/Netherlands/449/75	Psittacines, passerines	None known	None known
APMV-4/duck/Hong Kong/D3/75	Ducks	Geese	None known
APMV-5/budgerigar/Japan/Kunitachi/74	Budgerigars	None known	No infections of poultry reported
APMV-6/duck/Hong Kong/199/77	Ducks	Geese, rails, turkeys	Mild respiratory disease and slightly elevated mortality in turkeys; none in ducks or geese
APMV-7/dove/Tennessee/4/75	Pigeons, doves	Turkeys, ostriches	Mild respiratory disease in turkeys
APMV-8/goose/Delaware/1053/76	Ducks and geese	None known	No infection of poultry reported
APMV-9/domestic duck/New York/22/78	Ducks	None known	Inapparent infection of commercial ducks

*Serological tests may distinguish between turkey and psittacine isolates.

have been used as secondary live vaccines. 4) Hitchner's form (121), represented by mild or inapparent respiratory infections caused by viruses of the lentogenic pathotype, which are commonly used as live vaccines. 5) Asymptomatic-enteric form (166), which is chiefly a gut infection with lentogenic viruses causing no obvious disease. Some live commercial vaccines are of this pathotype.

Definitions and Synonyms

ND has been termed pseudo-fowl pest, pseudovogel-pest, atypische Geflugelpest, pseudo-poultry plague, avian pest, avian distemper, Ranikhet disease, Tetelo disease, Korean fowl plague, and avian pneumoencephalitis.

The nomenclature may also be confusing as sometimes infection of birds with any strain of the NDV may be termed ND. Strictly, ND should be reserved for infections with those viruses falling within the internationally accepted definition. To avoid confusion, the abbreviation vND will be used in this chapter for the disease caused by the defined virulent strains of virus.

Since the early 1980s there has been a continuing panzootic in pigeons. The strain of vNDV responsible has been termed "pigeon paramyxovirus type 1 (PPMV-1)," although this is for pragmatic purposes, and the virus will cause vND in poultry.

Economic Significance

The global economic impact of vND is enormous. Until the emergence of the highly pathogenic Asian H5N1 influenza virus this impact was unsurpassed by any other poultry virus and probably represented a bigger drain on the world's economy than any other animal virus. In developed countries with established poultry industries, not only are outbreaks of vND extremely costly,

but control measures, including vaccination, represent a continuing loss to the industry (158). Even countries free of vND usually face the cost of repeated testing to maintain that status and for the purposes of trade. In many developing countries vND is endemic and, therefore, represents an important limiting factor in the development of commercial poultry production and the establishment of trade links. Many countries rely on village chickens to supply a significant portion of dietary protein in the form of eggs and meat, especially for women and children. The constant losses from vND (227, 234) severely affect the quantity and quality of the food of people on marginal diets. Therefore, the economic impact of vND should not only be measured in direct losses in commerce but in some countries, the effect on human health and loss of potential socioeconomic growth should also be considered.

Public Health Significance

Apart from its contribution to malnutrition, NDV is a recognized human pathogen in its own right. Reports of disease have often been anecdotal but the best substantiated clinical signs in human infections have been eye infections, usually consisting of unilateral or bilateral reddening, excessive lachrymation, edema of the eyelids, conjunctivitis and subconjunctival hemorrhage (60). Infections are usually transient, and the cornea is not affected. There have been less well-substantiated reports that a more generalized infection may sometimes occur resulting in chills, headaches, and fever, with or without conjunctivitis (60). Evidence shows that both vaccinal and virulent [for poultry] strains of NDV may infect and cause clinical signs in humans. Human infections with NDV have usually resulted from direct contact with the virus such as from splashing infective allantoic fluid into

the eye in laboratory accidents; rubbing the eye with hands, etc., contaminated with virus after handling infected birds or their carcasses; and contamination of vaccination personnel especially when vaccines are given by aerosol. Such infections usually can be avoided by basic hygiene and appropriate clothing and eye protection. Casual contact with infected poultry represents a low risk of human infection. No reports exist of human-to-human spread.

History

It is generally considered that the first outbreaks of vND occurred in 1926, in Java, Indonesia (151), and in Newcastle-upon-Tyne, England (77). There are reports of disease outbreaks in Central Europe similar to what we now recognize as vND that predate 1926 (106), and Levine (160), citing Ochi and Hashimoto, indicated that the disease may have been present in Korea as early as 1924. Macpherson (163) considered the death of all the chickens in the Western Isles of Scotland in 1896 to be attributable to vND.

The name "Newcastle disease" was coined by Doyle as a temporary measure because he wanted to avoid a descriptive name that might be confused with other diseases (78). No better name has evolved over the past 75 years, although for the virus the synonym avian paramyxovirus type 1 (APMV-1) has gained some popularity in recent years. In fact, APMV-1 is often used to describe the low virulent strains to avoid using Newcastle disease that, according to definitions used by the World Organization for Animal Health and other international agencies, should be reserved for virulent viruses.

Some years after the 1926 outbreaks and recognition of the virus etiology, it became clear that other less severe diseases were caused by viruses indistinguishable from NDV by conventional methods. In the United States, a relatively mild respiratory disease, often with nervous signs, was first described in the 1930s and subsequently termed *pneumoencephalitis* (34). It was shown to be due to a virus indistinguishable from NDV in serologic tests (35). Within a few years, numerous NDV isolations that produced extremely mild or no disease in chickens were made around the world (29, 121, 166, 228).

The history of Newcastle disease in most countries has not been well-documented. Alexander (11) recorded the history in Great Britain in detail and considered it a good example of the effect that Newcastle disease may have on the poultry industry in a developed Western country.

Etiology

Classification

See "Introduction" at the beginning of this chapter.

Morphology

Negative contrast electron microscopy of NDV reveals very pleomorphic virus particles typical of members of the *Paramyxovirinae* subfamily. Generally, they are rounded and 100–500 nm in diameter, although filamentous forms of about 100 nm across
3.1. Negative contrast electron micrograph of Newcastle disease virus strain Ulster 2C showing a partially disrupted particle with nucleocapsid emerging. ×202,000, bar = 100 nm. (Collins)

and of variable length are often seen. The surface of the virus particle is covered with projections about 8 nm in length. In most electron micrographs, the "herring bone" nucleocapsid, about 18 nm across and showing helical symmetry, may be seen either free or emerging from disrupted virus particles (Fig. 3.1).

Chemical Composition

Paramyxoviruses characteristically consist of a single molecule of single-stranded RNA of about 5×10^6 molecular weight (148), which makes up about 0.5% by weight of the virus particle. Nucleotide sequencing of the NDV genome has shown it to consist of 15,186 nucleotides (200), although strains with 15,192 (126) and 15,198 (75) nucleotides have been described.

Virus particles have about 20–25% w/w lipid derived from the host cell and about 6% w/w carbohydrate. The overall molecular weight for an average virus particle is about 500×10^6, with a density in sucrose of 1.18–1.20 g/mL.

The six genes forming the genome of NDV code for seven proteins (154) are as follows: L protein is the RNA-directed RNA polymerase associated with the nucleocapsid; HN is responsible for the hemagglutinin and neuraminidase activities, forming the larger of the two types of projections seen on the surface of paramyxovirus particles; F, fusion protein, forms the smaller of the surface projections; NP, nucleocapsid protein; P, phosphory-

lated, nucleocapsid-associated, the P gene has an overlapping reading frame that codes for the cysteine-rich V protein; and M, matrix. The order of the genes for these proteins in the virus genome is 3′NP/V-M-F-HN-L5′. The host protein actin is also incorporated into virus particles.

Biologic Properties

Several biologic properties are associated with paramyxoviruses, which characterize the group.

Hemagglutination Activity

The ability of NDV and other avian paramyxoviruses to agglutinate red blood cells (RBCs) is due to the binding of the hemagglutinin-neuraminidase (HN) protein to receptors on the surface of the RBCs. This property and the specific inhibition of agglutination by antisera (57) have proven to be powerful tools in the diagnosis of the disease.

Chicken RBCs usually are used in hemagglutination (HA) tests, but NDV will cause agglutination of all amphibian, reptilian, and avian cells (156). Winslow *et al.* (260) showed that human, mouse, and guinea pig RBCs were agglutinated by all NDV strains tested, but the ability to agglutinate cattle, goat, sheep, swine, and horse cells varied with the strain of NDV. Other avian paramyxoviruses also appear to be able to agglutinate a wide range of RBCs, but the exact range may vary with isolate as well as serotype. Paramyxoviruses will agglutinate cells other than RBCs if they possess the correct receptors.

Neuraminidase Activity

The enzyme neuraminidase (mucopolysaccharide *N*-acetyl neuraminyl hydrolase EC 3.2.1.18) is also part of the HN molecule. An obvious consequence of the possession of this enzyme is the gradual elution of agglutinated RBCs (3). The exact function of the neuraminidase in virus replication is unknown, but it seems likely that neuraminidase removes virus receptors from the host cell which prevents the reattachment of released virus particles and virus clumping.

Cell Fusion and Hemolysis

NDV and other paramyxoviruses may bring about hemolysis of RBCs or fusion of other cells by essentially the same mechanism. Attachment at the receptor site during replication is followed by fusion of the virus membrane with the cell membrane, which may result in the fusion of two or more cells (similar to the syncytial formation that occurs when virus particles are budded from cells). The rigid membrane of the RBCs usually results in lysis from the virus membrane fusion.

Virus Replication

The strategy for replication employed by NDV is that of the negative strand viruses in general and avulaviruses specifically (154, 198).

The initial step is attachment of the virus to cell receptors, mediated by the HN polypeptide. Fusion of the viral and cell membranes is brought about by action of the fusion (F) protein, and, thus, the nucleocapsid complex enters the cell.

Intracellular virus replication takes place entirely within the cytoplasm. Because the virus RNA has negative sense, the viral RNA-directed RNA-polymerase (transcriptase) must produce complementary transcripts of positive sense that may act as messenger RNA and use the cell's mechanisms, enabling the translation into proteins and virus genomes. The F protein is synthesized as a nonfunctional precursor, F0, that requires cleavage to F1 and F2 by host proteases. The significance of this cleavage in the pathogenicity of NDV strains is discussed later in this chapter. The HN of some strains of NDV may also require posttranslational cleavage.

The viral proteins synthesized in an infected cell are transported to the cell membrane, which becomes modified by their incorporation. Following the alignment of the nucleocapsid close to modified regions of the cell membrane, virus particles are budded from the cell surface.

Susceptibility to Physical and Chemical Agents

The infectivity of NDV and other avian paramyxoviruses may be destroyed by physical and chemical treatments such as heat, irradiation (including light and ultraviolet rays), oxidation processes, pH effects, and various chemical compounds. The rate at which infectivity is destroyed depends on the strain of virus, the length of time of exposure, the quantity of virus, the nature of the suspending medium, and the interactions between treatments. No single treatment can guarantee destruction of all viruses but may result in a low probability of infective virus remaining. Lancaster (157) and Beard and Hanson (38) provide detailed reviews of the early work.

Knowledge of the heat inactivation of vND is important because the virus is likely to be present in meat and other products obtained from infected poultry. The Terrestrial Animal Health Code of the World Organisation for Animal Health allows international trade in processed poultry products, even from countries with enzootic vND, but merely states that these products should "have been processed to ensure the destruction of the ND virus" (190). Alexander and Manvell (14) have produced data on the inactivation of vNDV strain Herts 33 in artificially infected chicken meat homogenate and obtained the following D_t values (i.e., the time taken to reduce the virus titer by 90 percent or 1 $\log_{10}$ at the specified temperatures): 65°C 120 secs, 70°C 82 secs, 74°C 40 secs, and 80°C 29 secs.

Egg products also represent a hazard when derived from eggs laid by infected hens. Gough (98) studied the inactivation of vNDV in liquid whole egg, and from the data published in that study, Alexander and Chettle (13) deduced that the D_t value for strain Beaudette C (a strain considered to show some heat resistance) in liquid whole egg was 38 secs at a temperature of 64.4 °C. Although not calculating D_t values, King (142) obtained data that suggested for strains Ulster and California/1083/72 very much longer survival in albumen or yolk at 57°C. In a more comprehensive study using two low virulence strains, Ulster and B1, and the vNDV strain California/02, Swayne and Beck (240) conducted a series of experiments aimed at assessing the heat inactivation of ND viruses in various egg products at temperatures

used commercially. They concluded that commercial pasteurization processes are likely to reduce any infectious ND virus present to an acceptable level, but stress that little data exists on the titers of virus likely to be present in eggs.

Strain Classification

The term *strain* is generally used to mean a well-characterized isolate of the virus. The important objective in characterizing viruses is to group similar viruses. For NDV isolates, this has inevitably meant the distinction between viruses of high and low virulence for chickens or perhaps more pertinently between enzootic and epizootic viruses.

Pathogenicity tests are useful markers and guides to the importance of the isolate. They do not indicate epizootiologic links between strains with the same virulence. Certain unrelated biologic properties of viruses have been shown to vary with different strains and isolates, and these properties have been used to characterize and group isolates.

Antigenicity

Virus neutralization (VN) or agar gel diffusion techniques have shown minor antigenic variations between different strains and isolates of NDV (97, 199, 224). For all practical purposes, however, isolates of NDV have been considered to represent a single antigenically homogeneous group.

Monoclonal antibodies (MABs) have been employed to demonstrate antigenic variation of NDV strains and isolates (2, 17, 20, 79, 124, 128, 155, 173, 186, 216, 235).

Monoclonal antibodies may detect slight variations in antigenicity, such as single amino acid changes at the epitope to which the antibody is directed. As a result, they can detect differences not only between strains but between subpopulations of virus (111). Some workers have used MABs to distinguish between specific viruses. For example, two groups have described MABs that distinguish between the common vaccine strains, Hitchner B1 and La Sota (79, 173), and other MABs can separate vaccine viruses from epizootic virus in a given area (235).

The most comprehensive use of MABs for strain characterization and classification has been by Russell and Alexander (216) and Alexander *et al.* (17, 19, 20, 21). They used MABs to place strains and isolates of NDV into groups on the basis of their ability to react with the different MABs. Viruses in the same MAB group shared biologic and epizootiologic properties. Russell *et al.* (219) pointed out the similarity between groups of viruses formed on a genetic basis and those formed on the basis of similarities in antigenicity detected using MABs.

Monoclonal antibody typing was also used to establish the uniqueness of the variant NDV responsible for the pigeon panzootic and to confirm its presence in many countries (17, 20, 196).

Pathogenicity Tests

The first attempt to distinguish between or to group isolates by a laboratory test was by assessment of virulence. Hanson and Brandly suggested that strains of NDV could be conveniently grouped as "velogenic," "mesogenic," and "lentogenic" based on chicken embryo mortality at less than 60 hr, 60–90 hr and greater than 90 hr, respectively, after allantoic inoculation (112). The values obtained provided a guide to the disease produced in infected chickens. These terms have come to be applied to high-virulence, moderate-virulence, and low-virulence viruses regardless of the method of assessment.

Other tests devised to distinguish between strains give a direct assessment of the clinical signs or deaths in infected birds. This assessment enables quantification by designating scores according to the degree of severity and calculating a pathogenicity index. The most widely used tests are the intracerebral pathogenicity index (ICPI) in day-old chicks and the intravenous pathogenicity index (IVPI) in 6-week-old chickens. The ICPI test is required by the World Organisation for Animal Health (OIE) for the *in vivo* determination of virus virulence (see below).

Genetic Characterization

Improved techniques for nucleotide sequencing, the availability of sequence data of more ND viruses placed in computer databases, and the demonstration that even relatively short sequence lengths could give meaningful results in phylogenetic analyses have essentially led to the establishment of genetic characterization of NDV strains in recent years. Particular attention has been paid to the fusion gene as this lends itself to virulence predictions. Considerable genetic diversity has been detected, but viruses sharing temporal, geographical, antigenic, or epidemiological parameters tend to fall into specific lineages or clades, and this has proven valuable in assessing both the global epidemiology and local spread of NDV (7, 24, 67, 117, 144, 145, 162, 221, 225, 226, 241, 246). Aldous *et al.* (7) proposed that genotyping of NDV isolates should become part of the diagnostic virus characterization for reference laboratories by producing a 375-nucleotide sequence of the F gene, which includes the F0 cleavage site, routinely for all viruses and comparing the sequences obtained with other recent isolates and 18 viruses representative of the recognized lineages and sublineages.

One interesting observation is that viruses with specific genetic characteristics do not necessarily disappear as other variants arise and may continue to be isolated many years after their first appearance (162).

Although less data exist than for F, the sequences of the HN gene for several strains have been determined. An HN0 precursor protein is produced for some strains (i.e., Ulster 2C (180) and D26 (222)) but not others (i.e., the lentogenic Hitchner B1 (134); mesogenic Beaudette C (179); two velogenic strains, Australia Victoria (168) and Italien (253); and the pigeon variant virus (66), which all have termination codons located before the end of the HN gene so the HN0 protein is not produced, and posttranslational cleavage is not required). In certain circumstances, this potential extension has been used to distinguish between endemic viruses of low virulence and other viruses (88).

Laboratory Host Systems
Animals

NDV can infect and multiply in a range of nonavian (156) as well as avian (136) species following laboratory infection. The chicken, however, remains the most readily available and fre-

quently used laboratory animal, as well as the most important natural host of the disease.

Chicken Embryos

All avian paramyxoviruses replicate in embryonated chicken eggs. Because of their availability (especially from specific pathogen-free sources), their sensitivity for virus growth, and the high titers to which viruses grow in them, they are generally used for virus isolation and propagation.

Newcastle disease virus strains and isolates vary in their capacity and time taken to kill chick embryos. Virus titers are also influenced by strain, with the highest titers obtainable by those causing slow or no embryo death (100). With some strains, embryo death and virus growth are affected by the presence of maternal antibodies in the yolk (86).

The route of inoculation is also important (38). Inoculation of NDV via the yolk sac, as compared with the allantoic cavity, produced more rapid embryo deaths and caused deaths by strains that do not consistently kill by the latter route (82).

Cell Cultures

Newcastle disease virus strains can replicate in an enormous range of cells. For example, Lancaster (156) listed 18 primary cell types and 11 cell lines as susceptible. Many more have been added to the list since his 1966 report. Cytopathic effects (CPE) are usually the formation of syncytia with subsequent cell death, with the CPE having some relationship to the strain's virulence for chickens (205). Plaque formation in chick embryo cells is restricted to velogenic and mesogenic viruses unless Mg^{2+} ions and DEAE (33) or trypsin (212) are added to the overlay.

Because of relatively poor growth of NDV in most cell culture systems, they are impracticable for virus propagation for most purposes.

Pathogenicity

The virulence of NDV strains varies greatly with the host. Chickens are highly susceptible, but ducks may be infected and show few or no clinical signs, even with strains lethal for chickens (118).

In chickens, the pathogenicity of ND is determined chiefly by the strain of virus, although dose, route of administration, age of the chicken, and environmental conditions all have an effect. In general, the younger the chicken, the more acute the disease. With virulent viruses in the field, young chickens may experience sudden deaths without major clinical signs; however, in older birds the disease may be more protracted and with characteristic clinical signs. Breed or genetic stock does not appear to have a significant effect on the susceptibility of chickens to the disease (64). Natural routes of infection (nasal, oral, and ocular) appear to emphasize the respiratory nature of the disease (37), and intramuscular, intravenous, and intracerebral routes appear to enhance the neurologic signs (38).

Molecular Basis for Pathogenicity

During the replication of NDV, the functionally important fusion protein is produced as a precursor glycoprotein, F0, which has to be cleaved to F_1 and F_2 for the progeny virus particles to be infectious (213). This posttranslation cleavage is mediated by host cell proteases (182). If cleavage fails to take place, noninfectious virus particles are produced. Trypsin can cleave F0 for all NDV strains, and *in vitro* treatment of noninfectious virus will restore infectivity (183).

The importance of F0 cleavage was easily demonstrated, because viruses normally unable to replicate or produce plaques in cell culture systems were able to do both if trypsin was added to the agar overlay or culture fluid. Although all viruses could replicate and produce infectious progeny in the allantoic cavity, the viruses pathogenic for chickens could replicate in a wide range of cell types *in vitro* with or without added trypsin, whereas strains of low virulence could replicate only when trypsin was added (211, 212). Thus, F0 molecules of virulent viruses can be cleaved by a host protease or proteases found in a wide range of cells and tissues, but F0 molecules in viruses of low virulence were restricted in their sensitivity to cleavage by specific host enzymes. Consequently these viruses can grow only in certain host cell types.

Early reports of the deduced amino acid sequences of the F0 precursor, obtained from nucleotide sequencing of the F gene for a number of NDV strains (59, 65, 94, 168, 178, 223, 245), enabled comparison of viruses of low virulence to those that were velogenic or mesogenic. For all viruses, the amino acid at residue 116, the C terminus of the F2 protein at the site of cleavage, was arginine. The viruses of low virulence all had leucine at residue 117, the N-terminus of the F1 protein, and another basic amino acid at residue 113. In contrast, all velogenic or mesogenic viruses had phenylalanine at residue 117 and, with one exception, basic amino acids at residues 115 and 112 in addition to those at 113 and 116. The exception was the pigeon variant PMV-1 virus, which was identical to the virulent viruses but lacked a basic amino acid at position 112. Further studies have indicated that this variation was usual for pigeon variant PMV-1 viruses but had no significance in the variability of pathogenicity for chickens recorded with these viruses (66).

Thus, it would appear that the mechanism controlling the pathogenicity of NDV is very similar to that described for influenza viruses (251). The presence of additional basic amino acids in virulent strains means that cleavage can be effected by protease or proteases present in a wide range of cell types in different host tissues and organs. This ubiquitous enzyme has not been fully identified, but as with avian influenza viruses, it is likely to be one or more proprotein-processing, subtilisin-related endoprotease[s] of which furin is the leading candidate (87, 238). For lentogenic viruses, cleavage can occur only with proteases recognizing a single arginine, i.e., trypsin-like enzymes. Lentogenic viruses, therefore, replicate only in cells where there are trypsin-like enzymes, such as the respiratory and intestinal epithelia, whereas virulent viruses can replicate in cells located in a wide range of tissues and organs, resulting in a fatal systemic infection (211).

As more sequence data have become available, a degree of variation at the F0 cleavage site has become apparent. The reported cleavage site motifs are listed in Table 3.2. During the in-

tense investigations and surveillance work following the outbreaks of ND in Australia during 1998–2000, several viruses showing variation in the amino acids at the F0 cleavage site were isolated (254). These, too, are presented in Table 3.2. The variations in these naturally occurring viruses confirm that the minimum requirement for ND viruses to show high virulence for chickens appears to be the motif ^{113}RXR/KR*F^{117}. The reason for the absolute requirement for phenylalanine at position 117 is unclear and may not be part of the recognition motif of the ubiquitous protease. Studies to determine the precise minimum amino acid motif at the F0 cleavage site to confer virulence have been undertaken using cDNA clones of NDV and reverse genetics techniques (198). De Leeuw *et al.* (76) generated a range of viruses with substituted amino acids at the F0 cleavage site (Table 3.2). They concluded that virulence required F at position 117, R at 116, K or R at 115, and R not K at 113. Interestingly, all their generated mutants reverted to the virulent motifs ^{112}RRQRR*F^{117} or ^{112}RRQKR*F^{117} after a single passage in chicks.

Although the cleavage site amino acid sequence of the F0 protein is an excellent guide to real or potential virulence of ND viruses, remember that other factors associated with other virus genes and proteins might cause variation in virulence. For example, using reverse genetic techniques, it has been demonstrated that the HN protein may influence the virulence (125, 209).

Emergence of Virulent Viruses
The greater understanding of the molecular basis for virulence has given an insight into how viruses that cause vND may emerge. Hanson (108, 109) put forward three suggestions to account for the sudden emergence of virulent NDV: 1) The virus had always been in poultry, but was unnoticed until the development of commercial poultry industries; 2) the virulent virus was enzootic in another species in which it showed less severe disease; and 3) the virulent virus arose from virus of low virulence by mutation.

Until recent years the consensus opinion has been that the second explanation was the most likely. The first was considered possible but unlikely due to the widespread outbreaks of vND now seen regularly in backyard and village chickens in some parts of the world. The third was considered unlikely because there were no reports of other viruses mutating to virulence in this way, and the degree of genetic change needed would be too large for simple mutation.

The second explanation was apparently supported by the finding during the 1970–73 panzootic that virus was introduced into some geographical areas by the movement of captive caged birds, especially psittacine species (85, 250), which show some resistance to the viruses virulent for chickens (80, 81). Although captive caged birds have often been shown to be infected with virulent NDV (192, 228), it has been suggested this may be a result of contact with infected poultry (136). Equally, apart from cormorants in North America (152) and possibly pigeons, reports of reservoirs of virulent NDV in wild birds have been lacking.

The first hint that the third explanation, that virulent viruses arise by mutation from viruses of low virulence, may account for

Table 3.2. Amino acid sequences at the F0 cleavage site of NDV strains.

the emergence of virulent NDV came from studies on viruses responsible for vND outbreaks in Ireland in 1990. These viruses were shown to be closely related to variant viruses of low virulence usually isolated from waterfowl, but both were antigenically and genetically distinct from all other NDVs (21, 67). The virulent viruses showed four differences in the nucleotides of the part of the F gene coding for amino acids 112 to 117, three of these resulting in a change to the assumed minimum motif for virulence, and the fourth giving a lysine at 112 (11). Much better evidence for mutation to virulence has come from the 1998–2000 vND outbreaks in Australia (146, 254). Phylogenetic studies showed the virulent viruses responsible for the outbreaks in Australia in 1998 and 1999 to be extremely closely related to each other and to a virus of low virulence isolated from chickens in the same geographical area (103). This suggested that the virulent virus emerged by mutation, which, as shown in Table 3.3, in this instance required only two point mutations. Furthermore, viruses

showing other changes at the cleavage site, including those intermediate to the two viruses were isolated (Table 3.2). The overwhelming probability is that the virulent ND viruses emerging in Australia in 1998 were the result of mutation from viruses of low virulence, and there is no reason to suppose that other similar mutations have not taken place in the past. Shengqing *et al.* (229) produced experimental evidence that supported the emergence of virulent ND viruses from those of low virulence. They showed that a waterfowl isolate of low virulence, with the F0 cleavage site sequence ERQER*L, passed through chickens nine times by the air sac inoculation route and then given five passages by inoculation intracerebrally, became extremely virulent for chickens with the F0 cleavage site sequence KRQKR*F.

Pathobiology and Epidemiology

Incidence and Distribution

The almost universal use of ND vaccines in commercial poultry throughout the world makes assessment of the true geographic distribution of Newcastle disease (i.e., in terms of birds infected with virulent virus) difficult. Equally, often a distinction is made between ND in commercial poultry and village and backyard chickens when reporting outbreaks. Even though international monitoring of Newcastle disease is carried out by agencies such as the Food and Agriculture Organization of the United Nations (84) and the World Organisation for Animal Health, the figures produced may not represent the true distribution of vND.

No doubt exists that vND is either enzootic or a cause of regular epizootics in poultry throughout most of Africa, Asia, Central America, and parts of South America. In more developed areas, such as Western Europe, sporadic epizootics occur on a fairly regular basis despite the widespread use of vaccination.

The distribution of vND is dependent on the attempts at eradication and control made in different countries. The success of such measures is, in turn, dependent on the nature of the poultry industry (i.e., countries with mostly village chicken flocks have far greater problems than those with mostly large commercial flocks).

The nature of the spread of vND also affects the distribution. Alexander (11) considered that probably four panzootics of vND had occurred since the first recognition of the disease. The first panzootic represented the initial outbreaks of disease and appears to have arisen in Southeast Asia. Doyle (78) considered that the disease moved slowly through Asia to Europe and that isolated

outbreaks such as in England in 1926 were chance introductions ahead of the mainstream. This theory of panzootic spread of vND would mean that the virus, which had apparently arisen in 1926, took more than 30 years to spread worldwide and was still important in most countries in the early 1960s.

In marked contrast, the second panzootic appears to have begun in the Middle East in the late 1960s and to have reached most countries by 1973. The more rapid spread of the second panzootic could be because the poultry industry had undergone a major revolution in that it had developed into a major commercial industry with considerable international trade. In addition, the virus responsible for this panzootic appeared to be associated with an imported caged psittacine species. The enormous trade in these birds, which involved rapid, airborne shipments, was considered to be a major factor in the spread of the disease (85, 250).

The serious effects of the second panzootic on the poultry industries of most countries led to the development of vaccines and regimens that provided significant protection to poultry. In addition, most countries imposed new control measures for the importation of exotic caged birds. Alexander (11) considered that antigenic and genetic evidence (21, 162) indicates that there was probably worldwide spread of a third virulent virus during the late 1970s. The start and spread of this third panzootic are unclear, presumably as a result of the almost universal use of vaccines since the mid 1970s, which would have protected birds from disease but in most cases allowed replication and spread of the virus. Monitoring of viruses responsible for panzootics is further complicated, as it would appear that viruses with specific genetic or antigenic characteristics do not necessarily disappear, as other variants arise and may continue to be isolated many years after their first appearance (21, 162).

Another group of domesticated birds that was generally ignored as a potential source of vND, however, existed in large numbers in most countries. This group consisted of the pigeons and doves (*Columba livia*) that are kept for racing, show, or food purposes; in most European countries, this group may represent populations of several million birds. These were the birds primarily affected by the fourth panzootic of vND. The disease, which resembled the neurotropic form in chickens but without respiratory signs, apparently arose in the Middle East in the late 1970s (137). By 1981, it had reached Europe (45) and then spread rapidly to all parts of the world, largely as a result of contact between birds at races and shows and the large international trade in such birds. The variant nature of the virus enabled unequivocal demonstration of infection in 24 countries (17, 20, 196). Spread to chickens has occurred in several countries including Great Britain where 20 outbreaks in unvaccinated chickens occurred in 1984 as a result of feed that had been contaminated by infected pigeons (18). The disease in pigeons has been recognized for over 25 years but still seems to remain enzootic in racing pigeons in many countries, with regular spread to wild pigeons and doves and a continuing threat to poultry.

Natural and Experimental Hosts

From the available literature, Kaleta and Baldauf (136) concluded that in addition to the domestic avian species, natural or

experimental infection with NDV has been demonstrated in at least 241 species from 27 of the 50 orders of birds. These authors stressed the variation in severity of clinical signs, even with different species of a genus. Since that review, the number of species from which NDV has been isolated, with or without clinical signs, has greatly increased. It seems reasonable to conclude that the vast majority of, if not all, birds are susceptible to infection, but the disease seen with any specified strain of virus may vary considerably with host.

Transmission

In reviewing the modes of transmission of NDV between birds, Alexander (9) concluded that infection may take place by either inhalation or ingestion and that spread from one bird to another depends on the availability of the virus in an infectious form. It is tempting to assume that NDV is primarily transmitted by fine aerosols or large droplets that are inhaled by susceptible birds. Experimental evidence to prove this conclusively is, however, lacking. It is clear that infectious virus may be present in aerosols and that birds placed in an atmosphere containing such aerosols become infected. This is the basis for mass application of live vaccines by spray and aerosol generators (170). In naturally occurring infections, large and small droplets containing virus will be liberated from infected birds as a result of replication in the respiratory tract or as a result of dust and other particles, including feces. These virus-laden particles may be inhaled or impinge upon the mucous membranes, resulting in infection. The ability of such aerosols to form and to support infectious virus for a sufficient period for transmission, however, depends on many environmental factors.

During the course of infection of most birds with NDV, large amounts of virus are excreted in the feces. Ingestion of feces results in infection; this is likely to be the main method of bird-to-bird spread for avirulent enteric NDV and the pigeon variant virus (16), neither of which normally produces respiratory signs in infected birds. In experiments in which the virus was presented to the back of the buccal cavity, it was suggested that doses of vNDV as high as 10^4 EID$_{50}$ may be required to infect 3-week-old chickens by this route, which represented perhaps as much as a gram of feces (22).

Vertical transmission (i.e., passing of virus from parent to progeny via the embryo) remains controversial. The true significance of such transmission in epizootics of ND is not clear. Experimental assessment using virulent viruses is usually hampered by cessation of egg laying in infected birds. Infected embryos have been reported during naturally occurring infections of laying hens with virulent virus (38, 157), but this generally results in the death of the infected embryo during incubation. Cracked or broken infected eggs may serve as a source of virus for newly hatched chicks, as may virus-laden feces contaminating the outside of eggs. Virus may also penetrate the shell after laying (257), further complicating the assessment of true vertical or transovarian transmission. Infected chicks may be hatched from eggs infected with vaccinal or other lentogenic viruses that do not necessarily cause death of the embryo (68, 86). In naturally occurring infections, it is not clear how the embryos become infected, although La Sota vaccine has been shown to be present in most of the reproductive organs after vaccination (204).

Pospisil et al. (201) were able to demonstrate the presence of lentogenic virus in chick embryos and young progeny, including day-old chicks, of a vaccinated laying flock. Capua et al. (58), investigating the unexpected isolation of virulent virus from chick embryos, were able to isolate virulent NDV from cloacal swabs taken from the birds that had laid the eggs, despite high antibody titers to NDV, and from their hatched progeny. In experiments, Chen and Wang (61) demonstrated that when SPF eggs were infected with very low doses of vNDV not all the embryos died, and virus could be isolated from a small number of hatched chicks.

Spread

Lancaster and Alexander (9, 156, 157) reviewed the modes of spread of NDV. The following virus sources or methods have been implicated in various epizootics: 1) movement of live birds: feral birds, pet/exotic birds, game birds, racing pigeons, and commercial poultry; 2) contact with other animals; 3) movement of people and equipment; 4) movement of poultry products; 5) airborne spread; 6) contaminated poultry feed; 7) contaminated water; and 8) vaccines.

The importance of any of these factors will depend on the situation in which the epizootic occurs. In countries where poultry are kept exclusively in birdproof housing, the ability of feral birds to invade affected flocks and transfer the disease will be minimal, whereas birds kept on open range are more likely to be infected with strains carried by feral birds. In Canada and the northern United States, outbreaks of vND occurred in double-crested cormorants and pelicans in 1990 and 1992 (31, 247, 262), and sporadic outbreaks in cormorants have continued since that time. A virus, indistinguishable from the cormorant viruses using MAB panels and essentially the same genetically, was also isolated from turkeys showing signs of neurotropic velogenic ND that had been kept on range in North Dakota in the vicinity of diseased cormorants from which vNDV had been isolated (225, 247). Further studies resulted in the isolation of vND virus from cormorants on their wintering grounds in Florida, in 2002 (28). Nucleotide sequencing of a portion of the F gene of this virus showed 100% deduced amino acid for that part of the F protein with the 1992 North U.S. cormorant virus and the isolate from turkeys.

It was also thought that the 11 outbreaks confirmed in chickens and turkeys in Great Britain between early January and late April 1997 (23) may have been the result of primary introduction of the causative virus by migratory birds. Epidemiological investigations suggested that most of the outbreaks were the result of secondary spread by humans from one or two primary introductions. However, nucleotide sequencing and phylogenetic analysis showed very close similarity between the British isolates and the viruses responsible for vND outbreaks in Scandinavian countries in 1996, including an isolate from a feral goosander (24). The unusual patterns of movement of migratory birds at the end of 1996 and the beginning of 1997 suggest that they may have been the vehicle for the primary introduction of the vND virus into Great Britain.

In spite of continuing international trade in exotic caged birds and the frequent isolation of virulent NDV from such birds (228), the threat of introduction and spread by this source (as in the California epizootic in 1971–1972) (248) has been greatly reduced by strict importation quarantine procedures. However, smuggled birds or those removed prematurely from quarantine may still pose a threat (228); since 1973, virulent NDV has been isolated regularly from pet birds imported illegally or held in quarantine in the United States (192). There was particular concern in 1991 when outbreaks occurred in illegally imported pet birds in six states (56, 192); however, there was no spread to poultry.

Backyard game fowl (fighting cocks) have been involved in outbreaks of vND in the United States on three occasions, 1975, 1998, and 2002–2003 (32, 140, 147). The most notable outbreak occurred in southern California in 2002–2003 (140) in which more than 149,000 birds in 2,671 premises were destroyed to control the disease. The mobility and value of such birds increase the risk of spreading ND during outbreaks of disease because owners seek to avoid quarantine or possible destruction of the birds by regulatory authorities. It is suspected that the spread of vND from southern California to adjacent states of Nevada and Arizona was due to the movement of infected birds or contaminated materials. Although initially the disease was present primarily in backyard game fowl, the disease spread to 21 commercial table–egg layer flocks (3 million birds) in southern California. The highest risk factors for infected commercial flocks were the farm employees and proximity to infected backyard game fowl.

Airborne spread has been considered to be important in some epizootics such as the 1970–1971 outbreaks in England (127) but unimportant in others such as the 1971–1972 California outbreaks (248), even though the same virus appears to have been involved. In more recent outbreaks, airborne spread has generally not been considered to contribute to any spread that has occurred.

In some cases, more than one factor combines in the spread of the disease. For example, the 1984 outbreaks of vND in Great Britain were considered to be spread by feed that had been contaminated by infected feral pigeons (18).

Without doubt, the greatest potential for spread of NDV is by humans and their equipment. Humans may be infected in the conjunctival sac with NDV, and this could pose a method of spread, but a more probable method is the mechanical transfer of infective material (most probably feces). Modern transportation enables personnel to travel rapidly to any country in the world, so spread by humans should not be treated as merely a local or national threat.

Vaccination crews moving from farm to farm have been implicated in the spread of NDV (248), as have incomplete inactivation (233) and contamination of vaccines (40, 135).

Incubation Period

The incubation period of ND after natural exposure has been reported to vary from 2–15 days (average 5–6). The speed with which signs appear, if at all, is variable depending on the infecting virus, the host species and its age and immune status, infec-

tion with other organisms, environmental conditions, the route of exposure, and the dose.

Clinical Signs

Newcastle disease virus isolates can be broadly grouped into pathotypes on the basis of clinical signs, which in turn are affected by the strain of virus. Other factors also important in establishing the severity of the disease are the host species, host age, host immune status, coinfection with other organisms, environmental stress, social stress, route of exposure, and the virus dose (166).

With extremely virulent viruses, the disease may appear suddenly, with high mortality occurring in the absence of other clinical signs. In outbreaks in chickens due to the VVND pathotype, clinical signs often begin with listlessness, increased respiration, and weakness, ending with prostration and death. During the panzootic caused by this type of virus in 1970–1973, disease in some countries such as Great Britain (27) and Northern Ireland (166) was marked by severe respiratory signs, but in other countries these were absent. This type of vND may cause edema around the eyes and head. Green diarrhea is frequently seen in birds that do not die early in infection, and prior to death, muscular tremors, torticollis, paralysis of legs and wings, and opisthotonos may be apparent. Mortality frequently reaches 100% in flocks of fully susceptible chickens.

The neurotropic velogenic form of ND has been reported mainly in the United States. In chickens, it is marked by sudden onset of severe respiratory disease followed a day or two later by neurologic signs. Egg production falls dramatically, but diarrhea is usually absent. Morbidity may reach 100%. Mortality is generally considerably lower, although up to 50% in adult birds and 90% in young chickens have been recorded.

Mesogenic strains of NDV usually cause respiratory disease in field infections. In adult birds, there may be a marked drop in egg production that may last for several weeks. Nervous signs may occur but are not common. Mortality in fowl is usually low, except in very young and susceptible birds, but may be considerably affected by exacerbating conditions.

Lentogenic viruses do not usually cause disease in adults. In young, fully susceptible birds, serious respiratory disease problems can be seen, often resulting in mortality, following infection with the more pathogenic La Sota strains complicated by infections with one or more of a range of other micro-organisms. Vaccination or infection of broilers close to slaughter with these viruses can lead to colisepticemia or airsacculitis, with resulting condemnation.

The virus responsible for the panzootic in pigeons during the 1980s induced clinical signs in field infections of pigeons (249) and chickens (18) unlike those from other viruses. In both species, the predominant clinical features were diarrhea and nervous signs. In adult chickens, precipitous falls in egg production were seen, and high mortality was recorded in younger birds. This virus did not induce respiratory signs in uncomplicated infections of pigeons or chickens.

The clinical signs produced by specific viruses in other hosts may differ widely from those seen in chickens. In general, turkeys

are as susceptible as chickens to infection with NDV, but clinical signs are usually less severe (25, 50, 166). Although readily infected, ducks and possibly geese usually are regarded as clinically resistant even to the strains of NDV most virulent for chickens. However, outbreaks of severe disease in ducks infected with NDV have been described (118). Outbreaks of vND have been reported in most game bird species (156, 157), and the disease appears similar to that in chickens (43). In ostriches and other ratites, ND viruses virulent for chickens do not produce such pathogenic disease. Generally young ostrich chicks may show depression and nervous signs, but adults appear unaffected (10).

Pathology

Gross Lesions

As with clinical signs, the gross lesions and the organs affected in birds infected with NDV are dependent on the strain and pathotype of the infecting virus, in addition to the host and all the other factors that may affect the severity of the disease. No pathognomonic lesions are associated with any form of the disease. Gross lesions may also be absent.

Nevertheless, the presence of hemorrhagic lesions in the intestine of infected chickens has been used to distinguish VVND viruses from NVND viruses. (110, 113). These lesions are often particularly prominent in the mucosa of the proventriculus, ceca, and small and large intestine. They are markedly hemorrhagic and appear to result from necrosis of the intestinal wall or lymphoid tissues such as cecal tonsils and Peyer's patches.

Generally, gross lesions are not observed in the central nervous system of birds infected with NDV, regardless of the pathotype (166).

Gross pathologic changes are not always present in the respiratory tract, but when observed they consist predominantly of mucosal hemorrhage and marked congestion of the trachea (12). Airsacculitis may be present even after infection with relatively mild strains, and thickening of the air sacs with catarrhal or caseous exudates is often observed in association with secondary bacterial infections (38).

Gross pathology seen in other organs includes hemorrhage in the lower conjunctiva, focal necrosis of the spleen, and paratracheal edema, most generally observed near the thoracic inlet.

Chickens and turkeys infected in lay with velogenic viruses usually have egg yolk in the abdominal cavity. The ovarian follicles are often flaccid and degenerative. Hemorrhage and discoloration of the other reproductive organs may occur.

Gross lesions of velogenic viscerotropic Newcastle disease in susceptible chickens inoculated by the eye drop route are illustrated in Figure 3.2.

Microscopic Lesions

The histopathology of NDV infections is as varied as the clinical signs and gross lesions and can be affected greatly by the same parameters. In addition to the strain of virus and host, the route or method of infection may also be of paramount importance. For example, Beard and Easterday (37) were able to demonstrate similar histopathologic changes in the tracheas of chickens infected with either lentogenic or velogenic viruses by aerosol.

Most published descriptions of the histologic changes following NDV infections are related to the virulent pathotypes, and several descriptive reports or reviews of the literature have covered the histologic changes in the various organs during infection (37, 38, 166, 255). Briefly, the major changes are as follows.

Nervous System. Lesions seen in the central nervous system are those of a nonpurulent encephalomyelitis with neuronal degeneration, foci of glial cells, perivascular infiltration of lymphocytes, and hypertrophy of endothelial cells. Lesions usually are seen in the cerebellum, medulla, midbrain, brain stem, and spinal cord, but rarely in the cerebrum.

Vascular System. Congestion, edema, and hemorrhage are found associated with the blood vessels of many organs. Other changes that may be seen consist of hydropic degeneration of the media, hyalinization of capillaries and arterioles, development of hyaline thrombosis in small vessels, and necrosis of endothelial cells of the vessels.

Lymphoid System. Regressive changes found in the lymphopoietic system consist of the disappearance of lymphoid tissue. Hyperplasia of the mononuclear phagocytic cells in various organs, especially the liver, may take place in subacute infections. Necrotic lesions are found throughout the spleen. Focal vacuolation and destruction of lymphocytes may be seen in the cortical areas and germinal centers of the spleen and thymus. Marked degeneration of lymphocytes in the medullary region is seen in the bursa of Fabricus (237).

Intestinal Tract. Hemorrhage and necrosis of mucosal lymphoid tissue are seen in the intestinal tract with infections of some virulent forms of ND. Other lesions are related to changes in the vascular system.

Respiratory Tract. The effect of NDV infection on membranes of the upper respiratory tract may be severe and related to the degree of respiratory distress. Lesions may extend throughout the length of the trachea. Cilia may be lost within two days of infection. In the mucosa of the upper respiratory tract, congestion, edema, and dense cellular infiltration of lymphocytes and macrophages may be seen, particularly following aerosol exposure (37). The process appears to clear rapidly, and birds examined as early as six days after infection may be free from inflammation.

Cheville *et al.* (62) infected birds with two U.S. viscerotropic isolates, Texas 219 and Florida Largo. Marked lesions of the lung were seen with both viruses, the former producing congestion and edema of the parabronchi and the latter more extensive lesions consisting of hemorrhage and erythrophagocytosis in the alveolar areas of the parabronchi.

Edema, cell infiltration, and increased thickness and density of the air sacs may occur in chickens.

Reproductive System. Histopathologic changes in the reproductive tract are extremely variable. Biswal and Morrill (46) reported that the greatest functional damage was to the uterus or shell-

forming portion of the oviduct. Changes in female reproductive organs included atresia of follicles with infiltration of inflammatory cells and the formation of lymphoid aggregates. Similar aggregates were present in the oviduct.

Other Organs. Small focal areas of necrosis are seen in the liver and, sometimes with hemorrhage, in the gallbladder and heart. Lymphocyte infiltration has been reported in the pancreas. In infections with the viscerotropic velogenic viruses, hemorrhage and ulceration of the skin may occur, and congestion and petechiae of the combs and wattle are common. Conjunctival lesions may be associated with hemorrhage.

Immunity
Active Immunity
Cell-Mediated Immunity. The initial immune response to infection with NDV is cell mediated and may be detectable as early as 2–3 days after infection with live vaccine strains (91, 244). This has been thought to explain the early protection against challenge that has been recorded in vaccinated birds before a measurable antibody response is seen (26, 99). However, a later study (207) concluded that the cell-mediated immune response to NDV by itself is not protective against challenge with virulent NDV. The importance of cell-mediated immunity in protection conferred by vaccines is, therefore, not clear, and a strong secondary response to challenge similar to the antibody response does not seem to occur (244).

Humoral Immunity. Antibodies capable of protecting the host can be measured in VN tests. Because the VN response appears to parallel the HI response, however, the latter test is frequently used to assess protective response, especially after vaccination (27). Antibodies directed against either of the functional surface glycopolypeptides, the HN and the F polypeptides, can neutralize NDVs (214). In fact, MABs specific for epitopes on the F polypeptide have been shown to induce greater neutralization than those directed against HN in *in vitro* and *in vivo* tests (178, 174). Therefore, the successful reliance on the simple HI test to assess protection up until now may have been fortuitous.

When chickens survive NDV infection long enough, antibodies usually are detectable in the serum within 6–10 days. The levels largely depend on the infecting strain, but generally, peak response is at about 3–4 weeks. Decline in antibody titer varies with the titer achieved but is much slower than their development. Hemagglutination inhibition antibodies may remain detectable for up to one year in birds recovered from infection with mesogenic viruses or after a series of immunizations. Reinfection or immunization some weeks after the titer begins to decline produces a secondary response (27).

Local Immunity. Antibodies appear in secretions of the upper respiratory tract and intestinal tract of chickens at about the time humoral antibodies can be first detected. In the upper respiratory tract, the immunoglobulins appear to be chiefly IgA with some IgG (194). Similar excretions occur in the Harderian gland following ocular, but not parenteral, infection (194, 202). Malkin-

son and Small (164) demonstrated effective local immunity when they found that birds may be susceptible to infection at one site but protected at another. The exact function of local immunity in protection is not clear, although a role in protection of the respiratory tract independent of humoral immunity has been proposed (123). Eye-drop vaccination with Hitchner B1 resulted in replication of virus in the Harderian gland, which could be prevented by the presence of maternal IgG in lachrymal fluid (215). Replication of virus in the Harderian gland resulted in the production of lachrymal IgG, IgA, and IgM (215). In particular, the Harderian gland became the main site for IgA-antibody-forming cells in the chicken (218). Russell and Ezeifeka (217) stressed that IgM may be the class of antibody most actively involved in the clearance of virus in conjunctival infections.

Passive Immunity. Hens with antibodies to NDV will pass these on to their progeny via the egg yolk (116). Levels of antibody in day-old chicks will be directly related to titers in the parent. Allan *et al.* (27) estimated that each twofold decay in maternally derived HI titer takes about 4.5 days. Maternal immunity is protective and, thus, must be taken into account when timing the primary vaccination of chicks.

Immunosuppression. Suppression of the immune response has important effects on both the pathogenicity of infecting NDV strains and the protection levels achieved by vaccination. Under natural conditions, immunosuppression may occur due to infection with other viruses such as infectious bursal disease virus. The subsequent immunodeficiency may result in a more severe disease caused by some NDV strains and a failure to respond adequately to vaccination (83, 93, 195, 210). Immunosuppression from chicken infectious anemia virus also has been implicated in the failure of chickens to respond well to secondary inactivated NDV vaccine (53).

Diagnosis

The objectives in the diagnosis of NDV infections are to reach a decision on whether or not to impose control measures and to obtain evidence to support epidemiological investigations. None of the clinical signs or lesions of vND may be regarded as pathognomonic, and the wide variation in disease with virus strain, host species, and other factors means that at best, these can serve as only a suggestion of infection with NDV. Similarly, the presence of lentogenic NDV strains in birds in most countries and the almost universal use of live vaccines means that mere demonstration of infection, without definition of the infecting virus, is rarely adequate cause for control measures to be imposed. Additionally, vND may cause such devastating epizootics and can have such far-reaching effects on trade in poultry products that control measures usually are defined at a national or international level.

Isolation and Identification of Causative Agent
Direct Detection of Viral Antigens
Immunohistologic techniques offer a rapid method for the specific demonstration of the presence of virus or viral antigens in

organs or tissues. Immunofluorescence techniques for thin sections of trachea (120) or impression smears (169) and an immunoperoxidase technique for thin sections (107, 161) have been described and used in NDV infections.

Virus Isolation of NDV
Although molecular techniques, especially those developed to employ RT-PCR directly on samples from affected birds (95), mean that a positive diagnosis at least can be obtained rapidly without virus isolation, it is still important that, for primary outbreaks especially, the virus is isolated for proper characterization and future work.

Culture System. Virulent ND viruses can be propagated in many cell culture systems, and viruses of low virulence can be induced to replicate in some of them. It is possible to use primary cell cultures or even cell lines for routine isolation of NDV. The embryonated chicken egg, however, represents an extremely sensitive and convenient vehicle for the propagation of NDV and is used almost universally in diagnosis.

Embryonated chicken eggs should be obtained from a specific-pathogen-free (SPF) flock and incubated for 9–10 days at 37°C before use. If SPF eggs cannot be obtained, eggs from a flock free of NDV antibodies should be used. NDV strains in eggs containing yolk antibodies can be propagated, but the virus titer is usually greatly reduced, and such eggs should be avoided for diagnostic use.

Samples. The two main sites of replication of NDV in infected poultry appear to be the respiratory and intestinal tracts, so specimens taken should always include either feces, intestinal contents or cloacal swabs, and tracheal swabs or tracheal samples depending on the circumstances. Other specimens taken from carcasses should reflect the clinical signs prior to death and organs obviously affected.

Newcastle disease virus is relatively stable for long periods in nonputrefying tissues provided that the ambient temperature is low (156). Gough *et al.* (102), however, considered the transport of samples in a frozen or chilled state as very important in virus isolation. Omojola and Hanson (191) suggested that bone marrow may be a useful sample in countries where transport is slow, temperatures are high, and refrigeration is not available, as they were able to isolate virus from this site after several days at 30°C.

Isolation Method. Ideally, each sample should be treated separately. It is common, however, to pool organ and tissue samples, although tracheal and fecal samples are best kept separate. Antibiotic media is used to make 20% weight/volume suspensions of feces or finely minced tissues and organs. Swabs are placed in sufficient antibiotic medium to ensure full immersion.

The suspensions are held at room temperature for 1–2 hours and then centrifuged at 1000 g for 10 minutes. Each of five embryonated eggs should then be inoculated with 0.2 mL of the supernatant fluid into the allantoic cavity. The eggs are placed at 37°C and examined regularly.

Eggs dead or dying, or after a minimum of four days and a

Table 3.4. Examples of pathogenicity indices obtained for strains of Newcastle disease virus.

Virus strain	Pathotype	ICPI[a]	IVPI[b]	MDT[c]
Ulster 2C	Asymptomatic enteric	0.0	0.0	>150
Queensland V4	Asymptomatic enteric	0.0	0.0	>150
Hitchner B1	Lentogenic	0.2	0.0	120
F	Lentogenic	0.25	0.0	119
La Sota	Lentogenic	0.4	0.0	103
H	Mesogenic	1.2	0.0	48
Mukteswar	Mesogenic	1.4	0.0	46
Roakin	Mesogenic	1.45	0.0	68
Beaudette C	Mesogenic	1.6	1.45	62
Texas GB	Velogenic	1.75	2.7	55
NY parrot 70181	Velogenic	1.8	2.6	51
Italien	Velogenic	1.85	2.8	50
Milano	Velogenic	1.9	2.8	50
Herts 33/56	Velogenic	2.0	2.7	48

Data from (12, 27).
[a]ICPI, intracerebral pathogenicity index in day-old chicks.
[b]IVPI, intravenous pathogenicity index in six-week-old chickens.
[c]MDT, mean death time (hr) for chick embryos infected with one minimum lethal dose.

maximum of seven days, should be chilled to 4°C, and the allantoic/amniotic fluid should be harvested. The presence of virus can be detected by an HA test; nonhemagglutinating fluids should be passaged at least one more time. Hemagglutination may be caused by bacteria, and possible contamination should be assessed by culture. If bacteria are present, the contaminated fluids can be passed through a 450-nm membrane filter before repassaging in eggs.

Virus Characterization
The widespread presence of lentogenic strains in feral birds and the use of such viruses as live vaccines mean that isolation of NDV is rarely sufficient to confirm a diagnosis of disease. For such confirmation and to meet statutory requirements that may be in force, further virus characterization such as pathogenicity testing or nucleotide sequencing is necessary.

Pathogenicity Tests. The importance and impact of an NDV isolate will be directly related to the virulence of that isolate. Because field disease may be an unreliable measure of the true virulence of the virus, it is necessary to carry out laboratory assessment of the pathogenicity of the virus. In the past, three *in vivo* tests have been used for this purpose: 1) mean death time (MDT) in eggs, 2) ICPI, and 3) IVPI.

Examples of the values obtained in these three methods are shown for some well-characterized NDV strains in Table 3.4; it should be noted that the *in vivo* test prescribed by the World Organisation for Animal Health (OIE) is the ICPI test.

Although these pathogenicity tests have proved invaluable in distinguishing among vaccine, enzootic, and epizootic viruses

during outbreaks, some drawbacks to the tests and difficulties exist in the interpretation of results. For example, Pearson *et al.* (196) reported 10 NDV isolates from pigeons to have ICPI values between 1.2 and 1.45 and a range of IVPI values of 0 to 1.3, suggesting that the viruses be at least mesogenic; however, the lowest MDT recorded was 98 hour, a characteristic of lentogenic viruses. Meulemans *et al.* (176) characterized 27 PPMV-1 isolates from pigeons during 1998 and 1999. They showed that while these viruses all possessed F0 cleavage site motifs indicating vNDV and were antigenically indistinguishable from virus isolated in 1983–1984, the ICPI values for the 1998–1999 viruses gave a mean of 0.69 [range 0.21–1.27] compared to a mean value of 1.44 for the 1983–1984 viruses. In addition, work by Alexander and Parsons (15) on NDV (APMV-1) isolates from pigeons showed that both ICPI and IVPI values increased after passage through chickens or embryonated chicken eggs. This suggests that isolates adapted to birds other than poultry may not show their potential virulence for chickens in conventional pathogenicity tests.

In Vitro Tests for Pathogenicity. Only NDVs possessing additional basic amino acids at the cleavage site of the fusion protein are rendered infectious by nontrypsinlike proteases. Rott, therefore, suggested (212) that the ability of NDV isolates to form plaques in cell culture systems in the absence of trypsin represents a simple *in vitro* method for the detection of virulent viruses. As discussed previously, a much greater understanding of the molecular basis for pathogenicity has been obtained in recent years, and international definitions now allow for the detection of multiple basic amino acids at the F0 cleavage site to be used in place of *in vivo* tests for the confirmation of virulent ND virus (189). The use of molecular techniques in the diagnosis of ND, especially assessing the virulence of the infecting virus, is discussed later in this chapter.

Virus Property Profiles. Newcastle disease virus isolates show a marked variation in biologic and biochemical properties (see Introduction), and some workers used these properties to develop distinct profiles enabling the grouping of viruses for the purposes of diagnosis (38, 110). Under specific circumstances, single properties of the virus may be sufficient to distinguish between avirulent and virulent isolates and be usefully employed in diagnosis.

Monoclonal Antibodies. In addition to their use in routine diagnosis, panels of MABs can be used to characterize and group isolates by establishing profiles. Such typing on an antigenic basis represents a powerful tool for the diagnostician and epizootiologist, allowing rapid grouping and differentiation of NDV isolates (20, 214).

Serology
The presence of specific antibodies to NDV in the serum of a bird gives little information on the infecting strain of NDV and, therefore, has limited diagnostic value.

Nevertheless, in certain circumstances the demonstration that infection has taken place is sufficient for the needs of the diagnostician. Postvaccinal serology can be used to confirm successful application of vaccine and an adequate immune response by the bird.

Serologic Tests for Newcastle Disease Virus Antibodies
Antibodies to NDV may be detected in poultry sera by a variety of tests including single radial immunodiffusion (63), single radial hemolysis (114), agar gel precipitin (89), VN in chick embryos (36), and plaque neutralization (38). Enzyme-linked immunosorbent assays (ELISAs), which lend themselves to semiautomated techniques, have become popular, especially as part of flock screening procedures (232), and a variety of such tests have been described (4, 171, 176, 208, 231, 259). Good correlation has been reported between ELISA and HI tests (4, 54, 74). ELISA tests should be modified and validated for different host species; this problem can be overcome by use of competitive or blocking ELISAs employing one or more mAb to NDV.

Conventionally, antibodies to NDV and the other avian paramyxoviruses have been detected and quantitated by the HI test. Many methods for HA and HI tests have been described. Sera from other species (including turkeys) may cause low-titer, nonspecific agglutination of chicken RBCs, complicating the test. Such agglutination may be removed by adsorption with chicken RBCs before testing.

Although the HA and HI tests are not greatly affected by minor changes in the methodology, Brugh *et al.* (55) stressed the critical nature of the antigen/antiserum incubation period in test standardization and surveys have not always reported good reproducibility in HI tests among different laboratories (39). Variation in testing procedures, especially the antigen used, may account for the lack of reproducibility and laboratories should follow carefully procedures recommended by international agencies such as the World Organisation for Animal Health (189).

Differential Diagnosis
Viral HA activity may be due to any of the nine avian paramyxovirus serotypes or any of the 16 influenza type A hemagglutinin subtypes that are known to infect birds. Demonstration that the virus is of a specific serotype usually can be carried out by a simple HI test with specific polyclonal antisera.

Newcastle disease virus (APMV-1) shows some cross-reaction in HI tests with several of the other avian paramyxovirus serotypes, especially APMV-3 psittacine isolates, using polyclonal antisera (8). Although the potential for misdiagnosis largely can be eliminated by the use of control sera and antigens in conventional tests, the use of MABs in routine diagnosis can give an unequivocal result.

Molecular Techniques in the Diagnosis of ND
The conventional diagnostic techniques described previously cover detection and limited virus characterization but go only a little way toward supporting epidemiological investigations. In addition, these techniques are considered by many as slow and laborious, requiring unacceptable use of animals, and, above all, they are expensive. The development of molecular biological di-

agnostic techniques in recent years, added to our increasing knowledge of the molecular basis of the pathogenesis of vND, has led many workers to investigate the possibility that conventional diagnosis could be replaced by molecular-based techniques. An added attraction is that all three aspects of diagnosis possibly could be achieved in a single test. The various molecular approaches and techniques applied to ND diagnosis have been reviewed in detail by Aldous and Alexander (5). Most molecular techniques involve a polymerase chain reaction (PCR) and, because NDV has an RNA genome, reverse transcription (RT) to produce a DNA copy of the genome, which is an essential initial step.

Amplification of the DNA copy by PCR can be accomplished by using universal primers that merely identify NDV or its presence (95, 132); primers that amplify areas of the genome of viruses with specific properties, e.g., pathotype (138); or amplification that combines these, usually involving nested PCR (133, 138, 141, 149).

The generated PCR product may be designed to be specifically used in further molecular studies aimed at giving greater information on the properties or origins of the infecting virus. Such studies have included restriction enzyme analysis (30, 149, 184, 252), probe hybridization (6, 130, 131, 187, 203), and nucleotide sequencing for cleavage site analysis and epidemiological studies (24, 65, 66, 67, 72, 115, 117, 144, 145, 162, 165, 225, 226, 236, 241, 245, 246, 263).

Ideally, molecular techniques would allow the amplification of the virus genome directly from infected tissues to avoid the need to isolate the virus. However, this is hindered by the presence of PCR inhibitors in many organs and tissues, especially blood and feces (256). Nevertheless, Gohm *et al.* (95) pursued this strategy and reported success in amplifying a 182 bp product, including the cleavage site, directly from tissues of infected chickens. The main drawback was that no one tissue was always positive during a time course study, necessitating the need to sample a wide range of tissues and organs.

Several groups have reported the use of probes in a variety of tests that recognize specific sites on the NDV genome and, therefore, characterize the virus, at least identifying its virulence (6, 130, 187). The advantages of such techniques are that they are rapid, can be automated, and allow a large number of samples to be screened. The disadvantage is, similar to primary primers aimed at identifying the pathotype, that because ND viruses show considerable variation around the important cleavage site region, the designed probes are unlikely to recognize all ND viruses.

More recently, Wise *et al.* described a one-step real-time RT-PCR (rRT-PCR) assay that was shown to be highly sensitive in the detection of NDV-specific RNA in clinical samples (261). Using separate reactions, the assay can identify virulent (including many of the PPMV-1 viruses) and low virulent virus as well as mixtures of both pathotypes, which is an important feature in outbreaks when live vaccines may be used in control programs. The assay was developed and validated during an outbreak of virulent ND in the United States in 2002–2003 (140) and eventually replaced virus isolation as the primary diagnostic test for the con-

trol program. The assay is now authorized for use in 48 laboratories comprising the National Animal Health Laboratory Network (NAHLN) as a front-line surveillance tool for NDV in the United States.

Real-time RT-PCR assays have the advantage over conventional RT-PCR assays in that fluorogenic hydrolysis (Taqman) probes or fluorescent dyes are used to monitor the presence of target DNA after each PCR cycle, thus providing results in real time. In addition to speed, the primary advantage of the one-step PCR assays is the elimination of the post-amplification processing step, thus reducing laboratory contamination of samples. However, many smaller laboratories are at a disadvantage in using this technology because of the high start-up costs associated with purchasing the real-time thermocyclers.

Intervention Strategies

Regardless of whether ND control is applied at the international, national, or farm levels, the objective is either to prevent susceptible birds from becoming infected or to reduce the number of susceptible birds by vaccination. For the former strategy, each method of disease spread must be considered in prevention policies.

Management Procedures
International Control Policies
The raising of poultry and trade in their products are now organized on an international basis, frequently under the management of multinational companies. There is a desire to trade both poultry products and genetic stock. The threat of vND, however, has proved to be a great restraint on such trade. Bennejean (44) considered that worldwide control of vND will be approached only if all countries report outbreaks within their borders to international agencies. International agreements on these and other points are not simple, owing to the enormous variation in the extent of disease surveillance and diagnostic capabilities in different countries.

A prerequisite to formulating control policies, particularly internationally, would be agreement on what constitutes disease and to what viruses control policies should apply. Some countries do not vaccinate and would not want any form of NDV introduced to their domestic poultry. Others allow only specific live vaccines and consider some vaccines to be unacceptably virulent. Yet other countries have the continued presence of circulating highly virulent virus, which is not seen as overt disease because of vaccination. The World Organisation for Animal Health (OIE) is responsible to the World Trade Organization for the standardization of matters relating to animal health that would affect trade. The definition of vND adopted by OIE (189) reflects the current understanding of the molecular basis for virulence:

> *"Newcastle disease is defined as an infection of birds caused by a virus of avian paramyxovirus serotype 1 (APMV-1) that meets one of the following criteria for virulence:*
>   a) *The virus has an intracerebral pathogenicity index (ICPI) in day-old chicks (Gallus gallus) of 0.7 or greater. or*

b) *Multiple basic amino acids have been demonstrated in the virus (either directly or by deduction) at the C-terminus of the F2 protein and phenylalanine at residue 117, which is the N-terminus of the F1 protein. The term 'multiple basic amino acids' refers to at least three arginine or lysine residues between residues 113 to 116. Failure to demonstrate the characteristic pattern of amino acid residues as described above would require characterisation of the isolated virus by an ICPI test.*

In this definition, amino acid residues are numbered from the N-terminus of the amino acid sequence deduced from the nucleotide sequence of the F0 gene, 113–116 corresponds to residues 24 to 21 from the cleavage site."

National Control Policies

At the national level, control policies are directed at prevention of the introduction of virus and prevention of virus spread within the country. To prevent the introduction of NDV, most countries have restrictions on trade in poultry products, eggs, and live poultry; these vary greatly within the parameters allowed by OIE animal health codes.

Because of the link between exotic caged birds and the spread of NDV during the 1970–1974 panzootic (85, 250) and the known ability of psittacine birds to excrete NDV for many weeks after infection (80, 81), most importing countries have established quarantine procedures for importations.

The continuing panzootic of vND (APMV-1) in racing pigeons that began in the 1980s (249) produced a unique situation, in view of the potential spread to poultry (250). Due to the large number of international pigeon races that take place each year, national policies were created in some countries including the banning of races, restricting races, or enforcing vaccination of participating pigeons.

In many countries legislation exists to control vND outbreaks that may occur. Some countries have adopted eradication policies with compulsory slaughter of infected birds, their contacts, and products. Such policies usually include restrictions of movement or marketing of birds within a defined quarantine area around the outbreak. Others require prophylactic vaccination of birds even in the absence of outbreaks, and some have a policy of "ring vaccination" around outbreaks to establish a buffer zone.

Higgins and Shortridge (119) stressed the importance of tailoring control policies to the country and warned against the dogmatic application of policies successful in one country to another that may differ socially, economically, and climatically.

Control and Prevention at the Farm Level

Possibly the most important factors in preventing the introduction of NDV and its spread during outbreaks are the conditions under which the birds are reared and the degree of biosecurity practiced at the farm. Chapter 1, "Principles of Disease Prevention: Diagnosis and Control," provides a comprehensive discussion of disease prevention through sanitation and security practices.

Although many biosecurity measures may often be regarded as costly, onerous, and time-consuming by those involved, if such measures are implemented there is no doubt that the introduction of ND viruses to poultry flocks and the spread to the rest of the poultry industry will be dramatically reduced. Such measures are also likely to reduce the spread of other endemic diseases that may affect the birds and reduce their yield and should be seen as an important investment in the profitability of poultry production.

Vaccination

Ideally, vaccination against vND would result in immunity against infection and replication of the virus. Realistically, ND vaccination usually protects the bird from the more serious consequences of disease, but virus replication and shedding may still occur, albeit at a reduced level (25, 104, 193, 248).

Allan *et al.* (27) produced a comprehensive description of all aspects of ND vaccination and vaccine production. Other detailed reviews have been published by Meulemans (170) on the use of vaccination in the control of ND, by Cross (73) on vaccine production, and by Thornton (243) on quality control of vaccines.

It should be emphasized that in no circumstances can vaccination be regarded as an alternative to good management practice, biosecurity, or good hygiene in rearing domestic poultry.

Historical Aspects of Vaccination

Early studies demonstrated that inactivated infective material conferred protection on inoculated chickens, but problems in production and standardization discouraged its use on a large scale. Studies in the 1930s on the attenuation of virulent NDV strains by Iyer and Dobson led to the development of mesogenic vaccine strains that are still in use in some parts of the world (105, 129).

The identification of ND in the United States (35) led initially to the use of inactivated vaccines (122). The later observation that some of the enzootic viruses produced only mild disease resulted in the development of the mesogenic live vaccine Roakin (42) and, subsequently, the milder Hitchner B1 (121) and La Sota (96) strains, which are now the most widely used vaccines.

Inactivated vaccines, usually with the virus adsorbed to aluminum hydroxide, were most widely used in Europe up to the 1970–1974 panzootic, but their poor performance at that time resulted in the adoption of live vaccination with B1 and La Sota in most countries. This panzootic also supplied the impetus for the development of modern inactivated vaccines based on oil emulsions, which have proven highly effective.

Vaccination Policies

Some governments have legislation affecting the use and quality control of vaccines. Policies vary enormously, in line with the enzootic status or perceived threat of ND. Some countries, such as Sweden, ban the use of any vaccine, and others (e.g., The Netherlands) enforce vaccination of all poultry. Countries of the European Union have legislated to define the pathogenicity of viruses that will be allowed for use as vaccines in member states. The master seed of live vaccines must be tested under specified dose conditions and shown to have an ICPI value of less than 0.4, and the master seed of viruses used in inactivated vaccines must have an ICPI value less than 0.7 (71). Similar guidelines were adopted by OIE (188).

Table 3.5.   Examples of Newcastle disease viruses used as live vaccines.

Virus	Pathotype	ICPI[a]	Derivation	Use in chickens	Routes[b]
La Sota	Lentogenic	0.4	Field isolate	Primary	in, io, dw, sp, aer[c]
F (Asplin)	Lentogenic	0.25	Field isolate	Primary	in, io, dw, sp, aer[c]
Hitchner B1	Lentogenic	0.2	Field isolate	Primary	in, io, dw, sp, aer, bd
V4	Asymptomatic enteric	0.0	Field isolate	Primary	in, io, sp, aer, oral
Strain H[d]	Mesogenic	1.4	Attenuated by passage in eggs	Secondary	im, sc
Mukteswar[d]	Mesogenic	1.4	Attenuated by passage in eggs	Secondary	im, sc
Roakin[d]	Mesogenic	1.45	Field isolate	Secondary	im, ww

[a]ICPI, intracerebral pathogenicity index.

[b]aer = aerosol, bd = beak dipping, dw = drinking water, im = intramuscular, in = intranasal, oral = in food, sc = subcutaneous, sp = coarse spray, ww = wing web.

[c]These vaccines may give severe reactions when given by aerosol.

[d]Although still used in areas in which vND is endemic mesogenic vaccines fall within the OIE definition of viruses that cause vND.

Live Vaccines
Virus Strains. It is convenient to divide live NDV vaccines into two groups, lentogenic and mesogenic (Table 3.5). Note that the mesogenic vaccines fall within the current OIE definition of virus responsible for vND. They are used only in countries where vND is endemic and are suitable for secondary vaccination of birds because of their virulence. Even within the lentogenic group, however, is a considerable range in virulence, as demonstrated by Borland and Allan (47) who developed a stress index test to assess the potential effects of vaccines on susceptible chickens. The immune response increases as the pathogenicity of the live vaccine increases (206). Therefore, to obtain the desired level of protection without serious reaction, vaccination programs are needed that involve sequential use of progressively more virulent viruses or live virus followed by inactivated vaccine. Commonly used live vaccines and their pathogenicity indices for chickens are listed in Table 3.5.

Application of Live Vaccines.   The objective of live vaccines is to establish an infection in the flock, preferably in each bird at the time of application. Individual bird treatments such as intranasal instillation, eyedrop, and beak-dipping are often used for lentogenic vaccines. Mesogenic vaccines usually require inoculation by wing-web stabbing or intramuscular injection.

The main appeal of live vaccines is that they may be administered by inexpensive mass application techniques. Probably the most common method of application used worldwide is via the drinking water. Generally, water is withheld from the birds for a number of hours and then vaccine is applied in fresh drinking water at concentrations carefully calculated to give each bird a sufficient dose. Addition of vaccine to header tanks has also been used successfully. Drinking water application must be carefully monitored as the virus may be inactivated by excessive ambient heat, impurities in the water, and even the type of pipes or vessels used to distribute the drinking water. To some extent, virus viability can be stabilized by the addition of dried skim milk powder to the drinking water (90).

Mass application of live vaccines by sprays and aerosols is also very popular due to the ease with which large numbers of birds can be vaccinated in a short time. It is important to achieve the correct size of particles by controlling the conditions under which the aerosol is generated (27, 170). Aerosol application usually is limited to secondary vaccination to avoid severe vaccine reactions. Coarse sprays of large particles do not penetrate deeply into the respiratory tracts of birds and give less reaction, so these may be more suitable for the mass application of vaccine to young birds. Coarse spraying of chicks at 1 day old may result in the establishment of infection in the flock with the vaccinal virus despite maternally derived immunity. It is believed, however, that in these circumstances, infections are established by the nasal or ocular route as a result of head rubbing on the backs of other birds and not necessarily directly by the spray (170). Aerosol and coarse-spray generators are available commercially (150); in the United States, a cabinet for coarse-spraying of day-old chicks is widely used (92).

A vaccine, based on the Australian V4 virus, has been developed specifically for use in village flocks in tropical countries. The recommended method of administration of the vaccine is in coated, pelleted feed. Initial laboratory and field trials suggest that this method is efficacious (69), but later studies have recorded problems probably related to the type of feed used as a vehicle (185, 234).

Advantages and Disadvantages of Live Virus Vaccination.   Live vaccines usually are sold as freeze-dried allantoic fluid from infected embryonated eggs, are relatively inexpensive and easy to administer, and lend themselves to mass application. Local immunity is stimulated by infection with live viruses, and protection occurs very soon after application. Vaccine viruses may spread from birds that have been successfully vaccinated to those that have not.

Several disadvantages exist, the most important of which is that the vaccine may cause disease, depending upon environmental conditions and the presence of complicating infections. Therefore, it is important to use extremely mild virus for primary vaccination and, as a result, multiple applications of vaccine(s) usually are needed. Maternally derived immunity may prevent

successful primary vaccination with live virus. Although the ability of vaccinal virus to spread may be an advantage within the flock, spread to susceptible flocks, especially on multiage sites, can cause severe disease problems, particularly if dual infections with exacerbating organisms occur. Live vaccines may be killed easily by chemicals and heat and, if not carefully controlled during production, can contain contaminating viruses.

Inactivated Vaccines

Production Methods. Inactivated vaccines are usually produced from infective allantoic fluid treated with b-propiolactone or formalin to kill the virus and then mixed with a carrier adjuvant. Early inactivated vaccines used aluminum hydroxide adjuvants, but the development of oil-emulsion-based vaccines proved a major advancement. Different oil-emulsion vaccines vary in their formulation of emulsifiers, antigen, and water-to-oil ratios; most now use mineral oil (73).

Various seed viruses used in the production of the oil-emulsion vaccines include Ulster 2C, B1, La Sota, Roakin, and several virulent viruses. The selection criterion should be the amount of antigen produced when the virus is grown in embryonated eggs. Apathogenic viruses grow to the highest titers (101); therefore, it would seem an unnecessary risk to use a virus virulent for chickens.

One or more other antigens may be incorporated into the emulsion with NDV, and bivalent or polyvalent vaccines may include infectious bronchitis virus, infectious bursal disease virus, egg drop syndrome virus (Adenovirus 127), and reovirus (170).

Application of Inactivated Vaccines. Inactivated vaccines are administered by injection, either intramuscularly or subcutaneously.

Advantages and Disadvantages of Inactivated Vaccines. Inactivated vaccines are far easier to store than viable vaccines. They are expensive to produce and to apply because of the labor needed for their application. The labor expense can be partly offset by the use of polyvalent vaccines. Inactivated oil-emulsion vaccines are not as adversely affected by maternal immunity as live vaccines and can be used in day-old chicks (51). Some countries—e.g., the United States—have imposed a 42-day withdrawal period for oil-emulsion vaccines used in birds for human consumption. This restriction would limit the use of inactivated vaccines in some production sectors. Quality control of inactivated vaccines is often difficult, and mineral oils may cause serious problems to the vaccinator if accidentally injected (239). The major advantages of inactivated vaccine are the very low level of adverse reactions in vaccinated birds; the ability to use them in situations unsuited for live vaccines, especially if complicating pathogens are present; and the extremely high levels of protective antibodies of long duration that can be achieved.

Vaccination Programs

Vaccination programs and vaccines may be controlled by government policies. They should always be tailored to suit the prevailing disease situation and other factors, which include availability of vaccine, maternal immunity, use of other vaccines, presence of other organisms, size of the flock, expected life of the flock, available labor, climatic conditions, past vaccination history, and cost.

Timing of vaccination of broiler chickens can be especially difficult due to the presence of maternal antibodies. Because of their short life, broiler chickens are sometimes not vaccinated in countries where there is a low risk of ND.

Vaccination of laying hens always requires more than one dose of vaccine to maintain immunity throughout their lives (27). Actual programs depend on local conditions. In many countries, local customs or circumstances result in too little vaccination, overvaccination, or mistiming of vaccination, all of which may have serious consequences. The problems and pressures that may face the poultry farmer in tropical developing countries can frequently result in what has been described as "vaccine abuse" (119).

Interpretation of Vaccine Response

For NDV, the immune response is usually estimated by the HI titers obtained. Single vaccination with live lentogenic virus will produce a response in susceptible birds of about 2^4 to 2^6, but HI titers as high as 2^{11} or more may be obtained following a vaccination program involving oil-emulsion vaccine. The actual titers obtained and their relationship to the degree and duration of immunity for any given flock and program are difficult to predict. Allan *et al.* (27) presented predictions of the outcome of challenge of vaccinated young chickens with highly virulent NDV.

Vaccination of Other Poultry

Although vaccines developed primarily for chickens may be used effectively in other species, some differences in response may be apparent. For example, turkeys generally show a lower response, and as a result, they are often vaccinated first with La Sota followed by oil-emulsion vaccine (52). Some evidence exists, however, that La Sota may cause reaction in the respiratory tract (170), and that aerosol vaccination with lentogenic viruses causes pathologic lesions of the trachea (1). Considerable investigation is still being done into vaccination programs involving live and inactivated vaccines for use in turkeys (139, 153).

Guinea fowl and partridges have been successfully vaccinated with La Sota and/or oil-emulsion vaccines. Considerable investigation into the most suitable vaccines and regimens for pigeons has taken place due to the panzootic occurring in these birds during the 1980s (249).

Vaccination of ostriches and other ratites is not as well understood as other poultry, but doses and regimens have been suggested (10).

Future Developments

Molecular biology technology has enabled a much greater understanding of the pathogenicity (213) and antigenicity (214) of NDV and enabled cloning of the genes most closely involved (178). Groups working in this area have reported protective immunization with the HN gene expressed in recombinant fowl pox virus (48) and recombinant avian cells (64); or the F gene expressed in recombinant fowl pox virus (49, 242), vaccinia virus

(175), pigeon pox virus (159), and turkey herpesvirus (181, 220); or both HN and F expressed in fowl pox virus (143).

Avian Metapneumovirus

R. E. Gough and R. C.Jones

Definition and Synonyms

The clinical diseases that may result from avian metapneumovirus (aMPV) infections of turkeys or chickens have been termed turkey rhinotracheitis (TRT), swollen head syndrome (SHS), and avian rhinotracheitis (ART) based on clinical signs and lesions. However, these clinical signs and lesions are not specific for aMPV infections and can be confused with disease resulting from infections with other organisms such as *Bordetella avium, Ornithobacterium rhinotracheale* (ORT), infectious bronchitis virus (IBV), *Mycoplasma* species and other respiratory pathogens. Nevertheless, it is now universally accepted that the conditions referred to as TRT, SHS or ART can occur as a result of infection with aMPV. The more severe form of associated disease probably results from dual or secondary infection with other organisms, and for SHS, the characteristic "swollen head" appears as a result of infection with secondary adventitious bacteria, usually *Escherichia coli*.

Economic Significance

Avian metapneumovirus infections of poultry are associated with serious economic and animal welfare problems, particularly in commercial turkey flocks. Even in countries where vaccination against avian pneumovirus has become routine practice, the disease is still considered to be the most significant respiratory disease of turkeys, except for avian influenza (59). Since the initial outbreaks of aMPV infection in turkeys in the USA during 1997 losses in production have caused serious economic problems. It has been estimated that from 1997 to 2002 the losses to the Minnesota turkey industry were $15 million dollars per year (85). In commercial chickens the disease has less of an economic impact although in countries where infection is associated with SHS and losses in egg production aMPV can have a serious economic impact.

Public Health Significance

Although a similar metapneumovirus has been associated with upper respiratory disease in humans (hMPV) (102) there is no public health risks associated with aMPV infections in poultry.

History

Avian metapneumovirus was first described as a disease entity in turkeys in South Africa in the late 1970's (13). Later the dis-

ease was reported from Europe and the etiological agent was isolated at about the same time in the United Kingdom and France (73). A further two years passed before the agent responsible for the disease was characterised as a virus belonging to the family *Paramyxoviridae* and initially placed in the genus *Pneumovirus* (21). At about the same time that aMPV appeared in Europe and the Middle East a disease of chickens was observed which consisted of upper respiratory tract signs followed by a small number of flocks exhibiting swollen heads. This disease was known as "swollen head" syndrome (SHS) and was shown to be associated with a pneumovirus identical to what was then referred to as turkey rhinotracheitis (TRT) virus (1). During the early 1990s vaccines were developed for use in turkeys and chickens originating from the primary turkey isolates. However, by 1994 it was shown that two subtypes of aMPV existed, termed A and B (55) and it was subsequently shown that vaccines developed from a subtype A strain could confer protection against subtype B viruses (23). During the mid-1990s serological evidence of aMPV was reported from the Far East, often associated with SHS in chickens (23) and subtype A viruses were detected in chickens in Brazil in 1995 (7) and in turkeys in 2004 (34).   In 1997 aMPV was described in turkeys in the United States for the first time (88) and was later shown to be antigenically distinct from subtypes A and B (86). All subsequent isolates from turkeys in North America have been shown to be antigenically similar and are referred to as subtype C aMPVs. Interestingly the disease has not been observed in chickens in North America and although it first appeared in Colorado, infections by aMPV now appears to be confined to turkeys in the states of Minnesota, Iowa, Wisconsin and the Dakotas based on ELISA serology (12).

Viruses similar to subtype C, but of a different genetic lineage, have also been reported to occur in Muscovy ducks in France associated with respiratory signs and egg production problems (98).

In a more recent report from France retrospective molecular analysis of viruses isolated from turkeys in the 1980s indicated the presence of a fourth subtype of aMPV, designated subtype D (9,99).

Subtype A viruses have also been detected in pheasants in the U.K. associated with respiratory disease problems (42,105).

Etiology

Classification

Avian metapneumoviruses are members of the subfamily *Pneumovirinae*, belonging to the family *Paramyxoviridae*. The subfamily consists of two genera; *Pneumovirus* consisting of mammalian respiratory syncytial viruses and mouse pneumovirus, and *Metapneumovirus* in which avian pneumoviruses are placed (84). Until recently it was thought that aMPV was the sole member of the *Metapneumovirus* genus but recent reports have indicated that similar viruses have been detected in humans in several countries associated with respiratory tract infections (64, 102). Avian metapneumoviruses have been further classified into four subtypes (A, B, C and D) based on nucleotide and deduced amino acid sequence data (33).

Morphology

Negative contrast electron microscopy of avian metapneumovirus reveals pleomorphic fringed particles, usually roughly spherical, of 80–200nm in diameter, although occasionally round particles with diameters of 500nm or more can be seen (Fig. 3.1). Fringed filamentous forms 80–100nm in diameter and up to 1000nm long may also be present (Fig 3.2), particularly in preparations from organ culture propagation. Collins and Gough (20) reported the surface projections to be 13–14nm in length and the helical nucleocapsid to be 14nm in diameter with an estimated pitch of 7nm per turn.

Chemical Composition

The virus genome is non-segmented and composed of single-stranded negative sense RNA of approximately 14 kilobases. In sucrose gradients the bouyant density of an isolate from turkeys was 1.21g/ml with an approximate molecular weight of 500 x 10^6. The same virus was shown to have about eight structural polypeptides of which two were glycosylated and three non-structural virus-specified proteins (20). These have been identified as nucleoprotein (N), phosphoprotein (P), matrix protein (M), fusion protein (F), second matrix protein (M2),small hydrophobic protein (SH), surface glycoprotein (G) and a large, viral RNA-dependent RNA polymerase (L), flanked by a leader and trailer at the 3′ and 5′ ends, respectively (58).

Virus Replication

Few detailed studies on aMPV have been published but virus mechanisms are thought to be similar to related negative strand viruses such as respiratory syncytial virus (RSV). Study of RSV has shown that virus replication and transcription both start at the 3′ leader sequence (37). Because of polymerase dissociation, genes are transcribed and expressed at reduced levels ongoing from the leader to trailer of the genome. The development of a reverse-genetic system for aMPV (76) has confirmed that as for RSV, the minimum replicative unit is the ribonuclear complex which comprises the nucleocapsid, phosphoprotein and M2 protein together with the viral polymerase. This study showed that the SH and attachment proteins can be deleted to leave viable viruses, at least in tissue culture. This suggests that the fusion protein can also play a role in virus attachment in addition to glycoprotein G.

Susceptibility to Chemical and Physical Agents

Early studies with one of the first European turkey isolates of aMPV reported that the virus was sensitive to lipid solvents, stable at pH 3.0 to 9.0 and inactivated at 56°C after 30 minutes (21). More recently, studies with a subtype C strain of aMPV isolated from turkeys in Minnesota, USA reported a similar resistance to pH 5 to 9 for one hour. In addition, the study reported that the isolate had lost viability by 12 weeks at 4°C, 4 weeks at 20°C, 2 days at 37°C and 6 hours at 50°C. Several disinfectants were effective in reducing the viability of the virus; including quaternary ammonia, ethanol, iodophor, a phenol derivative and sodium hypochlorite (bleach). Surprisingly, after 7 days of drying at room temperature the aMPV isolate remained viable (100). The survival of an aMPV subtype C isolate in built-up turkey litter at

different temperature conditions has also been studied. The results from the study indicated that virus could survive for up to 60 days at a temperature of –12°C and viral RNA was still detectable in the litter kept at 8°C after 90 days (104).

Strain Classification

Early studies using cross neutralization, ELISA techniques and polypeptide profiling suggested there were few strain differences between European isolates of aMPV (8, 39). However, more detailed studies using monoclonal antibodies (mAbs) produced to a variety of isolates demonstrated considerable antigenic differences between strains (22, 28). Further confirmation of subtype differences was obtained following nucleotide sequence analysis of the G (attachment) glycoprotein which showed that two subgroups designated A and B existed within the one serogroup (55). Subtype A and B viruses have been isolated from, and can infect, both chickens and turkeys (23).

More recent aMPV isolates from turkeys in Colorado and Minnesota, USA, were shown to have no significant serological relationship with subtype A and B strains from Europe using neutralization tests with mono-specific and monoclonal antibodies (30). Further detailed molecular analyses of the N, P, M, F and M2 protein genes of European viruses and isolates from the USA revealed that subtype C viruses had over 90% nucleotide sequence identity within the five genes compared to between 40 and 70% sequence identity with subtype A and B viruses (92). Phylogenetic analyses of three subtypes (A, B and C) showed that A and B viruses were more closely related to each other than either were to subtype C viruses (86). Retrospective analysis of two viruses isolated in France in 1985, subsequently referred to as subtype D, showed differences in the G gene sequence from subtypes A, B and C isolates (9). Phylogenetic comparison of the four subtypes has shown that A, B, and D viruses are more closely related to each other than to subtype C viruses (5, 9, 99).

Laboratory Host Systems

Initial problems in the laboratory diagnosis and determination of the etiology of aMPV were due primarily to a lack of suitable laboratory propagation system. The infectious nature of the disease could be demonstrated by typical clinical signs appearing in susceptible turkey poults placed in contact with infected birds or inoculated with filtered mucus from affected birds (2).

Inoculation of infective mucus into the yolk sac of turkey or chicken embryos resulted in embryo mortality after 4 or 5 passages, but virus was demonstrated to be at a very low titer (2). Similarly, inoculation of turkey or chicken tracheal organ cultures (TOCs) resulted in ciliostasis, but again, virus only replicated to low titers (38,69). Isolates adapted to embryos or TOCs, however, were capable of replication in cultures of primary chicken and turkey embryo cells, mammalian cells such as VERO, BS-C-1 and MA104 cells, with a characteristic cytopathic effect of syncytium formation and relatively high virus titers. A continuous quail tumour cell line (QT-35) has also been used to propagate the virus (43).

Subtypes A and B can be isolated in TOC but subtype C viruses have only been isolated in cell cultures or fertile eggs.

Pathogenicity

Despite the high morbidity and occasionally high mortality associated with aMPV in the field, the pathogenicity of aMPV isolates has been difficult to assess in the laboratory. Experimentally, infected birds often show recognizable signs of rhinotracheitis, but these are milder than those seen in the field (109). Chickens show, at most, only mild respiratory disease in laboratory infections and nasal mucus may only be discernible after light squeezing behind the nostrils. Transmission studies in two-week-old broiler chicks with a turkey isolate of aMPV from Minnesota produced clinical signs of coughing and sneezing for up to 8 days post inoculation. Tissue and intestinal samples from the broilers were positive by PCR for up to 9 days post inoculation (89). An isolate of aMPV from chickens with SHS was able to produce rhinotracheitis in infected turkey poults (83). Presumably, the difference in pathogenicity between laboratory and field infections is related to the conditions under which the birds are kept and the presence or absence of exacerbative organisms. In laboratory studies concurrent infection of turkey poults with aMPV and respiratory bacteria, such as *E coli*, *Bordetella avium* and *Ornithobacterium rhinotracheale* (27,49,68), *Mycoplasma gallisepticum* (74) and lentogenic Newcastle disease (101), significantly exacerbate and prolong clinical signs and morbidity. In experimentally infected turkey poults pre-infection with *Chlamydophila psittaci* was also shown to significantly increase the severity of aMPV infection (103).

Pathobiology and Epidemiology

Incidence and Distribution

Apart from Australasia all major poultry rearing regions of the world have reported the presence of aMPV. Evidence for the presence of the virus in commercial poultry has frequently been based on serological evidence alone (23,33). Due to difficulties in identifying or detecting the virus the number of countries reporting the isolation and characterisation of the virus are relatively few. Although aMPV has been reported in turkeys in the United States since 1997 there have been no reports on the isolation or detection of the virus in commercial chickens, even though there is evidence of the disease in neighbouring countries (50).

Natural and Experimental Hosts

Turkeys and chickens, apparently of any age, are known natural hosts of aMPV.

Additionally, Picault *et al.* (82) found aMPV antibodies in flocks of guinea fowl (*Numida meleagris*) and were able to produce a rhinotracheitis-like disease in this species with virus isolated from aMPV affected turkeys. Swollen head syndrome (SHS) has also been reported in guinea fowl (61) and pheasants (78) associated with aMPV. In the United Kingdom aMPV has been detected in pheasants with respiratory signs and serological studies suggest that the virus is widespread in game birds (42,105). Avian metapneumovirus has been detected by RT-PCR and occasionally virus isolation, in nasal turbinates of sparrows, ducks, geese, swallows, gulls and starlings sampled in the north

central region of the United States and shown to be closely related to subtype C viruses isolated from commercial turkeys (11,12,90,91). Subtype C-like viruses have also been reported to occur in commercial Muscovy ducks associated with respiratory signs and egg production problems (98).

In experimental infections with a subtype A aMPV Gough *et al*. (40) demonstrated susceptibility with clinical signs in turkeys, chickens and pheasants and an immune response to the virus in guinea fowl, although pigeons, geese and ducks appeared to be refractory to the virus. Antibodies to aMPV have been reported in farmed ostrich in Zimbabwe (15) and also in seagulls in the Baltic (47). In transmission studies in mice, rats and waterfowl using a turkey aMPV isolate from Minnesota, virus was detected for up to 14 days in mice and 6 days in rats. No clinical signs were observed in the waterfowl, but viral RNA was detected by PCR for up to 21 days post infection (72).

Transmission

The infectious nature of aMPV was established by contact transmission from affected to susceptible turkey poults, or by inoculation with filtered or unfiltered mucus, nasal washings or other materials from the respiratory tract of affected birds (2,69). Cook *et al.* (27) demonstrated that the virus was transmissible from infected to susceptible turkey poults placed in direct contact for a 9-day period after infection. These authors stressed the apparent importance of direct contact as, in their experiments, virus failed to spread to susceptible birds housed in the same room but in a different pen. Similar results have been reported by Alkhalaf *et al.* (3) using a subtype C aMPV. There is no published evidence that aMPV can be vertically transmitted even though high levels of virus can be detected in the reproductive tract of laying birds (53,57).

In most countries where aMPV has appeared as a new disease, it has spread rapidly. For example, in the United Kingdom, the disease was reported from most of the turkey-producing areas of England and Wales within 9 weeks of the first outbreak of the disease (1,50). The methods by which such spread takes place are unclear and, even on a single site, spread is unpredictable. Contaminated water, movement of affected or recovered poults, movement of personnel and equipment, feed trucks, etc. have all been implicated in outbreaks, while airborne spread or vertical transmission also have been put forward as possibilities. At present, only contact spread has been confirmed. The fact that North America remained free of aMPV for so many years when the disease was endemic in South and Central America, Europe and other parts of the world suggests that direct contact is important for transmission and spread of avian pneumoviruses. This view is supported by the situation in the US, in which the disease is widespread in Minnesota but has not spread significantly to other turkey producing areas or into commercial chickens. It seems highly likely that the density of the poultry population, particularly turkeys, will have a significant influence on the degree of spread of the virus (50). Migratory birds, particularly wildfowl, have been suggested as transmitters of aMPVs, although evidence of infection in wild species does not necessarily confirm this. Minnesota, the epicentre of subtype C aMPV infection in the USA lies under major wildfowl flyways which reach from

Canada down to Central and South America. However, there has been no apparent spread of subtypes A and B viruses from South and Central America to the USA and no evidence of subtype C viruses spreading south.

Clinical Signs, Morbidity, and Mortality

The disease in turkeys has been described in detail elsewhere (23,60,73,93). Much of the reported variation in the clinical signs observed is attributed to management factors; such as overstocking, poor ventilation and damp conditions; or the presence of exacerbating adventitious agents that frequently occur with aMPV infections. Typically, clinical signs in young poults include snicking, rales, sneezing, nasal discharge, foamy conjunctivitis, swollen infraorbital sinus and submandibular edema. Coughing and head shaking are frequently observed particularly in older poults. In laying birds there may be a drop in egg production of up to 70% with an increased incidence of poor shell quality and peritonitis (53). Coughing associated with lower respiratory tract involvement may lead to prolapses of the uterus in breeding turkeys. When disease is seen, morbidity in birds of all ages is usually described as up to 100%. Flock mortality ranges from as low as 0.4% to as high as 50%, particularly in fully susceptible young poults. In uncomplicated infections recovery usually occurs between 10 and 14 days.

Avian metapneumovirus infection in chickens is less clearly defined and may not always be associated with clinical signs (23,51). The virus has been associated with swollen head syndrome (SHS) in chickens, which is characterized by the following clinical signs: swelling of the periorbital and infraorbital sinuses, torticollis, cerebral disorientation and opisthotonous, as a result of secondary *E. coli* infection. Usually less than 4% of the flock are affected although widespread respiratory signs are usually present. Mortality rarely exceeds 2% and in broiler breeders egg production is frequently affected. In commercial layers aMPV infection may also affect the quality of eggs (23,50). In laboratory studies the intravenous route of infection had a significant effect on the severity of clinical signs and egg production compared to the oculonasal route, in which egg production remained normal (31,48). There is evidence that infectious bronchitis virus together with *E. coli* may also be associated with SHS (35,71).

Pathology

Gross Lesions

Experimental infection of susceptible 5-week-old turkeys with a European isolate of aMPV resulted in complete deciliation of the trachea by 96 hours after infection (52). Following infection of laying turkeys a watery to mucoid exudate was found in the turbinates one to 9 days post infection, with excess mucus in the trachea (53). Various reproductive tract abnormalities were also reported by the same authors, including egg peritonitis, folded shell membranes in the oviduct, misshapen eggs, ovary and oviduct regression and inspissated albumin and solid yolk. Hens in lay may also present with prolapsed oviducts due to violent coughing. During natural field outbreaks, exacerbated by secondary pathogens, a variety of gross lesions have been described including airsacculitis, pericarditis, pneumonia and perihepatitis (23,41,51,87,93)

In aMPV infected chickens the only significant lesions noted

are those associated with SHS in broilers or broiler breeders. The major gross lesions include extensive yellow gelatinous to purulent edema in the subcutaneous tissues of the head, neck and wattles. Varying degrees of swelling of the infraorbital sinuses may also be seen (45,51,62,94).

Similar gross lesions have been reported to occur in commercially raised pheasant poults in Japan (78)

Microscopic

Detailed histological studies have been performed in experimentally inoculated turkey poults (66,73). At one to two days, post mortem examination of the turbinates revealed increased glandular activity, focal loss of cilia, hyperemia and mild mononuclear infiltration of the submucosa. Between 3 and 5 days damage to the epithelial layer and a copious mononuclear inflammatory infiltration in the submucosa was observed. Some transient lesions may also be seen in the trachea.

Experimental infection of chickens with turkey and chicken isolates have produced similar histological findings and these have been presented in detail elsewhere (16,66,67). In summary, the results provide clear evidence that aMPV can cause damage to the upper respiratory tract of chickens, although the damage is localized and transient.

Immunity

Active Immunity

Cell-Mediated Immunity. The results of laboratory studies suggest that the cell-mediated immune response provides the main resistance to infection of the respiratory tract with aMPV (56). Jones *et al.,* (54) showed that aMPV vaccinated, chemically bursectomised poults that were unable to seroconvert were still resistant to challenge with a virulent strain of aMPV.

Humoral Immunity. Many authors have described the humoral immune response of turkeys to aMPV infection, and these have been reviewed (73). Antibodies can be detected by ELISA, virus neutralization (VN) and indirect immunofluorescence. However, none of these tests are immunoglobulin specific. Following infection of turkeys aMPV antibodies were detected as early as 7 days post infection by ELISA and VN tests and were maintained for up to 89 days, when the trial was terminated (53).

Passive Immunity

Hens with aMPV antibodies will pass these to their progeny via the egg yolk. Titers will be directly related to the levels of circulating antibody in the parent bird. There is evidence that the presence of high levels of maternally derived antibody in one-day-old turkey poults will not prevent clinical disease following challenge with aMPV (75).

Diagnosis

Isolation and Identification of Avian Pneumovirus

Initially, virus isolation proved extremely difficult due to the fastidious nature of the virus, the frequency with which other sec-ondary organisms could be isolated, and the timing of virus isolation attempts (41,50,60). Successful virus isolation was achieved in chicken or turkey embryos or chicken tracheal organ cultures and these have been used on a routine basis. More recently molecular techniques particularly RT-PCR tests have been developed to detect the virus.

Choice and Timing of Samples for Isolation

Although virus has been isolated from trachea, lung and viscera of affected turkey poults, by far the most fruitful source of virus has been ocular/nasal secretions or tissue scraped from the sinuses/turbinates of affected birds. It is extremely important to obtain samples as early as possible after infection as virus may only be present in the sinuses and turbinates for 6 to 7 days at the most (33,40,50). Isolation of virus is rarely successful from birds showing severe signs; presumably the extreme signs are a result of secondary, adventitious bacterial infections in birds predisposed by earlier virus infection. This probably accounts for the lack of success in isolating virus from chickens with SHS, as the characteristic signs appear to be due to secondary *Escherichia coli* infection. Furthermore, for reasons that are unclear, virus isolation from chickens appears to be more difficult than from turkeys.

Due to the labile nature of the virus it is essential that samples requiring despatch to a diagnostic laboratory for attempted virus isolation are sent immediately on ice (41,50). Where delays in despatch are unavoidable samples should be frozen at –50 to 70°C.

Virus Isolation

The various methods used for the primary isolation of aMPV have been published in detail elsewhere (23,33,41,43,51). What is apparent from the European and more recently, the American experience, is that a multiple approach to diagnosis should be used in order to maximise the chances of successfully isolating the virus.

Tracheal Organ Cultures. These are prepared from turkey or chicken embryos shortly before hatching or 1- to 2-day-old chicks originating from aMPV antibody-free flocks. The cultures can be maintained for several weeks and following inoculation with samples they are observed for ciliostasis, which may take several passages before a consistent effect is observed (33). Some of the early isolates of subtype A and B viruses were isolated using this method. However, tracheal organ cultures were found to be unsuitable for the isolation of subtype C viruses as the isolates did not cause ciliostasis (30).

Culture in Embryonating Eggs. Six- to 8-day-old embryonating turkey and chicken eggs from aMPV-negative flocks have been used to isolate the virus following inoculation by the yolk-sac route. Usually, serial passage is required before the agent causes consistent embryo mortality. The method is therefore both time consuming and expensive, and may not be successful. However, this technique was used to isolate the original subtype C Colorado aMPV strain in 1997 (79,88) and more recently in the

outbreaks in Minnesota, U.S.A. This method was also used to isolate the original aMPV strain in South Africa in 1980 (13).

Cell Cultures. This method is not generally successful for the primary isolation of aMPV strains. Occasionally, chicken embryo cells and VERO cells have been used successfully (43). Where positive results were obtained multiple blind passages were required before the virus produced a consistent cytopathic effect (CPE). QT-35 cells have also proved suitable for the primary isolation of APV strains (43). Once adapted to growth in embryonated eggs and tracheal organ cultures the virus can be cultivated to high titers in a range of avian and mammalian cells. The virus produces a characteristic CPE with the formation of syncytia within seven days.

Virus Identification

The isolated virus shows a paramyxovirus-like morphology when examined by negative contrast electron microscopy (EM). Particles are pleomorphic, spherical (80–600nm) or filamentous (up to 1000nm). The surface projections are 13 to 14nm in length and the helical nucleocapsid that can sometimes be seen emerging from disrupted particles is 14nm in diameter with an estimated pitch of 7nm per turn (20,33).

The physiochemical properties of the isolated virus can be investigated to aid identification and these have been described in detail elsewhere (41).

Strains can be distinguished using monoclonal antibodies but more recently molecular methods have been developed based on differences in the nucleotide sequences of the attachment protein (G) and other protein genes (33).

Direct Detection of Viral Antigens

A number of assays have been developed to detect and demonstrate the presence of aMPV antigen in both fixed and unfixed tissues and smears. The most widely used are immunoperoxidase (IP), immunofluorescence (IF) and immunogold staining and these have been described in detail (1,33,53). These techniques have generally been applied during laboratory studies on the replication and pathogenesis of aMPV in turkeys and chickens, and have limited value as diagnostic tools.

Molecular Identification

In recent years significant advances have been made in the diagnosis of aMPV based on the development of RT-PCR techniques. There is no doubt that molecular techniques are significantly more sensitive and rapid than conventional virus isolation methods (17,23,33,41). An important consideration when using PCR methods is whether to use subtype specific or generic-type PCRs, designed to detect several if not all aMPV subtypes. In Europe, where all four subtypes of aMPV have been reported, this is clearly an important consideration, whereas in the USA where only subtype C viruses have been reported, it is of less importance. RT-PCR methods using primers targeted to the F, M, and G genes have been developed but are limited in specificity and may not detect all subtypes (33,41). PCR methods using primers directed to the conserved region of the N gene have been described with the abil-

ity to detect representative aMPV isolates of subtypes A, B, C and D (9). Using this method positive products can be further analysed to determine the subtype using subtype specific PCRs or by sequencing and restriction fragment length analysis. A variety of RT-PCR techniques have been developed and evaluated and these have been extensively reviewed elsewhere (18,33,63,77)

Serology

Due to difficulties in isolating and identifying aMPV serological methods have been developed to confirm infection in commercial poultry and other avian species. The ELISA is the most commonly employed method but other techniques include virus neutralization and indirect immunofluorescence (10,41). The serological response in chickens following infection or vaccination is often weak compared to the response in turkeys.

In common with all serological tests both acute and convalescent sera should be submitted for analysis. The sera should be heat treated at 56ºC for 30 minutes and if delays in testing are unavoidable stored at -20ºC.

ELISA

A variety of commercial and in-house kits have been developed for detecting aMPV antibodies (23,41,73). The test can be used for screening large numbers of sera but differences in sensitivity and specificity have been reported (23,70,97). This is principally due to variations in the antigenicity and purity of the antigen used to coat the ELISA plates. It has been shown that vaccinal antibodies may not be detected if heterologous strains of aMPV are used to prepare the coating antigen for the ELISA plates (36). Studies using ELISA kits incorporating subtype A or B antigens were found to be relatively insensitive for detecting antibodies to the Colorado strain of aMPV (30). Some competitive ELISA kits incorporate a specific aMPV monoclonal antibody that facilitates the testing of sera from different avian species. However, the kits were found to be unsuitable for the detection of antibodies against aMPV isolates from the US (30). More recently ELISAs have been developed and evaluated which incorporate whole virus antigens prepared from Colorado and Minnesota isolates of aMPV (4,19,65). More sensitive and specific ELISAs using M and N protein expressed antigens in sandwich-capture ELISAs for detecting subtype C antibodies have also been described (44).

Virus Neutralization

Antibodies to aMPV can be detected by standard neutralization techniques using sensitive cell cultures or tracheal organ cultures. The test in chicken embryo cells has been detailed elsewhere (41). Cross reactivity occurs with subtype A and B viruses although good correlation with ELISA and indirect immunofluorescence has been reported (10,33). However, the VN test is time consuming, expensive and unsuitable for mass serological screening of poultry flocks.

Fluorescent Antibody Test

A number of indirect immunofluorescent antibody tests have been described (33,73). These tests are useful as a research tech-

nique but have limited application for testing large numbers of poultry sera for aMPV antibodies.

Differential Diagnosis
Strain Variability
The morphological appearance of aMPV gives no indication of the strain or subtype. Subtype A and B viruses were originally differentiated on the basis of nucleotide sequence analysis of the attachment (G) protein gene (55) and mAB analysis (22,28), although they belong to the same serotype. With the emergence of subtype C in the USA, and evidence of subtypes C and D in France, it seems likely that further subtypes of aMPV remain undetected. It is also probable that current RT-PCR methods may fail to detect the presence of "new" subtypes of aMPV. Clearly a multi-diagnostic approach is required in order to detect further subtypes of aMPV, including virus isolation, electron microscopy and the development of more sensitive PCR methods (33).

Other Viruses
Paramyxoviruses, particularly Newcastle disease and APMV-3, infectious bronchitis, and influenza viruses may cause respiratory disease and egg production problems in chickens and turkeys that closely resemble aMPV infection. Paramyxoviruses and some avian influenza virions are similar in morphology but can be easily distinguished from aMPV as they possess hemagglutinin and neuraminidase activity. Infectious bronchitis virus can be differentiated from aMPV by morphological and molecular characteristics.

Bacteria and Mycoplasmas
A wide range of bacteria and *Mycoplasma* species can cause disease signs very similar to aMPV infection (50,59). These organisms often act as secondary opportunistic pathogens following aMPV infection and may cause considerable diagnostic problems. Only by isolating or identifying aMPV in the affected birds can a clear distinction be made.

Intervention Strategies
Management Procedures
It is now accepted that management factors will significantly influence the severity of aMPV infection in commercial poultry, particularly turkeys. Poor management practices such as inadequate ventilation and temperature control, high stocking densities, poor litter quality and general hygiene, multi-age stock and the presence of secondary pathogens can all exacerbate aMPV infection (41,51,59,93). Debeaking or vaccinating flocks at a critical time can also influence the severity of clinical signs and eventual mortality due to aMPV infection (6). As a general principle, good biosecurity is essential in preventing the introduction and spread of aMPV onto poultry farms as evidence suggests that wild birds may also act as carriers of the virus. Disinfection of delivery and catching crews, equipment and feed trucks should be routine practice.

Some success in reducing the severity of the disease by controlling secondary adventitious bacteria with antibiotics has been reported (46).

Vaccination Strategies
Both live attenuated and inactivated aMPV vaccines are available commercially for use in turkeys and chickens. Early work on the attenuation of the virus was difficult due to poor attenuation of the virus and problems in reproducing a suitable challenge model in the laboratory (96). However, there are now a number of reports on the successful attenuation of aMPV strains in a variety of cell cultures and their effective use as vaccines (14,24,25,26,80,106). The live attenuated vaccines have been shown to stimulate both systemic immunity and local immunity in the respiratory tract (56). In turkeys and particularly chickens the humoral antibody response is poor following primary live vaccination but birds may still be protected to challenge via cell mediated immunity in the respiratory tract (63). Similarly, high levels of maternally derived antibody will not prevent young turkey poults from developing clinical disease following exposure to virulent aMPV (75). Studies have shown that good cross protection occurs following vaccination with subtype A and B vaccines (29) and that vaccines produced from both subtype A and B strains of aMPV will confer protection against the Colorado subtype C strain of virus (23). To produce complete protection in adult birds oil-adjuvanted inactivated aMPV vaccines are administered to birds previously primed with live vaccines. A typical vaccination program for aMPV in turkeys would be application of a live subtype A or B strain, or combined at day-old using a coarse spray, repeated at 7 to 10 days and again at 4 to 6 weeks. The strategy is to produce cell mediated immunity in the respiratory tract. Breeding stock would additionally receive inactivated vaccine at 16 to 20 weeks. Vaccination reactions may occur due to the presence of secondary pathogens.

There is evidence that live infectious bronchitis vaccine can interfere with the replication of aMPV vaccines in chickens (32).

Future Developments
Recombinant vaccines that incorporate specific immunogens, such as the fusion (F) glycoprotein, in fowl pox virus (108) and a DNA plasmid (95) have also been evaluated. From the results obtained with the poxvirus recombinant vaccine it was concluded that experimental vaccination induced aMPV antibodies in experimental turkeys and produced some protection to challenge (108). Studies in turkeys on the immunity to an aMPV vaccine following in ovo vaccination have also been reported. The results indicated that this route of vaccination has several advantages compared to conventional methods of vaccination (107). In a recent report a cold adapted strain of aMPV was evaluated as a vaccine and was shown to produce protection to challenge for up to 14 weeks post vaccination (81).

Subunit and deletion mutant vaccines are also being developed and evaluated.

Avian Paramyxoviruses 2–9

D. J. Alexander and D. A. Senne

Introduction

The prototype strains of the eight other serotypes of avian paramyxovirus (APMV-2 to APMV-9) and their usual hosts are listed in Table 3.1.

Definitions and Synonyms

Very few synonyms have been used for the other avian paramyxoviruses. The term "Yucaipa" viruses has been applied to APMV-2 viruses, as the first isolate was APMV-2/chicken/California/Yucaipa/56, the prototype of the serogroup. Isolates of the APMV-5 serotype occasionally have been referred to as "Kunitachi" viruses, again after the prototype virus.

Economic Significance

The economic significance of avian paramyxoviruses other than Newcastle disease virus that infect poultry is that of viruses causing significant respiratory disease and egg production problems in laying birds. In uncomplicated infections of turkeys with APMV-3, this level of disease, especially in laying birds, has been considered to have sufficient economic impact to render the birds unprofitable and to justify the use of expensive inactivated vaccine (21, 28). However, the greatest contribution to disease and consequent economic impact is the exacerbative effect avian paramyxoviruses may have on other concomitant bacterial or virus infections. Lang *et al.* (37) considered that, in these circumstances, the disease was sufficiently serious to warrant "prompt disposal of the infected birds."

Public Health Significance

Although the ability of Newcastle disease viruses to infect humans has been well documented (see previous), no reports have been made of other APMV serotypes infecting humans. However, the potential may exist, and virus of APMV-2 serotype was isolated from cynomolgus monkeys (45).

History

Avian Paramyxovirus Type 2 (APMV-2)

In 1956, Bankowski *et al.* (17) isolated a paramyxovirus (27) from a chicken suffering from laryngotracheitis in Yucaipa, California. It was serologically distinct from Newcastle disease virus (NDV) and caused only mild respiratory disease in chickens. Serologic surveys of poultry in the United States indicated that this virus was widespread, more frequently infecting turkeys than chickens (18, 23). Subsequent investigations suggested that viruses of the same serotype were common in poultry around the world (4).

Testing during quarantine of imported caged birds since the early 1970s has frequently resulted in the isolation of APMV-2 viruses, primarily from passerines but also from psittacines (4, 49). Surveillance of wild birds during the 1970s often resulted in the isolation of APMV-2 viruses, most frequently from passerine species (4).

Avian Paramyxovirus Type 3 (APMV-3)

Paramyxoviruses representing a third serotype were isolated from turkeys in Ontario in 1967 and Wisconsin in 1968 and later detected serologically in turkeys in other states of the United States (52). Serologically related viruses have now been reported from turkeys in several countries in Europe.

APMV-3 viruses are also frequently isolated from captive caged birds in most countries where quarantine is imposed, most often from psittacine species, although passerines are also susceptible (4). There is evidence that these viruses differ antigenically from the turkey APMV-3 viruses (14).

Avian Paramyxovirus Types 4–9 (APMV–4 to APMV–9)

The initial isolations of other AMPV viruses were all made in the 1970s, those identified as APMV-4, APMV-6 and APMV-8 were as a result of surveillance studies of feral ducks and geese, usu-

ally for influenza viruses. APMV-4 and APMV-6 have been isolated from domestic ducks, but not APMV-8. APMV-9 serotype had consisted of a single isolate from domestic ducks in New York in 1978, until the isolation of a further member from a feral pintail duck (*Anas acuta*) in Italy in 2004 (24), which suggests this serotype probably also has wild bird reservoirs and worldwide distribution.

Etiology

Classification of Avian Paramyxoviruses
Information on the classification into order, family, subfamily and genus is given in the Introduction to this chapter.

Tumova *et al.* (53) suggested grouping avian paramyxoviruses on the basis of their antigenic relatedness in hemagglutination inhibition (HI) tests. The prefixes PMV-1, PMV-2, etc., were adopted to signify serotype, and the nomenclature proposed for naming influenza isolates (55) was used for the avian paramyxovirus isolates. Subsequently, the International Committee on Taxonomy of Viruses adopted the abbreviations APMV-1, APMV-2 etc. (47), and these abbreviations are used in this chapter (Table 3.1).

There has been no attempt to make more specific definition of a serotype, and further viruses have been grouped based on their relationships in HI tests. When neuraminidase inhibition (34, 35, 43, 52), serum neutralization (52) or agar gel diffusion (1, 11, 34, 36) tests have been used, however, similar groups have resulted.

Despite the consistency of the serologic groupings, some cross relationships exist between viruses of the different serotypes (4). Usually, these have been very minor, although Lipkind *et al.* (38, 40) considered them sufficient to suggest a phylogenic relationship between APMV-1, -3, -4, -7, -8, and -9 and between APMV-2 and -6. However, the relationship between APMV-1 and APMV-3 viruses appears to be closer and more important than the others.

Smit and Rondhuis suggested that there were low serologic reactions between NDV and APMV-3/parakeet/Netherlands/75 (51), which were later confirmed (6). In addition, prior infection of chickens with some APMV-3 viruses conferred protection against challenge with a virulent NDV strain (9). More recently, a monoclonal antibody against the pigeon variant APMV-1 inhibited APMV-3 viruses isolated from exotic birds in HI tests and bound to cells infected with these APMV-3 viruses (12, 26). Because turkey APMV-3 isolates also show relationships with APMV-1 viruses, but none could be demonstrated to react with this monoclonal antibody, other epitopes may be shared by the two serotypes.

Genetic data for APMV-2 to APMV-9 is extremely limited. Chang *et al.* (25) sequenced the entire genome of a APMV-6 isolate. Although the genome appeared to code for a SH protein, which was absent in APMV-1 viruses but present in members of the *Rubulavirus* genus, phylogenetic analyses placed the APMV-6 virus closer to APMV-1 than viruses from other *Paramyxovirinae* genera. Data was available for the hemagglutinin-neuramindase (HN) gene of APMV-2 and APMV-4 viruses and

the fusion (F) gene of APMV-2, phylogenetic analyses of these genes showed APMV-1, -2, -4 and -6 to form a cluster within the *Paramyxovirinae* subfamily, i.e. the *Avulavirus* genus.

Morphology
Negative contrast electron microscopy of members of the *Avulavirus* genus reveals very pleomorphic virus particles. Generally, they are rounded and 100–500 nm in diameter, although filamentous forms of about 100 nm across and of variable length are often seen. The surface of the virus particle is covered with projections about 8 nm in length. In most electron micrographs of avian paramyxoviruses, the "herring bone" nucleocapsid, about 18 nm across, may be seen either free or emerging from disrupted virus particles.

Chemical Composition
The number and molecular weights of the structural polypeptides for the other avian paramyxoviruses are similar to those reported for Newcastle disease virus, although minor variations in molecular weights have meant that PAGE profiles could be used to show similarities between isolates that coincide with the serogroups (7). Variation has also been reported within serogroups, especially for APMV-7 viruses (13).

Virus Replication
This is assumed to be similar to Newcastle disease virus (see previous discussion).

Susceptibility to Chemical and Physical Agents
This is assumed to be similar to Newcastle disease virus (see previous discussion).

Strain Classification
For most of the APMV serogroups, too few isolates have existed to examine strain relationships and classification. Some work has been done in this area for three of the serotypes infecting poultry.

Avian Paramyxovirus Type 2
Considerable antigenic and structural diversity has been recorded among APMV-2 viruses (2, 7), but these have not been related to any epizootiologic or biologic properties. Ozdemir *et al.* (46) prepared three MABs with hemagglutination inhibition activity against the APMV-2 type species and were able to place the 53 isolates tested with them into four groups.

Avian Paramyxovirus Type 3
APMV-3 virus isolates also show considerable diversity. There appears to be antigenic differentiation between those isolated from exotic birds and those from turkeys. This has been confirmed by MABs to APMV-3/turkey/England/MPH/81. With the use of these, Anderson *et al.* (14) showed that although some antibodies reacted with isolates from either source, others bound specifically to turkey viruses. Turkey isolates from the United States and Germany were distinguishable from turkey

isolates from Great Britain and France and possibly more closely related to exotic bird isolates. This division of APMV-3 isolates into two groups was supported by studies with a MAB to an APMV-1 pigeon variant isolate that was also able to react with APMV-3 isolates from exotic birds but not with those from turkeys (26).

Avian Paramyxovirus Type 7
APMV-7 virus isolates have shown marked antigenic variation, and there has been some debate as to whether or not they should all be placed in the same group. Alexander *et al.* (13) examined the antigenic relatedness of six APMV-7 viruses isolated from pigeons and doves and recorded considerable variation placing the viruses in three groups. Two of the groups, consisting of 3 and 2 viruses, appeared to have little relatedness, but viruses in both showed close relationships with the sixth virus examined.

Laboratory Host Systems
As with Newcastle disease virus, embryonated chicken eggs are considered the best medium for the isolation and propagation of the other avian paramyxoviruses. For some serotypes, yolk sac or amniotic inoculation may be the route of choice for isolation or replication (31, 44).

Pathobiology and Epidemiology
Distribution
Avian Paramyxovirus Type 2
APMV-2 viruses are found in feral birds, chiefly passerines, in European, Asian, African, and American countries (3, 30), probably accounting for their common isolation from imported caged birds (3). Isolations from domestic poultry have been rare, although problems associated with such viruses have been recorded in the United States, Canada, the former Soviet Union, Japan, Italy, Israel, India, and France in chickens or turkeys (2, 3).

Avian Paramyxovirus Type 3
APMV-3 viruses have also been isolated from imported exotic birds and other birds held in captivity, but, unlike APMV-2 viruses, there have been no reports of APMV-3 viruses from feral birds (3). APMV-3 virus infections of domestic poultry have been restricted to turkeys in Canada and the United States (52), Great Britain (41), France (15), and Germany (57). There have been no reports of naturally occurring infections of chickens with APMV-3 viruses, although they are fully susceptible (8).

Natural and Experimental Hosts
The general groups of birds reported to be infected with the different serotypes are shown in Table 3.1 and in more detailed reviews (2, 4). Isolations of avian paramyxoviruses from different species have been rarely associated with specific disease episodes. APMV-3 viruses have been related to disease in certain psittacine species such as encephalitis with high mortality in parakeets of the *Neophema* and *Psephotus* genera (51), steatorrhea and pancreatic lesions in *Neophema* parakeets (54), and

high mortality in lovebirds, *Agapornis roseicollis* (33). APMV-5 viruses appear to have a very limited host range being isolated only from budgerigars, *Melopsittacus undulatus,* in which infection resulted in high mortality (32, 43). Viruses antigenically related to APMV-7 viruses have been associated with deaths in snakes following respiratory and nervous disease signs (20).

Spread
Little information is available on the spread of other avian paramyxoviruses. For APMV-2 and APMV-3 serotypes, infection of poultry leads to shedding from the respiratory and intestinal tracts, so it is assumed that the methods of spread of NDV would also apply to these. APMV-2 viruses have been shown to infect feral passerines that may invade poultry houses, but, in the absence of any wild bird host for APMV-3 viruses, it seems most likely that this subtype has been introduced into different countries by the importation of infected poultry or by humans.

The prevalence of APMV-7 viruses in pigeons and doves, which frequently invade poultry houses or mingle with poultry kept outdoors, suggests that these may have been the source of the two reported outbreaks of APMV-7 in turkeys (48) and ostriches (56).

Incubation Period
Little work has been done on assessing the incubation period for the avian paramyxoviruses infecting poultry. Bankowski *et al.* (17) reported rales in chickens 4–6 days after they were inoculated intratracheally with APMV-2 virus. Tumova *et al.* (52) reported mild respiratory signs from day 2 after infection of adult turkeys with APMV-3 virus. Saif *et al.* (48) reported mild respiratory signs from day 2 in turkeys infected with the APMV-7 turkey isolate.

Clinical Signs
Avian Paramyxovirus Type 2
APMV-2 viruses have been associated with mild respiratory or inapparent diseases in chickens and turkeys (18, 23, 29). Unlike NDV, APMV-2 infections have been reported to be more severe in turkeys than chickens, and Lang *et al.* (37) reported severe respiratory disease, sinusitis, elevated mortality, and low egg production in turkey flocks infected with APMV-2 complicated by the presence of other organisms. APMV-2 viruses have been reported to be widespread in turkeys in Israel and associated with severe respiratory disease in complicated infections (39). In experiments conducted under field conditions, Bankowski *et al.* (19) demonstrated that APMV-2 infections of laying turkeys resulted in egg production losses with reduced hatchability and poult yield, but fertility was unaffected.

Avian Paramyxovirus Type 3
APMV-3 virus infections of domestic poultry appear to have been restricted to turkeys. Clinical signs are usually egg production problems, although these have been occasionally preceded by mild respiratory disease (10, 15, 16, 41, 52). Egg production usually declined rapidly with a large number of white-shelled eggs, although hatchability and fertility were rarely affected.

Avian Paramyxovirus Type 6

APMV-6 isolates have also been obtained from turkeys showing mild respiratory disease and egg production problems. Viruses of this serotype have been isolated frequently from domestic ducks in which the virus appears to be apathogenic (42, 50).

Avian Paramyxovirus Type 7

Saif *et al.* (48) reported the isolation of an APMV-7 virus from a series of outbreaks in turkeys. The clinical signs were primarily respiratory with elevated mortality (0.9%/wk) over a 4-week period. In laying hens, egg production was not affected significantly, but there was an increase in white-shelled eggs.

Diagnosis

Isolation and Identification of Causative Agent

The samples taken and methods involved for the isolation of other avian paramyxoviruses are identical to those for NDV. Inoculation of 6- to 7-day-old embryonated eggs via the yolk sac should also be considered, because greater success has been reported for this route with some viruses. APMV-5 viruses do not grow after inoculation into the allantoic cavity and require amniotic inoculation of embryonating eggs or propagation in primary cultures of chick embryo cells (43).

Serology

The same serologic tests used for NDV (APMV-1) can be used for the other avian paramyxoviruses. APMV-5 viruses have been reported as not agglutinating RBCs (43). Gough *et al.* (32) reported, however, the isolation of virus clearly related to APMV-5 viruses that agglutinated guinea pig RBCs well and chick RBCs to a lesser extent. Hemagglutination inhibition antibodies to APMV-3 viruses may be detected in turkeys and chickens showing high vaccine-induced titers to NDV, and ND-vaccinated birds infected with APMV-3 viruses show a rise in HI titer to both viruses (10, 22).

Differential Diagnosis

Viral HA activity may be due to any of the nine avian paramyxovirus serotypes or any of the 16 influenza type A hemagglutinin subtypes that are known to infect birds. Demonstration that the virus is of a specific serotype usually can be carried out by a simple HI test with specific polyclonal antisera.

Newcastle disease virus (APMV-1) shows some cross-reaction in HI tests with several of the other avian paramyxovirus serotypes, especially APMV-3 psittacine isolates, using polyclonal antisera (5). Although the potential for misdiagnosis largely can be eliminated by the use of control sera and antigens in conventional tests, the use of MABs in routine diagnosis can give an unequivocal result.

Intervention Strategies

Few, if any, countries have national control policies for the other avian paramyxoviruses, although, in some, vaccination is permitted for APMV-3 viruses. Despite the frequent isolation of APMV-2 and APMV-3 viruses from passerine and psittacine birds in quarantine (4), little usually is done to restrict the introduction of such birds.

At the farm level, bird proofing of poultry houses should greatly reduce the possibility of introducing paramyxoviruses such as APMV-2 by feral birds. Other preventive measures taken for NDV will apply equally to the other APMV types. Lang *et al.* (37) suggested depopulation for turkey flocks infected with APMV-2 virus if complicated by other organisms.

Management Procedures

Management procedures at the farm level pertaining to Newcastle disease, especially those relating to biosecurity, would also be effective at controlling infections by other avian paramyxoviruses.

Vaccination

The other avian paramyxoviruses do not cause overt disease with high mortality and, thus, their economic impact is considerably less than NDV. Nevertheless, the egg production problems that have been associated with infections of turkeys by APMV-3 viruses can be sufficiently severe to warrant vaccination; for several years, oil-emulsion vaccines to this serotype have been available in Europe and the United States (21, 28). They appear to be effective at preventing the serious egg production losses associated with APMV-3 infections in laying turkeys.

Chapter 4

Infectious Bronchitis

David Cavanagh and Jack Gelb Jr.

Introduction

Infectious bronchitis (IB), also called avian infectious bronchitis, is a common, highly contagious, acute, and economically important viral disease of chickens caused by coronavirus infectious bronchitis virus (IBV). The virus is acquired following inhalation or direct contact with contaminated poultry, litter, equipment, or other fomites. Vertical transmission of the virus within the embryo has never been reported, but virus may be present on the shell surface of hatching eggs via shedding from the oviduct or alimentary tract. The disease occurs in all poultry-producing countries. The highly transmissible nature of IB and the occurrence and emergence of multiple serotypes of the virus have complicated control by vaccination. Adult poultry (e.g., layers) are the source of new, previously unrecognized serotypes, also referred to as variants. Infectious bronchitis has no known human health significance.

In young growing chickens, IBV infection causes respiratory disease. Reduced weight gain and feed efficiency are observed in meat-type broiler chickens. Infection also predisposes broilers to bacterial airsacculitis, pericarditis, and perihepatitis. Mortality, up to 30%, often peaks at five to six weeks of age during the last two weeks of the broiler's life. Immunosuppression will further exacerbate disease and increase mortality. Mortality is much lower (<1%), and recovery is faster in outbreaks due to mild strains of IBV or those in which bacterial involvement is limited.

Some strains of IBV are nephropathogenic and cause renal (kidney)-induced mortality of up to approximately 25% in susceptible flocks.

Egg production and quality declines are noted in layer and breeder chickens. The virus may replicate in the oviduct and cause permanent damage in immature females or pullets resulting in limited egg production later in life. Infection of hens during lay may reduce egg production up to 10% or more depending on the immune status of the flock. Egg shells are commonly malformed and more susceptible to breakage, due to thinning of the shell. Eggs from breeds with pigmented shells may be paler than normal. Albumen from affected eggs is of a watery viscosity. Egg production often recovers following field infections of vaccinated layers but may be permanently depressed in highly susceptible flocks.

Coronaviruses with protein sequences very similar to those of IBV have been isolated from pheasants (*Phasianus colchicus*), turkeys, guinea fowl (*Numida meleagridis*), partridge (Alectoris sp.), peafowl (*Pavo cristato*), and the non-gallinaceous teal (*Anas*

sp.). As discussed later, evidence is accumulating that IBV has a wider host range than was previously believed (20). The turkey coronaviruses are described at length in Chapter 12.

History

Infectious bronchitis was first observed in the United States in North Dakota in 1930. A report by Schalk and Hawn in 1931 (51) of the clinical signs and preliminary laboratory studies of those cases is recognized as the first report of IB. Initially, IB was recognized as primarily a disease of young chicks. However, it was later observed to be common in semi-mature and laying flocks. Other manifestations of IB include egg-production declines in laying flocks, noted following the typical respiratory disease in the 1940s, and kidney lesions observed in the 1960s. The prevalence and economic importance of the disease resulted in efforts to prevent IB in laying flocks by controlling the exposure of chickens to IBV during the growing stage prior to the onset of egg production. This effort by Van Roekel in 1941 (59), which had some success, was the initial step toward the development of the vaccination programs used today.

Other early milestones include the establishment of the virus etiology by Beach and Schalm in 1936, the first cultivation of the virus in embryonating chicken eggs by Beaudette and Hudson in 1937, the development of the "H" vaccines—e.g., the ubiquitous H120 about 1960 (10), and the report in 1956 by Jungherr and colleagues that the Connecticut isolate of 1951 and the Massachusetts isolate of 1941 produced similar diseases but did not cross-protect or cross-neutralize (59). The Jungherr's report was the first demonstration that the etiology of IB included more than one serotype. More about the early history of IB research can be found in the review by Fabricant (59).

Incidence and Distribution

Infectious bronchitis is distributed worldwide. In the United States, several serotypes in addition to the originally identified Massachusetts (Mass) type of IBV have been identified, beginning in the 1950s (59, 93, 132). Mass-type strains have been isolated in Europe and Asia since the 1940s and up to the present, although other serotypes found in North America have not generally occurred on other continents. Dozens of other serotypes have been isolated in Africa, Asia, India, Australia, Europe, and South America (18–20, 31). Outbreaks of IB frequently have occurred, even in vaccinated flocks. The virus strains isolated from

those outbreaks are often, but not always, (137) found to be a serotype distinct from the vaccine type. Several serotypes can co-circulate in a given region.

Etiology

Classification

Infectious bronchitis virus is a member of the *Coronaviridae*, which includes two genera, *Coronavirus* and *Torovirus*. The *Coronaviridae* family is, together with the *Ateriviridae* and *Roniviridae*, within the order *Nidovirales* (58). IBV is in Group 3 of the Coronavirus genus, together with coronaviruses from other avian species (58, reviewed in 19). Groups 1 and 2 comprise mammalian coronaviruses that differ extensively from IBV with respect to genome organization and gene sequences. A torovirus has been implicated in enteric disease of turkeys (see Chapter 13).

Morphology

Infectious bronchitis virus is round to pleomorphic in shape. It possesses an envelope that is approximately 120 nm in diameter with club-shaped surface projections (spikes) about 20 nm in length (Fig. 4.1). The spikes are not packed as closely as the rod-shaped spikes of paramyxoviruses. Ribonucleoprotein (RNP or core) structures released from spontaneously disrupted particles could be visualized by shadowing but not by negative-staining. For the most part, the RNP was observed as strands of only 1–2 nm in diameter, but coiled structures of 10–15 nm diameter occasionally were observed. The appearances of toroviruses and coronaviruses in the electron microscope can be very similar (56).

Infectious bronchitis virus strains differ in their density in sucrose gradients; particles with a full complement of spikes have a density of 1.18 g/mL, and lesser-spiked particles may be as low as 1.15 g/mL. Centrifugation forces of greater than 100,000 g should be avoided, as loss of spikes, or at least the S1 subunit that is believed to form most of the globular head of the spike protein, can occur. Incubation at 37°C sometimes results in the loss of the S1 subunit (159). The S2 glycopolypeptide, which anchors the S protein in the membrane, is not linked to S1 by disulphide bonds.

Chemical Composition

Infectious bronchitis virus virions contain three major structural proteins (i.e., that are components of virus particles [virions]): the spike (S) and membrane (M) glycoproteins and the internal nucleoprotein (N) (58, 112). In addition, there are small amounts of a fourth protein (small membrane protein, E), which is essential for virus particle formation. The S protein comprises two or three copies of each of two glycopolypeptides, S1 and S2 (approximately 520 and 625 amino acids, respectively). Hemagglutination-inhibiting (HI) and most of the virus-neutralizing (VN) antibodies are induced by S1 (22, 86, 106), as is protective immunity (94)

Only about 10% of the M protein is exposed at the outer virus surface. The N protein surrounds the single piece of single-stranded, positive sense, RNA genome (to form the RNP) that comprises approximately 27,600 nucleotides, the whole of which
4.1. Virion of avian IBV illustrating club-shaped projections. Preparation negatively stained with phosphotungstic acid. ×3300,000. (Berry and Almeida)

has been cloned and sequenced for several strains. "Infectious clone" systems have been developed for IBV, enabling the manipulation of any part of the genome (16, 17, 167).

Virus Replication

It is the S glycoprotein that is responsible for attachment of IBV to host cells. Indeed, experiments with recombinant IBV in cultured cells showed that the S protein is a determinant of host cell range (16). Whether S determines any tropisms within chickens and/or host range with regard to infection of other avian species remains to be demonstrated. The virus replicates in the cytoplasm, five subgenomic messenger RNAs being produced by a discontinuous transcription mechanism. Three of these mRNAs, 2, 4 and 6, are responsible for production of the S, M and N virion proteins, respectively, while the other two mRNAs, 3 and 5, encode three and two proteins, respectively. One of the gene 3-encoded proteins is the E protein; the other proteins encoded by genes 3 and 5 are nonstructural proteins that are not incorporated in virus particles. Genetic manipulation has shown that these four nonstructural proteins are not essential for replication but are probably helpful to the virus during replication *in vivo* (17, 78). New virus starts to appear 3–4 hours after infection, with maximum output per cell being reached within 12 hours at 37°C. Virions are assembled at internal membranes (e.g., Golgi membranes, not at the cell surface).

Resistance to Chemical and Physical Agents

Thermostability

Most strains of IBV are inactivated after 15 minutes at 56°C and after 90 minutes at 45°C. Long-term storage of IBV at –20°C should be avoided, but infectious allantoic fluid has remained viable after storage at –30°C for many years (reviewed in 21). Infected tissues stored in 50% glycerol are well preserved, and tissues in this medium can be shipped to a laboratory for diagnosis without refrigeration. Outdoors, survival up to 12 days in spring and 56 days in winter has been reported.

Lyophilization

Infectious allantoic fluid lyophilized, sealed under vacuum and stored in a refrigerator, has remained viable for at least 30 years (reviewed in 21). Attenuated vaccines are lyophilized in the presence of sucrose or lactose to preserve potency and extend shelf life.

pH Stability

In one survey, the reduction in titer following a pH 3 treatment at room temperature for 4 hours varied from 1–2 log10, for most isolates, to 5 log10 for others (reviewed in 21). Infectious bronchitis virus in cell culture was more stable in medium at pH 6.0 and 6.5 than at pH 7.0 to 8.0.

Chemical Agents

Infectious bronchitis virus is ether-labile, but some strains survived 20% ether at 4°C for 18 hours (reviewed in 21). All infectivity was destroyed by 50% chloroform at room temperature after 10 minutes and 0.1% sodium deoxycholate at 4°C for 18 hours. Infectious bronchitis virus is considered to be sensitive to the common disinfectants. Several have been compared for activity against another coronavirus, transmissible gastroenteritis virus of swine. Treatment with a final concentration of 0.05 or 0.1% beta-propiolactone (BPL) or 0.1% formalin eliminated IBV infectivity. Only the BPL treatment had no adverse effect on IBV hemagglutination antigen activity.

Strain Classification

Many methods are used to differentiate and classify isolates of IBV, and they have been thoroughly compared by de Wit (50). Serotype and more recently genotype classification, based on features of the S protein, are used to classify strains. Dozens of serotypes and genotypes of IBV have been detected, and many more will surely be reported in the future. Traditionally, IBV serotypes have been defined by VN and HI tests. Serotype-specific antibody is induced by the S1 subunit of the S protein. VN and HI are not commonly used for serotyping because of the limited availability of the increasing number of reference sera, corresponding to different serotypes, which are required for analysis. Some laboratories have used monoclonal antibodies that are specific to a given serotype, the antibodies corresponding to epitopes formed by the S1 protein. These monoclonal antibodies can be used in enzyme-linked immunosorbent assays (ELISAs), which are more economical than VN assays. However, serotype-specific monoclonal antibodies are only available for a small number of serotypes. Routinely now, laboratories are using reverse transcriptase polymerase chain reactions to produce DNA copies of IBV genes, usually the S1 part of the S protein gene, followed by sequencing or, less frequently, restriction endonuclease analysis. (See the "Confirmation of Infectious Bronchitis Virus by Nucleic Acid-Based Methods" section later in this chapter.) Such nucleic acid approaches then define IBV isolates by genotype rather than by serotype. Sequence analysis of field strains suggests that the evolution of IBV involves recombination during mixed infection (23, 92, 107, 112, 170). Consequently, IBV isolates with S genes of very similar sequence can vary substantially in other parts of the genome. The term "genotype" has no precise meaning and is defined operationally and arbitrarily by an author. That said, strains of a given serotype tend to have S1 amino acid identities of approximately 90% or greater; strains with this degree of sequence identity could be said to belong to the same S1 genotype. It is possible for isolates to be of the same S1 genotype and yet not of the same serotype or, at least, to cross-react poorly (24, 27). Sequence data of many isolates of IBV strongly supports the view that IBV evolution includes recombination. Probably all IBVs are recombinants, and probably at many positions within a given genome. However, it is not possible to state when recombination events occurred or which were the immediate parents of whichever part of the genome is being reported.

Serum Antibody Analysis

As stated previously, dozens of serotypes of IBV are known, defined by VN and HI tests. Virus neutralization has been performed with several systems (reviewed in 50). Cross-neutralization analysis of field isolates of Arkansas (Ark) and Delaware 072 has indicated the existence of subtypes of these serotypes (130, 137).

Strain classification by HI tests has also been investigated (reviewed in 50). The HI antibody response following a single exposure and resulting infection can be highly strain specific, even differentiating the Holland from the M41 strains of the same serotype (i.e., Massachusetts). The specificity of the early response and the limited cross reactivity are the basis for a procedure for serotyping isolates by HI. In contrast, Cook et al. (37) compared the HI test with the VN test in TOCs and concluded that the HI test was subject to high and variable cross-reactions and that IBV strains were more clearly differentiated by the VN test. Both studies based the evaluations on the results from primary sera, because secondary sera are much more broadly reactive (65). IBV must be treated with certain enzyme preparations, the active component of which is a neuraminidase (152), to generate HA activity (reviewed in 50, 64). The use of the HI and VN tests to characterize IBVs has declined as the application of RT-PCR and sequencing has increased.

Monoclonal Antibody Analysis

Monoclonal antibodies have been developed against several serotypes of IBV, although this is only a small proportion of the number of serotypes known to exist (85, 87, 88, 98, 101, 106). The VN epitopes, as defined by monoclonal antibody analysis, are situated largely in the first and third quarters of the S1 gly-

copolypeptide (24, 106). Antigenic groups of Australian isolates characterized by monoclonal antibodies correlated better with *in vivo* cross-protection data than groups defined by antisera (85). The use of monoclonal antibodies to identify isolates is discussed further in "Diagnosis."

Nucleic Acid Analysis

The sequence of the whole genome has been established for several isolates, and the sequence of the structural protein genes has been reported for a very large number of IBV strains. The gene that has been sequenced most frequently is that encoding the S1 subunit of the spike glycoprotein, as it is the S1 protein that determines serotype and, most importantly, is the major inducer of protective immunity. Moreover, the great sequence variation exhibited by the S1 protein (171) is believed to be largely responsible for strains of one serotype being able to replicate and cause disease, despite immune responses induced by another serotype. A great many S1 protein subunit gene sequences have been published and deposited in nucleotide sequence data banks, and gene sequences of some additional isolates have been published in data banks only. Comparison of the deduced S1 amino acid sequences has revealed that many of the serotypes defined by VN tests commonly differ by about 20–25%, and occasionally, by approximately 40% or more (68). Exceptions, however, exist. For example, the Connecticut 46 and Massachusetts 41 strains are in different serotypes, yet their S1 proteins differ by only 7.6% of amino acids (4.6% of nucleotides). Similarly, several isolates that had 97% amino acid identity with Dutch isolate D274 were defined in serum VN tests as belonging to different serotypes (24). These findings and the sequencing of VN-monoclonal-antibody escape mutants (98) suggest that only a few S1 epitopes induce the major VN antibodies and that a few key mutations in these epitopes might result in changes to a new serotype. Relationships established by more than one research group using VN tests do not always agree either with each other or with sequence analysis. For example, Johnson and Marquardt (93) considered that Arkansas 99 and Connecticut 46 were different serotypes, consistent with the finding that they differ by 29% in the first 200 S1 residues; whereas previously they had placed them in the same serotype. Experiments suggest that the degree of cross-protection between strains decreases as the differences between their S1 sequences increases (25, 68, 111).

Moderate sequence variation may be exhibited within a serotype. Thus, isolates of the North American Arkansas (Ark) serotype had S1 identities of ≥93% (nucleotide) and ≥89% (amino acid) among each other (137). Analysis of isolates of the 793/B (4/91; CR88) serotype from several countries isolated over a 15-year period indicated nucleotide and amino acid identities of ≥96% and ≥92%, respectively (15, 28).

Extensive sequence comparisons, from gene 2 (S) down to the 3′ end of the genome, suggest that recombination is a feature of IBV evolution (23, 92, 108, 170). Thus, it must not be assumed that if two isolates have very similar S proteins, deduced by whatever technique, that they are necessarily very similar in all other genes. Additional aspects of nucleic acid analysis are discussed in "Diagnosis."

4.2. Comparison of normal 16-day-old embryo (left) and curled, dwarfed, and infected embryo of the same age (right).

Laboratory Host Systems

Chicken Embryos

Most isolates of IBV replicate well in 10- to 11-day-old embryonating chicken eggs following inoculation of the allantoic cavity; field isolates often require adaptation via several (three or more) serial passages to achieve high titers of virus in the allantoic fluid (AF). Characteristic lesions such as stunting (dwarfing) and curling of the embryo and its feet (121) occur with increasing passage as does the incidence of embryo mortality. Upon opening the air cell end of the egg, the embryo is seen curled into a spherical form with feet deformed and compressed over the head and with the thickened amnion adhered to it (Fig. 4.2). A common internal lesion of the IB-infected embryo is the presence of urates in the mesonephros of the embryonic kidney. This lesion is not pathognomonic for IBV infection and is observed in embryos infected with avian adenovirus.

Embryo survival of 90% through the 19th day of incubation is characteristic of IBV field isolates upon primary isolation. In contrast, embryo mortality by the 10th passage may be as high as 80%. Characteristic embryo changes are seen several days after inoculation of the virus (121). Only slight movement of a dwarfed embryo may be observed during candling.

The optimum age of embryo inoculation, and the temperature and length of incubation for maximum infectivity titer of the Beau-

dette strain following allantoic cavity inoculation have been studied and reviewed (97). In general, inocula of about 103 tracheal organ culture infectious doses or 10^4 EID_{50} of IBV have yielded near maximum titers by 36–40 hours at 37°C. Microscopic lesions in embryos infected with IBV-M41 strain have been studied by Loomis *et al.* (121). Congestion with perivascular cuffing and some necrosis of the livers by the sixth day after inoculation was observed. Lungs were pneumonic, characterized by congestion, cellular infiltration, and serous exudate in the bronchial sacs. Interstitial nephritis with edema and distension of the proximal convoluted tubules and the presence of casts was noted in the kidney. Glomeruli were not altered. The chorio-allantoic membrane (CAM) and amniotic membrane were edematous. No inclusion bodies were observed. Coronaviruses isolated from pheasants have been propagated readily in chicken embryos.

Cell Cultures

Chicken kidney cells form syncytia, which quickly round up and detach from the culture surface, appear as large spheres with the refractile contents. Syncytia in Vero cells infected with Vero cell-adapted IBV-Beaudette contain numerous nuclei, and the cells remain attached to the culture surface longer.

The lag phase of IBV is 3–4 hours, with peak titers by 12 hours, although maximum titers in culture medium could be later (e.g., 24–30 hours, depending on the multiplicity of infection (16, 17, 78)). Titration of IBV in embryonating eggs gives higher titers (10- to 100-fold) than in CEK or CK cells. Infectious bronchitis virus strains, which had been passaged in embryos and many times in CK cells, replicated in chicken embryo fibroblast cultures, but to titers several log10 less than in CK cells (16, 139). The Beaudette, M41, and Iowa 97 strains have been propagated successfully in the African green monkey Vero cell line, which has been used for many fundamental studies of IBV Beaudette replication (116). Of 10 strains examined, two and none replicated in BHK-21 and HeLa cells, respectively, the titers in BHK cells being lower than in CK cells (16, 139). In summary, CK cells are widely used with many isolates of IBV, and only the Beaudette strain has been used extensively in Vero cells.

Pheasant coronavirus replicates well in embryonating chicken eggs (73), although not in chicken tracheal organ cultures. TCoV has not been grown successfully in cell cultures; turkey embryos are used (see Chapter 12).

Organ Cultures

The propagation of IBV in organ cultures of trachea and other tissues has been reviewed by Darbyshire (47). Tracheal rings are prepared from 20-day-old embryos and maintained singly in roller tubes. Following infection with IBV, ciliostasis, which is easily observed by low-power microscopy, occurs within 3–4 days, earlier with high-titering inocula. Tracheal organ cultures have proved very useful for the isolation, titration, and serotyping of IBV, because no adaptation of field strains is required for growth and the induction of ciliostasis. However, some strains with affinity for other tissues do not cause consistent ciliostasis. When titrated in tracheal rings, preparations of the Belgian B1648 nephropathogenic strain gave the appearance of being of low titer, whereas titration in embryonating eggs revealed the titer to be high (D. Cavanagh, unpublished observation). Pheasant coronavirus replicates to only very low titer in chicken tracheal organ cultures.

Pathogenicity

Infectious bronchitis is primarily a disease of chickens. Infection is initiated via the respiratory tract regardless of the tissue tropism of the strain (respiratory, kidney, gonad). The virus replicates and produces lesions in many types of epithelial cells, including those of the respiratory tract (nasal turbinates, Harderian gland, trachea, lungs, and air sacs), kidney, and gonads (oviduct, testes) (11). The virus also grows in many cells of the alimentary tract (esophagus, proventriculus, duodenum, jejunum, bursa of Fabricius, cecal tonsils, rectum, and cloaca) many times with little pathobiological clinical effect (6, 100, reviewed in 19). Some Asian strains may cause lesions in the proventriculus. The virus commonly persists in the alimentary tract in young chickens (5) and in layers in the absence of clinical disease (96). Some live vaccine strains such as the Arkansas in the United States have been shown to persist in the respiratory tract especially when administered in combination with another attenuated strain (e.g., Massachusetts) (5).

Infectious bronchitis virus strains damage the respiratory epithelium often predisposing young chickens to secondary infections with pathogenic bacteria. Airsacculitis and systemic colibacillosis are common outcomes of virulent IBV infection especially in broiler chickens (127). Laboratory inoculation with M41 followed by aerosol administration of an 02 or 078 strain of *E. coli* produced disease often observed under commercial conditions. An interval of 4 days between IBV and *E. coli* challenges produced airsacculitis, pericarditis, and perihepatitis. Administration of IBV alone did not induce lesions (142). Experimentally, chickens inoculated with IBV and *E. coli* had more severe and persistent respiratory lesions than those inoculated with IBV alone. *E. coli* was isolated from the tracheas of chickens inoculated with IBV and *E. coli* more frequently than from chickens inoculated with IBV alone. There was neither increased numbers of *E. coli* nor significant lesions in the respiratory tract of the group inoculated with *E. coli* alone (133). Laboratory studies demonstrated ascites in 15% of broilers infected with M41 followed four days later by *E. coli* innoculation (166).

Infection with IBV has long been recognized to enhance disease and shedding caused by pathogenic avian mycoplasma. *M. gallisepticum* and *M. imitans* also exacerbate the consequences of infection by IBV (reviewed in 61). Interaction between combinations of Newcastle disease and infectious bronchitis live vaccine, *M. gallisepticum* and *E. coli* resulted in profuse multiplication of *E. coli* with severe and persistent histological lesions and mortality in SPF chickens inoculated at one-week of age (134). Virulent IBV given three days prior to an aerosol exposure to *Mycoplasma synoviae* was shown to increase the incidence of arthritis in layer pullets. Strain M41 induced a higher incidence than D1466 in birds given *M. synoviae* (114). Another report showed the pathogenic M41 strain of IBV rapidly activated an apparent latent *M. gallisepticum* in the trachea induced by oral

fluoroquinolone treatment of SPF chickens (148). In a case-controlled study of pheasants, sinusitis was commonly observed and was associated with *M. gallisepticum* in the trachea and conjunctiva. Sinusitis was also attributed to the presence of pasteurella and avian coronaviruses, the most common infectious agents detected (174).

Immunosuppression increases the severity of respiratory disease associated IBV–*E. coli* combined infections and produces significant economic losses (136). Commercial broilers infected with infectious bursal disease virus (IBDV) are more susceptible to develop secondary infection of the respiratory tract with *E. coli*, resulting in significant economic losses. Phagocytosis of *E. coli* by macrophage was markedly reduced in chickens infected with IBDV and IBV. IBDV immunosuppression prolonged IBV shedding (150).

Vaccination for IBV and lentogenic field strains of Newcastle disease virus has been used to control airsacculitis in broilers. Vaccination using the Massachusetts serotype H 120 vaccine at one day of age prevented broilers from developing clinical IB and significantly reduced *E. coli* airsacculitis after challenge with M41 and *E. coli* strain 506 (127).

Nephropathogenic strains may not produce significant respiratory lesions (72) or clinical signs (179). Field isolates, regardless of originating tissue, infect via the respiratory tract and produce lesions of varying severity in the trachea depending on their virulence.

Cumming (46) enumerated some of the management factors that contribute to IB-related kidney disease in Australia. Greater mortality was seen in males, where there was cold stress, in certain breeds, and/or where animal by-products were the major component of high-protein diets. Some of these factors known to exacerbate the clinical disease have been used in experimental models to evaluate the clinical outcome of interaction between such factors and different IBV strains. Chickens fed increased levels of dietary calcium followed by infection with the nephropathogenic Gray IBV strain frequently developed urolithiasis and kidney lesions, but a similar infection introduced 8 weeks prior to feeding chickens a diet including increased levels of calcium did not induce urolithiasis (72).

Other differences in virulence of IBV strains have been noted. Passage of IBV in chicken embryos gradually results in a decrease in virulence for chickens; this is the traditional way of developing IB vaccines. At least some attenuated strains cause little or no ciliostasis after application to chickens by eye drop and nasal instillation, although they do cause ciliostasis following inoculation of tracheal organ cultures (60, 77). As attenuated virus may replicate to lower titers in the nose than does virulent virus (77), the maintenance of ciliary activity in the trachea may be at least in part because the initial replication in the nares produces only low amounts of virus, which have little subsequent effect on the trachea. Although some strains of IBV are highly nephropathogenic, causing extensive and reproducible kidney disease in experimental conditions, many strains of IBV may be associated with nephritis to some degree in the field; environmental factors are probably important as to whether kidney complications are significant. Tissue tropism of a Connecticut serotype strain of IBV could be altered from respiratory to kidney tissues by *in vivo* serial passage of the virus via the cloacal route (168). Following 13 such passages, the virus grew better in kidney tissues and caused more obvious lesions there than did the parent virus. The kidney and other non-respiratory organs are sites of persistence of IBV infectious virus being periodically shed in nasal secretions and feces (55,63).

Virulence for the reproductive tract may also differ among IBV strains. Presence of maternal antibody could prevent damage to the oviduct during an early-age IBV infection (32). In susceptible layers, different IBV strains produced a range of effects varying from shell pigment changes with no production drop to production drops of 10–50% (82). From China (178), outbreaks of a "proventricular-type" IBV infection in broiler chickens have been reported since 1996. The disease is characterized by swollen and hemorrhagic ulceration of proventriculi and mortality ranging from 15–80%. Also reported in China (180) have been chicks showing depression, swollen eyes with lacrimation, and diarrhea followed by obvious signs of respiratory disease. The morbidity of this disease was 100%, and the mortality was 20%. Postmortem examination showed that the primary lesion was swelling of glandular stomach. IBV was isolated, one isolate being named QX IBV.

Coronaviruses isolated from pheasants differ in gene sequence from IBV to an extent similar to that exhibited by different serotypes of IBV (24). When three isolates of coronavirus from pheasants were inoculated into chickens, no signs of disease were observed (118), leading to pheasant coronavirus (PhCoV) being officially considered as a species distinct from IBV. PhCoV is associated with both respiratory and kidney disease in pheasants (4, 27, 73, 118, 143). Turkey coronavirus, which has not been observed to cause disease in chickens following experimental inoculation, is associated with enteric disease in turkeys (see Chapter 13). The H120 vaccinal strain of IBV has been isolated from peafowl (Pavo cristatus) in China, and a nephropathogenic (in chickens) strain of IBV has been isolated from a teal (Anas sp.) (119). In both cases these birds were being raised domestically in the vicinity of chickens. In neither case was disease reported in the peafowl or teal. A coronavirus with all gene sequences having high identity with IBVs was isolated from a partridge in China. In Brazil a coronavirus having antigenic identity with IBV has been isolated from domestic guinea fowl, in the proximity of commercial chickens that were exhibiting mortality, enteritis, and low feed consumption. The virus caused respiratory distress and watery feces in both chickens and guinea fowl following experimental inoculation. Whether the guinea fowl virus was a *genuine* guinea fowl virus or an IBV that had transferred to the guinea fowl from chickens is not known. The point is perhaps moot. Taken together, the preceding observations indicate that IBV can replicate in avian species other than chickens, indeed in birds that are not gallinaceous, and that coronaviruses of other birds can replicate in chickens, although not necessarily causing disease. Coronaviruses have been detected in graylag goose, mallards, and pigeons. Limited sequencing suggests that these viruses should be assigned to Group 3, like IBV, but has also shown that these viruses were clearly not very closely related to IBV (e.g., they had one or two additional genes located after the

N protein gene (20, 95)). A coronavirus has also been isolated from a green-cheeked Amazon parrot (*Amazon viridigenalis Cassin*), though, on the basis of limited sequence data, this would appear to be substantially different from IBV (74) and possibly not a Group 3 coronavirus. A Group 2 coronavirus has been isolated from a Manx sheerwater (*Puffinus puffinus*) (138).

Pathogenesis and Epizootiology

Natural and Experimental Hosts

As explained previously, it is no longer considered that the chicken is the only host for IBV, although it is possible that it is only in the chicken that IBV would cause disease.

Age of Host Commonly Affected

All ages are susceptible, but the disease is most severe in baby chicks, causing some mortality. As age increases, chickens become more resistant to the nephropathogenic effects, oviduct lesions, and mortality due to infection (2,44, 157).

Transmission, Carriers, and Vectors

Infectious bronchitis virus spreads rapidly among chickens in a flock. The disease is highly contagious and has a very short incubation period. Susceptible birds placed with infected chickens usually develop clinical signs within 24–48 hours. Virus was isolated consistently from the trachea, lungs, kidney, and bursa of chickens at 24 hours and through the seventh day after aerosol exposure (80). The frequency of virus isolations declined with time and varied with the infecting strain, but IBV was isolated from the cecal tonsils at 14 weeks and from feces 20 weeks post infection (3). Re-excretion of IBV has also been detected from hens that had been virus-negative for several weeks following recovery from inoculation at one day of age. Virus was isolated from tracheal and cloacal swabs collected at the point of lay and 19 weeks of age (96). The nature of the persistence of IBV infection remains undefined, although the kidney may be one of the sites of persistent infection (55). IBV vaccine virus may persist in various internal organs for up to 163 days or longer (63). During this period, the virus may be periodically shed in nasal excretions and feces. Reports of extended and intermittent shedding are evidence of the potential risk of flock-to-flock transmission via contamination of personnel or equipment.

The frequency of airborne spread between flocks is unknown, although it is generally considered that IBV spreads readily. In view of the recent discovery of IBV in species other than the chicken, it should be considered that some other species of bird may act as vectors of IBV.

Incubation Period

The incubation period of IB is dose dependent and is as short as 18 hours for intratracheal inoculation and 36 hours for ocular application.

Clinical Signs

The characteristic respiratory signs of IB in chicks are gasping, coughing, sneezing, tracheal rales, and nasal discharge. Wet eyes
4.3. Thin-shelled, rough, and misshapen eggs laid by hens during an outbreak of IB. (Van Roekel)

may be observed, and an occasional chick may have swollen sinuses. The chicks appear depressed and may be seen huddled under a heat source. Feed consumption and weight gain are significantly reduced. In chickens greater than 6 weeks of age and in adult birds, the signs are similar to those in chicks, but nasal discharge does not occur as frequently, and the disease may go unnoticed unless the flock is examined carefully by handling the birds or listening to them at night when the birds are normally quiet.

Broiler chickens infected with one of the nephropathogenic viruses may appear to recover from the respiratory phase and then show signs of depression, ruffled feathers, wet droppings, increased water intake and mortality (46, 175). When urolithiasis is associated with IB in layer flocks, there may be increased mortality, but otherwise the flock appears healthy (13, 42).

In laying flocks, declines in egg production and quality are seen in addition to respiratory signs. Infectious bronchitis virus, however, has been isolated from cloacal swabs or cecal tonsil samples from breeder or layer flocks with slight production drops and the production of pale unpigmented shell eggs, but no respiratory signs. The severity of the production declines may vary with the period of lay (57) and with the causative virus strain (82). Six-to-eight weeks may elapse before production returns to the pre-infection level, but in some cases, this is never attained. In addition to production declines, the number of eggs unacceptable for setting is increased; hatchability is reduced; and soft-shelled, misshapen, and rough-shelled eggs are produced (43) (Fig. 4.3).

Internal quality of eggs, as observed when breaking eggs on a flat surface, may be inferior. The albumen may be thin and watery without definite demarcation between the thick and thin albumen of the normal fresh egg. (Fig. 4.4).

Infectious bronchitis virus infection of one-day-old chicks can produce permanent damage to oviducts leading to reduced egg production and inferior quality eggs when the chickens come into lay. The severity of oviduct lesions is likely to be less in infections of older chickens, and some serotypes may fail to produce any pathologic change even in infections of one-day-old chicks. Presence of specific maternal antibody was also shown to protect oviduct from damage due to IBV infection in early life (32).

Coronavirus infection of laying pheasants has been associated with poor hatchability, small size, and variable color—pale buff to greenish brown, compared to the more normal dark olive brown
4.4.   Contents of two eggs. Normal egg (bottom). Egg from chicken exposed to IBV at one day of age (top). Note watery albumen with yolk separated from thick albumen. (Hofstad)

4.5.   Kidney lesions associated with IB caused by T strain of virus. Note swollen kidneys with tubules and ureters distended with urates. (Cumming)

(118). On another game farm from which a coronavirus was isolated, 15% of breeding pheasants died rapidly, the only clinical sign being sneezing. On that occasion, egg production and hatchability were down, but egg quality was unaffected. In a group of pheasant poults, no respiratory signs were reported, although by 10 weeks of age mortality had reached 45%. The sick birds were reported as having ruffled feathers, with drooping wings (118).

Morbidity and Mortality

All birds in the flock become infected, but mortality is variable depending on virulence of the infecting serotype; age; status of immunity, either maternal or active; and stresses such as cold or secondary bacterial infections. Moderate to severe mortality has been noted with some of the respiratory and nephropathogenic strains, such as Delaware 072 and Australian T strain, respectively. Sex, breed, and nutrition are additional factors that contribute to the severity of kidney disease (45, 46). Mortality may be as high as 25% or more in chickens less than 6 weeks of age and usually is negligible in chickens greater than 6 weeks. Mortality in urolithiasis cases ranged from 0.5–1.0% per week.

Mortality of 45% by 10 weeks of age has been reported on a pheasant game farm, from which a coronavirus was isolated (118). Mortality can also occur in adult pheasants; 15% died on one farm.

Gross Lesions

Infected chickens have serous, catarrhal, or caseous exudate in the trachea, nasal passages, and sinuses. Air sacs may be foamy during the acute infection (Fig. 4.6 A), then become cloudy and contain a yellow caseous exudate. Areas of pneumonia may be observed around the large bronchi. Nephropathogenic infections produce swollen and pale kidneys with the tubules and ureters often distended with urates (45, 179) (Fig. 4.5).

Fluid yolk material may be found in the abdominal cavity of chickens that are in production, but this is also seen with other diseases that cause a marked drop in egg production. Permanent lesions in the oviduct may be a consequence of IBV infection of one-day-old chicks and are a cause of reduced egg production when reaching maturity. The middle third of the oviduct is most severely affected and may be nonpatent and hypoglandular. In addition, effects of IBV infection on the reproductive tract of chickens in production have been detailed by 155. They observed reduced length and weight of the oviduct in infected birds as well as regression of the ovaries.

The most noted lesions associated with the infection of pheasants by coronaviruses in the field are visceral urate deposition ("visceral gout") and urolithiasis with gross swelling of the kidneys, which are pale (118, 143).

Histopathology

The mucosa of the trachea of chickens with IB is edematous. There is a loss of cilia, rounding and sloughing of epithelial cells, and minor infiltration of heterophils and lymphocytes within 18 hours of infection. Regeneration of the epithelium starts within 48 hours. Hyperplasia is followed by massive infiltration of the lamina propria by lymphoid cells and the formation of a large number of germinal centers, which may be present after seven days. If air sac involvement occurs, there is edema, epithelial cell desquamation, and some fibrinous exudate within 24 hours. Increased heterophils can be observed later with lymphoid nodules, fibroblast proliferation, and regeneration by cuboidal epithelial cells (149) (Fig. 4.6 A–F).

Intraocular inoculation of H120 vaccine virus resulted in the replication of the virus in the Harderian gland (as well as in respiratory tissues) with histologic changes characterized by the presence of Russell bodies in plasma cells and the exfoliation of tubular epithelial cells (165).

The kidney lesions of IB are principally those of an interstitial nephritis (Fig. 4.6 G–H). The virus causes granular degeneration, vacuolation and desquamation of the tubular epithelium, and massive infiltration of heterophils in the interstitium in acute stages of the disease. The lesions in tubules are most prominent in the medulla. Focal areas of necrosis may be seen as well as indications of attempted regeneration of the tubular epithelium. During recovery, the inflammatory cell population changes to lymphocytes and plasma cells. In some cases, degenerative changes may persist and result in severe atrophy of one or all of the divisions of the nephrons. In urolithiasis, the ureters associated with atrophied kidneys are distended with urates and often contain large calculi composed mainly of urates (149).

Ultrastructural studies of infected kidney tissues revealed epithelial cells of the lower nephron and ducts to be the primary targets for IBV replication (29, 30). Infected epithelial cells containing virus particles were more abundantly found in the collecting ducts, collecting tubules, distal convoluted tubules, and Henle's loops than in the proximal convoluted tubules. Cytoplasmic changes in the infected epithelial cells were characterized by swelling of the mitochondria, dilation of Golgi vesicles, and an increase in the amount of rough endoplasmic reticulum (RER). Virus particles were seen budding from the RER, and as the virus replication progressed, virus particles were enclosed in dilated RER, cytoplasmic vesicles, or virus containing electron-dense bodies.

Experimental IB infection of the oviduct of mature hens resulted in decreased height and loss of cilia from epithelial cells; dilation of the tubular glands; infiltration by lymphocytes, other mononuclear cells, plasma cells, and heterophils; and edema and fibroplasia of the mucosa of all regions of the oviduct (149, 155). The histopathology of IB and comparisons with other diseases are given in detail in a book by Riddell (149), a review of renal pathology by Siller (156), and more recent investigations (29, 30, 179).

Histopathological analysis of pheasant poults infected with a coronavirus revealed moderately severe interstitial nephritis. There was tubular infiltration with predominantly mononuclear cells, tubule dilation, flattening of lining of epithelium, cast formation, and focal necrosis (118, 143).

Immunity

Active

Aspects of immunity to IBV have been reviewed previously (19, 55). Both breed- and strain-related genetic resistance to IBV infection have been described in chickens (8, 14, 39, 141, 157). More investigations, however, are warranted to assess the genetic resistance of commercial lines of chickens. Chickens just recovered from the natural disease are resistant to challenge with the same virus (homologous protection), but the extent of protection to challenge with other IBV strains (heterologous protection) varies. Factors that complicate studies of the mechanism and duration of immunity to IB are the multiple serotypes that are recognized (see "Incidence and Distribution"), the variation in virulence observed among strains (see "Pathogenicity"), and the different manifestations of IBV infection for which protection may be needed (see "Clinical Signs").

Challenge of vaccinated birds with homologous virus results in much lower titers of recovered challenge virus, and for a shorter period, than in unvaccinated birds (36, 53, 113, 144). When the challenge virus is of a heterologous type, the challenge virus may replicate to high titers and cause clinical disease. Experiments with recombinant IBV having a heterologous S gene have confirmed that it is differences in the S protein that determine poor cross-protection (77).

Respiratory protection is usually evaluated 3–4 weeks after an IB infection or immunization and has been done in several different ways. Challenge routes include tracheal, intranasal, and by eyedrop. The failure to recover IBV from the trachea at 4–5 days post challenge has been used as a single criterion of immunity (79). More comprehensive evaluations have included two or more additional criteria of resistance to challenge, including the failure to isolate virus from the kidney and oviduct, no clinical signs of IB, no tracheal lesions, or the presence of tracheal ciliary activity (11, 48, 77, 176). Accumulating scores from the different criteria are used to indicate the range of protection from full to partial or none. An alternative approach is an evaluation of vaccinated chickens for protection against mortality from a challenge with a mixture of IBV and *E. coli*. This method showed evidence of more vaccinal cross-protection than found with other assessments of tracheal immunity (36).

Protection against mortality from nephritis is important as evidence of satisfactory vaccinal immunity in which nephritis is a major clinical problem (104, 147). The ability to reduce or prevent egg-production declines from a challenge infection is evidence of IB protection in a laying flock (12).

Although it is established that the S1 subunit of the S protein induces VN and HI antibodies and protective immunity (86, 94, 124, 158), knowledge of the mechanism of protection against

clinical disease is incomplete. Local respiratory tissue immune mechanisms are important in protection. However, the role of local antibody in preventing reinfection is unclear. Some studies have reported neutralizing antibody in nasal secretions to play a role in preventing re-infection (81) and that the Harderian gland contributes to local immunity (49). The protective role of antibody is also evident by the fact that chickens immunocompromised by IBDV infection suffer more severe episodes of IBV infection than their immunocompetent counterparts (150, 161). IBV antibody was detected in tears of vaccinated chickens both by ELISA and virus neutralization assay (66). However, antibody levels in tears were not accurate indicators of IBV immunity as determined by respiratory challenge by IBV. Antibody does not appear to be the only source of resistance, however, as demonstrated in chickens treated with cyclophosphamide or bursectomized in ovo and then exposed to IBV (33, 38). In those trials, no antibody could be detected, but the chickens resisted IBV challenge. Evidence of cell-mediated immune responses to IBV (60, 140) are lymphocyte transformation assays of live and inactivated virus vaccinates (163), cytotoxic lymphocyte activity (34, 153, 154), delayed type hypersensitivity (35), natural killer cell activity (160), and histologic evidence for significant T-cell (especially CD4+ phenotype) infiltration in the respiratory and kidney tissues of IBV-infected chickens (90). Cytotoxic T lymphocyte responses peaked at 10 days after IBV infection and correlated well with the decline of IBV in lungs and kidney (163). IBV-specific CTL epitopes were mapped to within the carboxy-terminal 120 amino acids of the nucleocapsid protein (164).

Passive

Maternally-derived antibody (MDA) can reduce both the severity of vaccinal reaction and the efficacy of the vaccine if the vaccine is of the same type used in the breeder flock immunization (104, 105). Despite this, vaccination of maternally immune one-day-old commercial chicks is routinely performed. In one study, MDA provided protection against challenge at one day and one week but not at two weeks of age (129); whereas in another study, MDA did not reduce the titer of re-isolation of challenge virus given at two days of age (177). Mondal and Naqi (130) showed that chicks hatched with high levels of MDA had excellent protection (>95%, assessed by non-recovery of challenge virus) against challenge at one day of age but not at seven days (<30%). This protection significantly correlated with levels of local respiratory antibody and not with serum antibody. A high percentage of both MDA+ and MDA- chicks failed to produce IBV antibody when vaccinated at one day of age by the intraocular route. In addition, MDA+ chickens had a weaker virus-neutralizing antibody response to a second IBV vaccination compared to MDA- birds. MDA+ chicks experienced a more rapid decline in MDA after one-day-of-age vaccination compared to their unvaccinated counterparts.

Diagnosis

Diagnosis of IB is based on the clinical history, lesions, seroconversion or rising IBV antibody titers, IBV antigen detection by a number of antibody-based antigen capture assays (described later), virus isolation, and, increasingly, by detection of IBV RNA. Diagnosis of IB should include, if possible, identification of the serotype or genotype of the virus because of the great antigenic variation exhibited by IBV strains and the availability of vaccines designed for different serotypes. The many approaches to the detection of IB virus or antibodies induced by it have been described and critically compared by de Wit (50). At the outset, it should be stated that no technique, whether based on antibodies or nucleic acid technology, is totally satisfactory for confirmation of infection by a specific IBV serotype in the field.

Isolation and Identification of the Causative Agent

Although primarily a respiratory pathogen, IBV can grow in non-respiratory (kidney, oviduct, alimentary tract) tissues. Knowledge of the pathogenesis of IBV, reviewed by Dhinaker Raj and Jones (55), has been instructive for the detection of the virus. Factors to be taken into account include the time elapsed between infection and sampling and the immune status of the bird at infection. These and other factors have been discussed by de Wit (50).

Virus Isolation

The trachea is a primary target for IBV and is, therefore, a preferred sampling site, especially within the first week of infection. The sample could be either tracheal swabs or tracheal tissue collected at post mortem. In individual chickens, titers of IBV are maximal by day four or five after which they decline rapidly. Cloacal swabs or cecal tonsils collected during post mortem examination, however, can be of particular value in cases in which more than one week may have elapsed since the start of infection. This is in part because the virus grows initially in the upper respiratory tract and spreads to non-respiratory organs. Consequently, the virus generally is cleared from the trachea sooner than from the intestinal tissues. Additionally, evidence exists that IBV can persist, especially in non-respiratory tissues e.g., kidney (3, 96, 122). Samples from the lung, kidney, and oviduct should also be considered depending on the clinical history of the disease. Sample selection from extremely large flocks can be a difficult problem. The placement of susceptible sentinel chickens in a problem flock has been successful when direct sampling methods in the flock had failed (67). Sentinels are removed for direct sampling after one week of contact exposure. Procedures for sample collection and processing for IBV isolation have been described in detail (50, 67).

Samples for virus isolation commonly are inoculated into embryonating chicken eggs or tracheal organ cultures preferably from a specific-pathogen-free source. Fluids should be harvested after 48–72 hours from either culture system for blind passage into another set of cultures. Samples should receive at least 3–4 blind passages before being called negative based on failure to cause death or lesions in embryos. Ciliostasis may be observed upon initial passage in tracheal organ cultures. These observations are not in themselves sufficient to confirm the presence of IBV; the virus presence must be confirmed by serological meth-

ods (e.g., VN, HI, ELISA), immunohistochemistry, nucleic acid analysis, or by electron microscopy. Antiserum collected at four weeks postinoculation should be suitable for use in two-way comparisons by VN test to determine the serotype of the isolate (50, 64).

Coronaviruses in pheasants have been detected by sampling respiratory tissues and kidneys (118) and by oral swabs collected when respiratory signs were evident (27). The viruses could be grown in chicken eggs after allantoic sac inoculation (118). In contrast, coronaviruses detected by RT-PCR in graylag goose, mallards, and pigeons could not be propagated in chicken eggs following allantoic sac inoculation (95).

Confirmation of Infectious Bronchitis Virus by Antibody-Based Methods

Detection of IBV directly using postmortem material may be attempted by a number of methods (reviewed in 50; 64). Sections or scrapings of the trachea mucosa and other tissues taken from birds at postmortem can be examined by immunofluorescence or immunoperoxidase assays, using IBV-specific polyclonal sera or monoclonal antibodies (76). The results are not always easy to interpret, especially from field specimens because of nonspecific reactions. Tracheal material can also be used in agar gel precipitin tests (AGPT), which has a sensitivity greater than might be expected (50). Bhattecharjee *et al.* (9) infected tracheal organ cultures with IBV and revealed the presence of the virus by immunofluorescence without fixation of the cultures using low power microscopy.

If virus propagation in embryonating eggs is attempted, then confirmation of the presence of IBV can be made by the AGPT test. Because the amount of IBV precipitin antigen in infected chicken embryos can sometimes be low, however, sections of the chorioallantoic membrane or cells sedimented from the allantoic fluid can be used for immunofluorescence or immunoperoxidase assays. Infectious bronchitis virus in allantoic fluid, or after growth in tracheal organ cultures, may also be detected and identified as to serotype, using monoclonal antibodies in indirect or antigen-capture enzyme-linked immunosorbent assay (ELISA) (reviewed in 50; 85, 88, 93, 122, 35).

Coronaviruses isolated from pheasants have, to date, been poorly cross-reactive in HI and VN tests using sera raised against IBV serotypes. The use of immunofluoresence or antigen-capture ELISAs, in conjunction with IBV antibodies, has not been attempted with coronaviruses from pheasants. Nucleic acid-based approaches have been successful extensively for demonstrating the presence of coronaviruses in pheasants. Antigenic cross-reaction between turkey coronaviruses and IBV has been demonstrated (120), and ELISAs have been used to detect coronavirus antibodies in turkey sera (75, 120, 165, 173).

Confirmation of Infectious Bronchitis Virus by Nucleic Acid-Based Methods

RT-PCRs have been applied directly to material from infected chickens or after preliminary amplification of the virus in embryonating eggs. Well-chosen RT-PCRs are sufficiently sensitive to detect IBV RNA extracted from mouth, tracheal swabs, or cloacal swabs (i.e., it is not essential to first isolate/amplify the virus in embryos). That said, because of the ubiquitous use of live IB vaccines, simply getting a positive PCR result is not sufficient for diagnosis; sequence of the PCR product should be compared with the corresponding sequences of vaccine strains.

RT-PCR genotyping methods have largely replaced HI and VN serotyping for determining the identity of a field strain. The molecular basis of antigenic variation has been investigated, usually by nucleotide sequencing of the gene coding for the spike (S) protein or, more specifically, nucleotide sequencing of the gene coding for the S1 subunit of the S protein in which most of the epitopes to which neutralizing antibodies bind are found (98, 106). An exact correlation with HI or VN results has not been seen, in that while different serotypes generally have large differences (20–50%) in the deduced amino acid sequences of the S1 subunit, other viruses that are clearly distinguishable in neutralization tests show only 2–3% differences in amino acid sequences (24). However, there is, in general, good agreement between data represented by the S1 sequence and the VN serotype. It is important to note that it is not possible at the present time to differentiate vaccine and pathogenic field strains on the basis of sequencing the S gene.

Advantages of genotyping methods include a rapid turnaround time and, importantly compared to VN and HI tests, the ability to detect a wide variety of genotypes, depending on the tests used. Clinical samples such as swabbings from the trachea or cloaca may be directly tested provided sufficient titer of the virus is present. Passage in embryonating eggs may be necessary to increase viral titer prior to RT-PCR analysis.

Restriction fragment length polymorphism (RFLP) RT-PCR differentiates IBV genotypes based on unique electrophoresis banding patterns of restriction enzyme-digested fragments of S1 following amplification of the gene by RT-PCR (5, 125).

S1 genotype-specific RT-PCR may be used to identify field isolates as IBV genotypes using universal primers and their specific genotypes using strain or type specific primers (102). S1 gene primers specific for genotypes Massachusetts (Mass), Connecticut, Arkansas, JMK, DE/072/92 and California have been developed (102).

Both the RFLP RT-PCR and S1 genotype-specific methods have limitations, however. Unknown variant serotypes may be detected as IBV using universal primers, but the specific serotype cannot be identified until the strain is sequenced and specific primers are designed.

Nucleotide sequencing of the S1 gene is the most useful technique for the differentiation of IBV and is the genotyping method of choice in many laboratories. RT-PCR product cycle sequencing of the hypervariable amino terminus region of S1 may be used diagnostically to identify previously unrecognized field isolates and variants (60, 103, 115, 145). Comparison and analysis of sequences of unknown field isolates and variants with reference strains for establishing potential relatedness are significant advantages of sequencing.

Dot blot hybridization has been reported as a simpler alternative to sequencing and RFLP technology that may not be available in some countries. Slot blot hybridization using RT-PCR

template DNA of the hypervariable regions of S1 was immobilized onto nitrocellulose membrane used to identify and characterize IBV strains. Digoxigenin-labeled probes from reference and unknown field viruses were synthesized and hybridized to template DNA. All reference strains could be distinguished and isolates could be identified by genotype if they were at least 95% identical to a reference strain (131).

The major uses of RT-PCR tests pertaining to the S gene are virus identification and its application in the understanding of epidemiology during IBV outbreak investigations. Similarities based on sequencing of S gene have also been shown to be a better predictor of cross-challenge results than traditional serotyping by VN (111). Genetic tests based on RT-PCR of the S gene do not provide information defining viral pathogenicity.

When only small amounts of viral RNA have been available (e.g., on swabs), nested PCRs, in which some of the DNA produced in the first PCR is used in a second PCR using two further oligonucleotides, have been used. However, nested PCRs are arguably too sensitive for routine diagnostic use. On the one hand, one might amplify low levels of residual vaccine virus, that would be misleading. On the other, tiny amounts of contaminating DNA may be amplified, giving a false positive.

Two strategies would seem to be worthy of further investigation. One is to do a single RT-PCR on RNA extracted from trachea or from swabs, using as much RNA as possible, using all the RT product in the PCR, and generating relatively small DNA products (e.g., approximately 600 bp or fewer). The genotype of IBV can be determined either by use of genotype-specific oligonucleotides or by sequencing the product. If sequencing is to be used, then "universal" oligonucleotides can be used in the RT-PCR; that is, oligonucleotides designed to work with many, if not all, types of IBV (1, 26, 102, 103). In that way, one is less likely to miss new types of IBV compared with the use of selected genotype-specific oligonucleotides.

The second approach is to first amplify the virus, from tissue or swabs, in embryonating eggs. This approach has been used extensively by Jackwood and colleagues (89) and Gelb and colleagues (68, 102, 103, 137). The growth of IBV in eggs prior to RT-PCR is preferable to the use of RNA extracted directly from swabs when relatively large (approximately 2000 bp) PCR products are required (109).

The high degree of similarity of the genomes of coronaviruses from turkeys and pheasants compared with IBV means that these viruses may be detected using some of the universal oligonucleotides designed for IBV (26).

Serology

The multiple IBV serotypes and the antigenic variation noted within the described types add complexity to the selection of an appropriate serologic method and the analysis of test results. All IBV serotypes would seem to have common epitopes (group-specific antigens), which is not surprising given the moderately high amino acid sequence identity within the N and M proteins and the S2 part of the spike protein. IBVs also induce type-specific antibodies, of course, determined by epitopes of the S1 protein.

The ELISA, immunofluorescence, and immunodiffusion tests bind antibody to group- as well as to type-specific antigens, hence these tests cannot differentiate serotypes. Following a first infection with IBV, most of the VN and HI antibody response is serotype-specific. A second infection, even with the same serotype, results in a more broadly reactive serum. As chickens in the field will almost certainly have been vaccinated against IB, and possibly infected more than once by field virus, field sera are not very useful for serotyping. Thus, single infection sera, raised experimentally using SPF chickens, are used for serotyping.

Routine serology is usually done with VN, HI, or ELISA tests, reviewed by de Wit (50). The group-specific AGPT can be used, but precipitating antibodies are short-lived, and the test may lead to under detection. Positive AGPT results are indicative of recent infection. De Wit *et al.* (51) vaccinated one-day-old broiler chicks with maternally derived antibody and nine-week-old SPF chicks with the H120 vaccine strain; neither group of birds gave antibody detectable by the AGPT. After challenge the AGPT was positive, sensitivity being about 40%. Infection with a virus of the same serotype as the vaccine may lead to poor production of antibodies, as detected by the AGPT (51, 52). Overall, the AGPT is not recommended for detection of IBV antibodies, being better used for detection of IBV antigen.

IBV ELISAs are group-specific (51, 99). The method is used widely, and kits for conducting the procedure are commercially available. ELISAs first detects IBV antibodies within one week of infection, earlier than by HI or VN tests (51, 52, 126, 128). Two serum samples are required, one at the first sign of infection and one a week or more later; delay of the first sampling can prevent detection of seroconversion. IgM is induced very soon after IBV infection and transiently, and thus detection of IBV-specific IgM is indicative of recent infection (reviewed by 51, 54). Some results are conflicting; detection of IgM is not routinely done as yet.

VN and HI tests for IBV antibodies generally are considered to be type-specific, although there are cross-reactions between serotypes, especially in the HI test. Sera collected after single infections, including vaccination, can be strain-specific, let alone serotype-specific (51, 65, 99). This may limit the use of the HI test to monitor vaccine response. For example, an HI test with the M41 as antigen performed poorly when used to detect antibodies following vaccination with H120, although both viruses are of the same serotype, as defined by VN tests.

Cross-reactions are most evident when sera are collected after a field or experimental infection of broilers that have previously been vaccinated against IB—the usual situation in the field—and in sera from layers, which may have had multiple IB infections in addition to several IB vaccinations. Notwithstanding the low cost, simple equipment and speed of the HI test makes it a very useful procedure for routine diagnosis; the limitations must simply be borne in mind, and alternative analytical techniques should be available when doubt arises (50).

A monoclonal antibody-based blocking or competition ELISA has been described for the detection of antibodies to North American serotypes Massachusetts and Arkansas in the sera of experimentally inoculated chickens (99). Chicken serum containing IBV antibodies was added to virus-coated microtiter plates

followed by serotype-specific monoclonal antibody. Chicken antibody specific to an IBV serotype blocked binding of monoclonal antibody specific to the same serotype, and the blocking was proportional to the concentration of antibody in chicken serum. Specificity of the blocking ELISA compared well with that of the VN test.

Differential Diagnosis

Infectious bronchitis may resemble other acute respiratory diseases such as Newcastle disease (ND), infectious laryngotracheitis, low pathogenicity avian influenza, and infectious coryza. Newcastle disease caused by velogenic viscerotropic or neurotropic strains of paramyxovirus type 1 produces much higher mortality than IB. Lentogenic ND infections with pneumotropic strains and low pathogenicity strains of avian influenza produce mild to moderate respiratory disease with low mortality and, thus, may resemble IB. Laryngotracheitis tends to spread more slowly in a flock, but respiratory signs may be more severe than with IB. Infectious coryza can be differentiated on the basis of facial swelling that occurs only rarely in IB. Production declines and shell quality problems in flocks infected with the egg drop syndrome (EDS) adenovirus are similar to those seen with IB, except that internal egg quality is not affected in the case of EDS (57).

Intervention Strategies

Management Procedures

Ideal management includes strict isolation and repopulation with only day-old chicks, following the cleaning and disinfection of the poultry house. Current commercial production methods, which include limited clean-out and disinfection between broiler flocks, and multiple flock ages on a layer farm complex, make control more difficult and have necessitated the use of immunization to attempt to prevent production losses due to IB. Immunization is also used in isolated single-age laying flocks to prevent the heavy production losses that may result from an IBV infection of a susceptible flock during the laying cycle.

Vaccination

Types of Vaccine

Both live and inactivated virus vaccines are used in IB immunization. Live vaccines are used in meat type (broiler) chickens and for the initial vaccination and priming of breeders and layers pullets. Infectious bronchitis virus strains used for live vaccines are attenuated by serial passage in embryonating chicken eggs (see "Pathogenicity") (84, 104, 123). Extensive passage is avoided to prevent a reduction in immunogenicity. The degree and stability of such attenuation probably varies among vaccines. Evidence that some vaccines increased in virulence after backpassage in chickens (83) demonstrates the potential for enhancement of virulence of such vaccines by a cyclic infection in a flock. The use of fractional doses of IB attenuated vaccines has been associated with enhancing cyclic infections in a flock and an increase in vaccine-associated virulence.

Massachusetts serotype vaccines are very commonly used in many countries. If virus of this type is isolated from a Massachusetts-vaccinated flock with respiratory clinical signs, there may be a tendency to believe that it is simply re-isolated vaccinal virus and that some other serotype must be responsible for the disease. This may not be the case; virulent virus of the Massachusetts serotype is still present in many countries. Vaccine strains are selected to represent the antigenic spectrum of isolates in a particular country or region. The Massachusetts (M41) strain, H120, and other vaccines of the Massachusetts serotype are used widely around the world. New types subsequently may be included when the prevalence of the new type is established. In the United States, strains belonging to Massachusetts, Connecticut, and Arkansas (Ark) serotype are widely used; whereas other serotypes such as DE072 are used regionally. In some European and Asian countries, strains of serotypes D274, D1466, and 4/91 (also known as 793/B and CR88), first isolated in Europe, are used in addition to H120 and other Massachusetts vaccines. Some countries in Asia also have vaccines based on local strains (117). Only vaccines based on local isolates are permitted in Australia (104, 169).

Despite the application of Ark DPI vaccine in the Delmarva region of the United States, there have been infections by Ark serotype strains that have caused economic loss. Variants of the Ark serotype may have arisen by selection, in chickens in the field, of minor virulent populations within the attenuated vaccinal virus preparation (137). The authors suggested that the Ark DPI should be used all year round, rather than seasonally as is sometimes the case with this vaccine, as virulent subpopulations may then be less likely to rise to prominence.

IBV vaccine has been shown to interfere with the replication of attenuated avian pneumovirus, although it did not prevent the induction of protective immune responses by the pneumovirus (40). Vigorous growth of both vaccinal and field strains of IBV probably reduce the replication and, hence, efficiency of detection, of pneumovirus in the field (26).

Inactivated oil-emulsion vaccines (12) are administered in breeders and layers prior to the onset of egg production. Layer pullets may be vaccinated between 10 and 18 weeks depending on the immunization program. The seed viruses for inactivated vaccines need not be attenuated as they will be inactivated using formalin, beta propiolactone, or other suitable inactivant. Mineral oil adjuvants are commonly used to formulate the vaccine (91). The efficacy of inactivated vaccines depends heavily on proper priming with a live vaccine(s). Inactivated vaccines must be administered to birds individually, by intramuscular or subcutaneous injection. Inactivated vaccines induce serum antibody production and provide protection to internal tissues, kidney and reproductive tract. In contrast to live vaccines, inactivated vaccines are not nearly as effective at preventing infection of the respiratory tract following challenge with the homologous virulent virus. Inactivated vaccines do reduce the incidence of virus present in the respiratory tract of challenged chickens and, thus, limit transmission to other susceptible birds (110).

New "variant" strains may be used to prepare inactivated autogenous vaccines for controlling IB without the risks of using a live variant that could spread to and potentially cause disease in

nearby flocks. Inactivated variant vaccines may offer better protection against challenge with the virulent live variant IBV than inactivated vaccines containing standard serotypes such as Massachusetts and Connecticut (110).

Application Methods

Live vaccine combinations of IBV with NDV are used frequently. If the IBV component is in excess, there may be an interference with the NDV response (162). No similar interference with the IBV response has been reported.

Experimental administration of live vaccine can be individually by eye drop, intratracheal (7), or intranasal. An embryonal injection method has also been used experimentally. Commercial mass application methods include coarse spray (7), aerosol, and drinking water (146). Mass administration methods are popular because of convenience, but problems in attaining uniform vaccine application can occur, and the aerosol method may cause more severe respiratory reactions. Close attention must continually be paid to the settings and maintenance of the spraying equipment. Vaccines applied by the drinking water method are susceptible to inactivation by sanitizers added to control bacterial and fungal contamination of the watering system. Removal of those sanitizers prior to vaccination and the incorporation of powdered skim milk at a 1:400 concentration have been shown to stabilize the virus titer during vaccine administration (70).

Inactivated vaccines require injection of individual birds. In the poultry industry, these vaccines are administered between 10 and 18 weeks of age and are given 2–4 weeks after a series of 3–4 priming immunizations with live vaccine. They are often given in combination with other inactivated vaccines.

Broilers are most commonly vaccinated with live IB vaccine in the hatchery (i.e., at one day of age). A second vaccine of the same or different serotype may be given at 10–18 days of age. Experiments examining the efficacy of day-old IB vaccination are described in the section "Passive Immunity." Broiler breeders and commercial layers are likely to be first inoculated with live IB vaccine at about 2–3 weeks of age. Timing of initial immunization varies due to titer of maternal antibody in chicks and vaccination methods used. Schedules of subsequent immunization at 7–12 or 16–18 weeks of age, and at point of lay, vary with flock management and needs for control of IB, as well as other flock diseases. In the United States, many commercial egg-type chickens are vaccinated at 8–10-week intervals throughout the laying cycle with Massachusetts vaccine administered by drinking water or aerosol.

As yet no IB vaccines have been applied *in ovo*; all reduce hatchability to uneconomic levels.

Genetic manipulation of the IBV genome (17, 78) offers the prospect that a virulent IBV could be attenuated very precisely, as well as enabling spike gene swapping to make a vaccine suitably for a new serotype (16).

An experimental recombinant vaccine using the S1 gene from the Vic S strain of IBV was constructed in fowl adenovirus (FAV) serotype 8. Broiler chickens orally vaccinated at hatching or six days later were protected when given a homologous (Vic) or heterologous (N1/62) strain challenge at day 35 of age. The construction of a recombinant FAV expressing S1 demonstrates the potential of an alternative vaccination strategy against IBV (94).

Future Vaccines

There are probably dozens, at least, of sero/genotypes of IBV awaiting discovery, which will pose challenges to the poultry industry and to vaccine developers. It will only be economically feasible to develop new vaccines against a tiny number of new types of IBV. Therefore, control of IB will continue to involve "juggling" with a very small selection of vaccines, plus good management. Given that IBV replicates at a great many epithelial surfaces, it is possible that some of the yet-to-be-discovered IBV types will be associated with new clinical manifestations. Given what we have learned recently about IBV and IBV-like viruses in other species, we can speculate that some new IBV types may originate in other bird species, possibly requiring adaptation to chicken to become pathogenic. Genetic manipulation systems for IBV offer the prospect of a new era of genetically more defined and stable vaccines, and possibly ones for application *in ovo*.

Treatment

No specific treatment exists for IB. Provision of additional heat to eliminate cold stress, elimination of overcrowding, and attempts to maintain feed consumption to prevent weight loss are flock management factors that may help reduce losses from IB. Treatment with appropriate antibacterials may be indicated to aid in reducing the losses from airsacculitis resulting from infection by secondary bacterial pathogens. Electrolyte replacers, supplied in the drinking water, are recommended and were used in Australia to compensate for the acute loss of sodium and potassium and to thereby reduce losses from nephritis. The recommended concentration for treatment is 72 mEq of sodium and/or potassium, with at least one-third in the citrate or bicarbonate salt form (46).

Chapter 5
Laryngotracheitis

J. S. Guy and M. Garcia

Introduction

Laryngotracheitis (LT) is a viral respiratory tract infection of chickens that may result in severe production losses due to mortality and/or decreased egg production. Severe epizootic forms of infection are characterized by signs of respiratory depression, gasping, expectoration of bloody mucus, and high mortality. Mild enzootic forms of infection are encountered increasingly in developed poultry industries and manifest variously as mucoid tracheitis, sinusitis, conjunctivitis, general unthriftiness, and low mortality. Laryngotracheitis virus (LTV) is a pathogen normally selected for exclusion from specific-pathogen-free chicken flocks.

Economic Significance

The economic significance of LT has not been precisely determined. However, the poultry industry of the United States can expect to experience multimillion dollar losses each year as a consequence of LTV-induced mortality and decreased egg production, and similar losses likely occur in intensive poultry industries of other countries.

Public Health Significance

No evidence suggests that LTV is transmissible to human beings and other mammals.

History

The disease was first described in 1925 (126), but some reports indicate that it may have existed earlier (14, 78). It has been given several different names including laryngotracheitis, infectious laryngotracheitis, and avian diphtheria. Some early investigators also referred to the disease as infectious bronchitis. The term laryngotracheitis was used as early as 1930 (15, 66) and the name infectious laryngotracheitis was adopted in 1931 by the Special Committee on Poultry Diseases of the American Veterinary Medical Association. The cause of LT was first shown to be a filterable virus by Beaudette (18). Subsequently, in 1934, Brandly and Bushnell devised a method for immunization of chickens based on application of virulent virus to the cloaca (26). Laryngotracheitis was the first major avian viral disease for which an effective vaccine was developed.

Etiology

Classification

Laryngotracheitis virus is classified as a member of the genus *Iltovirus* within the family *Herpesviridae*, subfamily *Alphaherpesvirinae* (44). The virus has been shown to be genetically distinct from other alphaherpesviruses based on DNA sequence analyses, and these findings have led to its recent classification as a single member of the genus *Iltovirus* (44, 127). The virus is taxonomically identified as *Gallid herpesvirus 1* (44, 155).

Morphology

Electron micrographs of LTV-infected chicken embryo cell cultures demonstrate the presence of icosahedral viral particles similar in morphology to herpes simplex virus (Fig. 5.1). Watrach *et al.* (184) described the hexagonal nucleocapsids of LTV to be 80–100 nm in diameter. The nucleocapsids have icosahedral symmetry and are composed of 162 elongated hollow capsomeres (43, 184).

The complete virus particle has a diameter of 195–250 nm and consists of an irregular envelope surrounding the nucleocapsid. Nucleocapsids may be observed within enveloped particles when these are penetrated by stain; if stain does not penetrate particles, they may be difficult to distinguish from cell debris. The envelope contains viral glycoprotein spikes as fine projections on its surface.

Chemical Composition

The nucleic acid of LTV is composed of DNA with a buoyant density of 1.704 g/mL, a value consistent with other herpesviruses (141). The molecular weight of LTV DNA is approximately 100×10^6, with the genome having two isomeric forms (119, 121). Laryngotracheitis virus DNA has been reported to have a guanine plus cytosine ratio of 45% (141), a value lower than many other animal herpesviruses. The DNA genome consists of a linear 155-kb double-stranded molecule composed of unique long (UL) and unique short (US) regions flanked by inverted repeats (97, 122). Recently, the complete nucleotide sequence of the LTV genome was assembled from 14 different published sequences (173). The assembled LTV genome was shown to consist of a 148-kb molecule having a UL region of 113 kb, and a US region of 13 kb; the UL and US regions were shown to be flanked by two 11-kb inverted repeats. The LTV genome contains a total of 77 predicted open reading frames; 62 of these are located in the UL region, 9 in the US region, and 3 in the inverted repeats.

Early studies using partial genome sequence data from the LTV thymidine kinase gene and upstream overlapping genes demonstrated DNA homology between LTV and various other alphaherpesviruses (67, 106). Subsequently, using sequence data for the entire LTV genome, and other herpesvirus genomes, revealed that Psittacid herpesvirus 1 (PsHV-1) and LTV represent a unique clade of avian alphaherpesviruses that are distinct from Marek's disease-like viruses (*Mardivirus*) (173). The LTV and the PsHV-1 genomes share a unique block of five open reading frames, and a large internal inversion in the unique long region similar to an inversion previously found in the genome of the pseudorabies virus, a porcine alphaherpesvirus (182, 198).

The glycoproteins of LTV, like other herpesviruses, are responsible for stimulating humoral and cell-mediated immune responses (192). Early studies by York *et al.* (195, 197) identified five major envelope glycoproteins with molecular weights of 205, 160, 115, 90, and 60 kD to be the major immunogens of LTV. Subsequently, characterization of LTV glycoproteins utilizing monospecific antisera or monoclonal antibodies has been undertaken in several laboratories. Several glycoproteins that are homologous to those of human herpes simplex virus have been identified in LTV; these are designated glycoprotein B (gB) (142), gC (114, 180), gN (56), gM (55, 56), gG (117), and gJ (180). The gJ protein was initially identified as a 60 kDa protein and named gp60 (118). Later work indicated that gJ was expressed as multiple proteins of 85, 115, 160, and 200 kD sizes, and gC was expressed as a single 60 kD protein.

Recent studies with viruses having deletions in genes coding for gJ, gM, and gN genes (LTV deletion mutant viruses) have shown that these glycoproteins are not essential for virus replication (49, 56, 58). Another study examining a LTV with a double gI/gE gene deletion demonstrated that these two viral glycoproteins are essential for virus replication (48).

Virus Replication

Replication of LTV appears to be similar to that of other alphaherpesviruses such as pseudorabies virus and herpes simplex virus (68, 143, 156). The virus initiates infection by attachment to cell receptors followed by fusion of the envelope with the host cell plasma membrane. The nucleocapsid is released into the cytoplasm and transported to the nuclear membrane; viral DNA is released from the nucleocapsid and migrates into the nucleus through nuclear pores. Transcription and replication of viral DNA occur within the nucleus.

Transcription of LTV DNA occurs in a highly regulated, sequentially ordered cascade similar to that of other alphaherpesviruses (86, 143). Approximately 70 virus-coded proteins are produced; several are enzymes and DNA-binding proteins that regulate viral DNA replication, but most are viral structural proteins. Viral DNA replication occurs by a rolling circle mechanism with the formation of concatemers (19). DNA concatemers are cleaved into monomeric units and packaged into preformed nucleocapsids within the nucleus. DNA-filled nucleocapsids acquire an envelope by migration through the inner lamellae of the nuclear membrane (68). Enveloped particles then migrate through the endoplasmic reticulum and accumulate within vac-

Note the peripheral accumulations of chromatin and centrally located amorphous material; the latter forms part of the inclusion body. ×18,500. (Watrach)

uoles in the cytoplasm (68). Enveloped virions are released by cell lysis or by vacuolar membrane fusion and exocytosis.

Susceptibility to Chemical and Physical Agents

Laryngotracheitis virus is sensitive to the effects of lipolytic agents such as chloroform and ether (54, 130). Laryngotracheitis virus infectivity survives for several months when stored at 4°C in suitable diluents such as glycerol or nutrient broth. However, the thermostability of LTV infectivity has been the subject of reports which vary considerably. For example, the infectivity of LTV has been reported to be rapidly inactivated by heat when exposed to 55 °C for 15 minutes or 38 °C for 48 hrs (101). Conversely, Meulemans and Halen (130) found that 1% of the infectivity of a Belgian strain was retained after 1 hr at 56 °C. Cover and Benton reported that LTV was destroyed in 44 hr at 37°C in tracheal tissues within chicken carcasses or in chorioallantoic membranes (CAMs) after 5 hr at 25 °C (39). These results are, however, greatly at variance with several earlier reports (101) that indicated the capability of LTV infectivity to survive in tracheal exudates and chicken carcasses for periods of 10–100 days at ambient temperatures of 13–23 °C. Additional studies are needed to resolve these discrepancies.

A solution of 3% cresol or 1% lye will inactivate LTV in less than 1 minute; laboratory bench surfaces can be readily decontaminated with commercial iodophors or halogen-detergent mixtures. Studies with microaerosolized hydrogen peroxide have indicated that complete inactivation of LTV infectivity was achieved with a 5% hydrogen peroxide mist as a fumigant for poultry house equipment (133).

Strain Classification

Antigenicity

Laryngotracheitis virus strains appear to be antigenically homogeneous based on virus-neutralization, immunofluorescence tests, and cross-protection studies (39, 169). However, minor antigenic variation among strains has been suggested by findings that some strains are neutralized poorly by heterologous antisera (145, 158, 169).

Molecular Classification

Molecular methods for differentiating LTV strains include restriction endonuclease analyses of viral DNA (70, 74, 119, 121), DNA hybridization assays (120), polymerase chain reaction (PCR) procedures combined with restriction fragment length polymorphism (RFLP) analyses of amplified DNA (PCR-RFLP) (31, 38, 42, 60, 65, 76, 115), PCR-RFLP combined with gene sequencing (75), and gene sequencing alone (136). Restriction endonuclease cleavage of viral DNA and electrophoretic separation of DNA fragments have been shown to distinguish different LTV strains (119, 121). Restriction endonuclease analysis of LTV DNA has been used extensively in epidemiological studies of field outbreaks to differentiate modified-live vaccine viruses from non-vaccine (wild-type) LTV strains (7, 70, 74, 107, 109).

Reciprocal DNA:DNA hybridization using cloned DNA fragments has been shown to discriminate LTV strains (120). However, additional testing of this method is needed to determine the accuracy of this method for differentiating LTV strains.

Recent advances in our understanding of the LTV genome based on nucleotide sequence studies, and the assembly of the complete LTV genome based on published sequences (173), have provided the basis for strain differentiation using genetic differences identified by PCR-RFLP and/or gene sequencing. Several PCR-RFLP assays have been described that differentiate vaccine and nonvaccine LTV strains (31, 38, 42, 60, 65, 76). Polymerase chain reaction-RFLP analysis of the infected cell protein 4 (ICP4) gene was shown to discriminate between vaccine and nonvaccine isolates from Taiwan (31) and Northern Ireland (65). In both reports, outbreak-related viruses obtained prior to the introduction of modified-live LTV vaccines were identified as nonvaccine virus, while vaccine viruses were identified as the cause of outbreaks after the implementation of LTV vaccination. Using a single nucleotide polymorphic site previously identified in the ICP4 gene (65), a PCR-RFLP assay allowed the detection and differentiation of vaccine and nonvaccine viruses directly from field cases in the United Kingdom (42). In another study, PCR-RFLP combined with nucleotide sequence analysis of the glycoprotein G (gG) and the thymidine kinase (TK) genes allowed the differentiation of non-vaccine from vaccine viruses in Korea (75), and the analysis of both these genes allowed the identification of a viral isolate that might have originated from a recombination event between a vaccine and a nonvaccine virus. Kirkpatrick *et al.* (115) utilized PCR-RFLP to differentiate among isolates of LTV strains in Australia. They showed that reliable differentiation of LTV strains required the examination of multiple genes (gG, TK, ICP4, ICP18.5 genes, open reading frame [ORF] B-TK) and that most of the recent LT outbreaks in Australia were not caused by vaccine viruses (115).
5.2. Chicken embryos at 14 days of age. Normal embryo and chorioallantoic membrane (CAM) (*right*). Laryngotracheitis virus-infected embryo is stunted, and CAM has numerous foci of necrosis and cell proliferation (*left*).

Nucleotide sequence analyses of the UL47 and gG genes allowed the identification of vaccine and nonvaccine viruses involved in LT outbreaks in Ontario (136).

Pathogenicity

Naturally occurring LTV strains vary in virulence from highly virulent strains that produce high morbidity and mortality in exposed chickens to strains of low virulence that produce mild-to-inapparent infection (39, 101, 144, 145, 167, 174). Laryngotracheitis virus strains also were shown to differ based on virulence for chicken embryos (94), plaque size and morphology in cell culture (157), and plaque size and morphology on chorioallantoic membrane (CAM) of embryonated chicken eggs (145). Differentiation of LTV strains of varying virulence, particularly wild-type and modified-live vaccine viruses, is an important practical problem. Assessment of mortality patterns in embryonated chicken eggs was proposed as a biological system for differentiating LTV strains (94) as they found that mortality patterns correlated closely with virulence.

Laboratory Host Systems

Laryngotracheitis virus might be propagated in embryonated chicken eggs and a variety of avian cell cultures. In embryonated chicken eggs the virus causes formation of opaque plaques on the CAM resulting from necrosis and proliferative tissue reactions (Fig. 5.2). Chorioallantoic membrane plaques generally have opaque edges and a central depressed area of necrosis. Plaques can be observed as early as 2 days postinoculation (PI) and embryo deaths occur 2–12 days PI. Survival time of inoculated embryos decreases with additional egg passages (23, 25, 28).

Laryngotracheitis virus has been propagated in a variety of avian cell cultures including chicken embryo liver (CEL), chicken embryo lung, chicken embryo kidney (CEK), and chicken kidney (CK) cell cultures (33, 88, 128, 129). Hughes and Jones (88) compared several different laboratory host systems for efficiency of LTV isolation and propagation. The CEL and CK cells were found to be the preferred culture systems, with CEK cells, chicken embryo lung cells, and CAM inoculation of em-

bryonated chicken eggs being less sensitive. Chicken embryo fibroblast cells, Vero cells, and quail-origin cells have been determined to be poor substrates for LTV propagation (88, 162).

Viral cytopathology may be observed in cell culture as early as 4–6 hr PI with a high multiplicity of infection. Cytopathology consists of increased refractiveness and swelling of cells, chromatin displacement, and rounding of the nucleoli. Cytoplasmic fusion results in formation of multinucleated giant cells (syncytia) (Fig. 5.3). Intranuclear inclusion bodies can be detected as early as 12 hr PI, with the highest concentration occurring 30–36 hr PI. Large cytoplasmic vesicles develop in the multinucleated cells, which become more basophilic as cells degenerate (151).

Laryngotracheitis virus also may be propagated in avian leukocyte cultures. Initially, LTV was shown to replicate in avian leukocyte cultures derived from chicken buffy coat (34), and later the virus was shown to replicate in macrophage cultures obtained from bone marrow and spleen (27). Calnek *et al*. (30) determined that macrophage cultures were as susceptible to LTV infection as CK cells, but replication of most LTV strains examined was restricted. Both cell genotype and virus genotype influenced the extent of restriction of virus replication. Other cell types including lymphocytes, thymocytes, buffy-coat leukocytes, and activated T cells were either refractory or nearly refractory to LTV infection.

Laryngotracheitis virus also has been shown to replicate in LMH cells, a continuous avian cell line derived from a chemically induced chicken liver tumor (162). However, propagation of LTV in LMH cells requires adaptation, thus this cell line is unsuitable for diagnostic purposes involving primary isolation. They may, however, be useful for other purposes; for example, in research laboratories studying virus-host cell interactions.

Pathobiology and Epidemiology

Incidence and Distribution

Laryngotracheitis virus has been identified in most countries and remains a serious disease wherever susceptible poultry populations occur, especially in large numbers (22). In areas of intensive production and large concentrations of poultry such as in the United States, Europe, China, Southeast Asia, and Australia, LT is usually well controlled in layers by the use of modified-live virus vaccines. For intensive broiler production, the short growth cycle and high level of quarantine on sites can reduce the need for prophylactic vaccination. Within developed countries, LT viruses have tended to persist as endemic infections within backyard and fancier chicken flocks.

Natural and Experimental Hosts

The chicken is the primary natural host of LTV. Although the disease affects all ages, the most characteristic signs are observed in adult birds. Viral multiplication is limited to respiratory tissues, with little or no evidence of viremia (11, 85).

Several workers have described a form of LT in pheasants and pheasant-chicken crosses (41, 87, 111). Winterfield and So (189) were able to induce lesions in the upper respiratory tract of young turkeys. They also reported the isolation of LTV from the trachea
5.3. Chicken embryo kidney cell monolayer, 72 hr after inoculation with laryngotracheitis virus. A multinucleated giant cell (syncytium) has formed with many nuclei containing inclusion bodies. May-Grünwald-Giemsa, ×320.

of a peafowl. Previous failures to infect turkeys (24, 166) would indicate an age-dependent resistance in this species. Starlings, sparrows, crows, doves, ducks, pigeons, and guinea fowl appear to be refractory to LTV (16, 26, 166); however, Yamada *et al*. reported subclinical infection and seroconversion in ducks (190).

Embryonated eggs of turkeys and chickens are susceptible to LTV, while duck eggs are susceptible to a lesser degree (101, 190) and eggs of guinea fowl and pigeons are not susceptible.

Transmission, Carriers, Vectors

Natural portals of entry for LTV are through the upper respiratory and ocular routes (17, 18). Ingestion can also be a mode of infection, although exposure of nasal epithelium following ingestion is required with this route (154). Transmission occurs more readily from acutely infected birds than through contact with clinically recovered carrier birds (see "Pathogenesis").

Mechanical transmission can occur by use of contaminated equipment and litter (18, 50, 64, 113). Egg transmission of virus contained in the interior or exterior of the egg has not been demonstrated.

Incubation Period

Clinical signs generally appear 6–12 days following natural exposure (110, 165). Experimental inoculation via the intratracheal route results in a shorter incubation period of 2–4 days (20, 99, 165).

5.4. Dyspnea exhibited by an adult chicken with laryngotracheitis. Note dried blood exudate around nostril and along the lower beak (*arrow*). (Munger)

Clinical Signs

Laryngotracheitis virus causes an acute respiratory disease in chickens. Characteristic clinical signs include nasal discharge and moist rales followed by coughing and gasping (Fig. 5.4) (14, 110). Marked dyspnea and expectoration of blood-stained mucus is characteristic of severe epizootic forms of the disease (14, 78, 79, 98, 165).

Severe epizootic forms of LT were described commonly in earlier years. However, in recent years mild enzootic forms of LT have been more commonly observed in the intensive poultry producing areas of Europe, Australia, New Zealand and the United States (39, 123, 145, 165, 167, 185). Clinical signs associated with mild enzootic forms include unthriftiness, decreased egg production, watery eyes, conjunctivitis, swelling of infraorbital sinuses, mild tracheitis, persistent nasal discharge, and hemorrhagic conjunctivitis.

The course of the infection varies with the severity of lesions. Generally, most chickens recover in 10–14 days, but extremes of 1–4 weeks have been reported (14, 78).

Morbidity, and Mortality

Severe epizootic forms of the disease cause high morbidity (90–100%) and variable mortality; mortality can vary from 5% to 70% but usually is in the range of 10–20% (14, 78, 165). Mild enzootic forms of the disease described in Great Britain, Australia, the United States, and New Zealand result in morbidity as low as 5% and very low mortality (0.1–2%)(39, 123, 145, 150, 167, 185).

Pathology

Gross

Gross lesions may be found in the conjunctiva and throughout the respiratory tract of LTV-infected chickens, but they are most consistently observed in the larynx and trachea. Tissue changes in tracheal and laryngeal tissues may be mild, consisting only of ex-

cess mucus (123), or severe with hemorrhage and/or diphtheritic changes. In severe forms, mucoid inflammation is observed early in infection with degeneration, necrosis, and hemorrhage occurring in later stages. Diphtheritic changes are common and may be seen as mucoid casts that extend the entire length of the trachea. In other cases, severe hemorrhage into the tracheal lumen may result in blood casts (Fig. 5.5A), or blood may be mixed with mucus and necrotic tissue. Inflammation may extend down the bronchi into the lungs and air sacs.

In mild forms of LT, gross lesions may consist only of edema and congestion of conjunctiva and infraorbital sinuses, and mucoid tracheitis (45, 123).

Microscopic

Microscopic changes vary with the stage of the disease (see Figs. 5.5B–F). Early microscopic changes in tracheal mucosa include the loss of goblet cells and infiltration of mucosa with inflammatory cells. As the viral infection progresses, respiratory epithelial cells enlarge, lose cilia, and become edematous. Multinucleated cells (syncytia) are formed and lymphocytes, histiocytes, and plasma cells migrate into the mucosa and submucosa after 2–3 days. Later, cell destruction and desquamation result in a mucosal surface either covered by a thin layer of basal cells or lacking any epithelial covering; blood vessels within the lamina propria may protrude into the tracheal lumen. Hemorrhage may occur in cases of severe epithelial destruction and desquamation with exposure and rupture of blood capillaries.

Intranuclear inclusion bodies are found in epithelial cells by 3 days PI (146). Inclusion bodies generally are present only in the early stages of infection (1–5 days) (73, 178); they disappear as infection progresses, a result of necrosis and desquamation of epithelial cells.

Ultrastructural

Electron microscopic studies have shown that the first cellular changes occur in the nucleus of epithelial cells during formation of viral capsids (151). Viral capsids bud through the nuclear membrane, acquiring lipid envelopes, and aggregate into large masses within vacuoles in the cytoplasm. The cloudy swelling observed in light microscopic studies of early cellular changes has been associated with the presence of these large masses of viral particles in the cytoplasm (183).

Pathogenesis of the Infectious Process

Laryngotracheitis virus infection of susceptible chickens results in virus replication in epithelium of larynx and trachea, and potentially other mucous membranes such as conjunctiva, respiratory sinuses, air sacs and lungs. Laryngotracheitis virus strains generally are highly cytolytic in these tissues, particularly trachea, potentially resulting in severe epithelial damage and hemorrhage.

Several studies have independently confirmed that infectious virus usually is present in tracheal tissues and tracheal secretions for 6–8 days PI (11, 85, 147, 154); the virus may remain at very low levels up to 10 days PI (187). No clear evidence exists for a viremic phase of infection. Extratracheal spread of LTV to trigeminal ganglia was first reported by Bagust *et al.* (11); the

virus was detected in trigeminal ganglia of chickens 4–7 days after tracheal exposure with a virulent Australian LTV strain. Reactivation of latent LTV from the trigeminal ganglia 15 months after vaccination of a flock has since been reported from Germany (104). Williams *et al.* (187), with the use of polymerase chain reaction (PCR) technology, have confirmed that the trigeminal ganglion is the principal site of LTV latency. Hughes *et al.* (90) reported the re-excretion of LTV from latently infected chickens following the stress of re-housing and the onset of re-production.

Clinically inapparent LTV infection of the respiratory tract is a major feature of LTV persistence. Pioneering observations by Komarov and Beaudette (116) and Gibbs (63), who collected laryngeal and tracheal swabs and inoculated susceptible chickens, indicated a "field" carrier rate of approximately 2% for periods up to 16 months after a disease outbreak. In studies with tracheal organ cultures explanted from chickens experimentally infected with Australian wild-type LTV and vaccine strains, latent tracheal infections were demonstrated for similar periods in 50% or more of infected chickens (8, 177). In a recent study using PCR it was determined that latent infections of the trachea and the trigeminal ganglion can be simultaneously established by vaccine and challenge strains early after experimental infection (76). Repeated tracheal swabbing of small groups of chickens that had been experimentally infected with either a mildly pathogenic United Kingdom field strain or LT vaccine strains detected intermittent and apparently spontaneous shedding of LTV between 7 and 20 wk after infection (89, 91). Treatment with immunosuppressive drugs (e.g., cyclophosphamide, dexamethasone) has not been successful in reactivating latent LTV (8, 89, 90).

Immunity
Active
A variety of immune responses are generated following LTV infection (102). Virus-neutralizing antibodies become detectable within 5–7 days PI, peak around 21 days PI, then wane over the next several months to low levels. Virus-neutralizing antibodies may be detectable for a year or more (84). Antibodies may be detected in tracheal secretions from approximately 7 days PI (8, 196) and plateau at days 10–28 PI. The numbers of IgA- and IgG-synthesizing cells in the trachea increased substantially in experimentally infected chickens between days 3 and 7 PI (196). Cell-mediated immunity (CMI) has not been extensively studied owing to the complexity of CMI studies; however, delayed-type hypersensitivity responses to LTV have been demonstrated (197). The duration of CMI responses to LTV following infection is not known.

Humoral immune responses to LTV, although associated with infection, are not the primary mechanism of protection, and a poor correlation generally has been found between serum antibody titers and immune status of flocks (102). In addition, Fahey and York (51), with the use of bursectomized chickens, have demonstrated that mucosal antibody is not essential in preventing replication of virus in vaccinated chickens. The principal mediator of LT resistance is the local cell-mediated immune response in the trachea (51). Bursectomized and cyclophosphamide-

treated chickens fail to mount humoral immune responses following LT vaccination but develop full immunity (51, 152). Fahey *et al.* (53) demonstrated that LT resistance could be transferred using spleen cells and peripheral blood leukocytes from congenic immune donors.

Sinkovic (171) and Fahey *et al.* (52) determined that susceptibility of chickens to LTV declined with age. Sinkovic (171) also found that meat-type males were more susceptible than meat-type females and that high environmental temperature (35°C) resulted in higher mortality from LTV infection in heavy adult breeds than in light adult breeds.

Passive
Maternal antibody to LTV is transmitted to offspring via the egg (21). However, maternal antibody does not confer protection to infection or interfere with vaccination (52, 171).

Diagnosis

In general, LT diagnosis requires laboratory assistance as other respiratory pathogens of poultry can cause similar clinical signs and lesions. Only in cases of severe acute disease with high mortality and expectoration of blood can LT be reliably diagnosed on the basis of clinical signs. Otherwise, diagnosis of LT should be based on one or more confirmatory laboratory diagnostic procedures including detection of intranuclear inclusion bodies, virus isolation, detection of LT virus antigens in tracheal tissues or respiratory mucus, detection of LT virus-specific DNA, or serology (176).

Histopathology
Laryngotracheitis is characterized by the development of pathognomonic intranuclear inclusion bodies in respiratory and conjunctival epithelial cells. Intranuclear inclusion bodies may be detected in tissues stained with Giemsa or hematoxylin and eosin. Cover and Benton (39) reported that the choice of fixative was important, and that a fixative having a low pH was required for detection of inclusion bodies. Diagnosis of LT based on demonstration of inclusion bodies in tissues has been shown to be considerably less sensitive than virus isolation. Keller and Hebel (108) showed that inclusion bodies could be detected in 57% of 60 specimens, while virus was isolated from 72% of the same specimens. Similarly, Guy *et al.* (73) found that histopathologic detection of inclusion bodies was a highly specific method for diagnosis of LT when compared with virus isolation, but sensitivity was poor.

Rapid methods for histopathologic identification of LTV inclusion bodies have been described by Pirozok *et al.* (140) and Sevoian (168); both techniques require as little as 3 hr for preparation of tissues as compared with 24–48 hr with the use of conventional histologic processing methods. Pirozok *et al.* (140) developed a method employing Carbowax, a water-soluble embedding medium that eliminates the need for dehydration steps, thus markedly decreasing processing time. Sevoian (168) developed a procedure in which fixation and dehydration of tissues could be performed simultaneously.

Isolation and Identification of Causative Agent

Isolation of LTV may be accomplished by inoculation of suspensions of respiratory exudate, conjunctival exudate, or homogenates of appropriate tissues onto the CAM of 9–12-day-old embryonated chicken eggs or onto susceptible cell cultures (see Laboratory Host Systems). Clinical samples may include trachea, larynx, lung, conjunctiva, or exudate collected by swabbing these sites. Samples must be collected early in the course of infection, as experimental studies indicate that LTV is not detected or detected inconsistently after approximately 6 days PI (11, 73, 191). Samples should be transported promptly to the laboratory, preferably on wet ice.

The CAM route of inoculation is utilized most commonly for LTV isolation as it is the most sensitive of the embryonated egg inoculation routes and results in titers 10^2 or greater than other routes (82, 100). Chorioallantoic membrane plaques can be observed as early as 2 days PI; these generally have opaque edges and a central depressed area of necrosis (Fig. 5.2).

Chicken embryo liver cells and CK cells are the cell cultures of choice for LTV isolation. Viral cytopathology may be observed in cell culture within 24 hr PI and consists of increased refractiveness and swelling of cells, chromatin displacement, rounding of the nucleoli, and formation of multinucleated giant cells (syncytia) (Fig. 5.3). A maximum of two serial passages in CEL and CK cell cultures are required to ensure detection of LTV in clinical samples (8, 88).

In a comparison of the CAM inoculation route and a variety of cell cultures, Hughes and Jones (88) found CEL cells to be the most sensitive laboratory host system for LTV isolation, although CK cells were a satisfactory alternative. Both CEL and CK cells were superior to CAM inoculation of embryonated eggs.

Definitive identification of LTV in infected CAM material may be accomplished using histopathology, fluorescent antibody (FA) procedures, immunoperoxidase procedures (167), or polymerase chain reaction (PCR) procedures. Electron microscopy, FA, or IP may be used to identify LTV in infected CEL and CK cells.

A variety of different procedures have been described for identification of LTV in clinical samples; these include electron microscopy, methods for detection of viral antigens (FA, IP, enzyme-linked immunosorbent assays [ELISA]), and methods for detection of viral DNA (DNA hybridization techniques, PCR techniques). Electron microscopy has been utilized to detect LTV in tracheal scrapings (88, 179). As diagnosis is dependent upon visualization and morphologic identification of herpesviruses, this approach is successful only when large numbers of virus particles are present in clinical samples. Hughes and Jones (88) found that virus particles were observed only when clinical samples contained a minimum of $10^{3.5}$ infectious virus/ 0.1 mL.

Wilks and Kogan (186) reported the detection of LTV antigens in tracheal tissue from day 2 through day 14 PI using an FA procedure, but others (11, 85) have reported considerably shorter periods (6–8 days PI) for successful detection using FA procedures. With the use of an IP procedure, Guy *et al*. (73) were able to detect LTV antigens in frozen sections of tracheal tissues from day 1 to day 9 PI (Fig. 5.6), and the IP procedure was shown to be

5.6.   Immunoperoxidase staining of tracheal epithelium of chicken, 4 days after intratracheal inoculation with laryngotracheitis virus. Staining is localized to large focal areas of the tracheal mucosa (*arrow*). ×150.

more sensitive than FA for detection of LTV in tissues. Timurkaan *et al*. (174) were able to detect LTV antigens in formalin-fixed, paraffin-embedded tracheal and laryngeal tissues of chickens from day 3 to day 9 PI. Similarly, Sellers *et al*. (167) utilized the IP procedure to detect LTV antigens in formalin-fixed, paraffin-embedded tissues.

Immunoperoxidase and FA detection of LTV antigens in tissues of infected chickens require a source of LTV-specific antibody. These LTV-specific antibodies have been prepared for use in FA and IP by animal immunization procedures (11, 85, 174, 186) and by use of monoclonal antibody technology (1, 180, 197). Monoclonal antibodies are advantageous in that large quantities of highly specific antibody may be produced, potentially allowing worldwide distribution and standardization of LTV diagnostic procedures.

ELISA procedures for detection of LTV antigens in tracheal exudate have been developed (135, 191). York and Fahey (191) described an antigen capture ELISA using monoclonal antibodies to LTV. This ELISA was shown to be as accurate as virus isolation, but faster, and more accurate than either FA or agar gel precipitation tests (103) for detecting LTV.

More recently, methods for detection of LTV DNA in clinical samples have been described. Keam *et al*. (105) and Key *et al*. (112) described procedures for detection of LTV DNA utilizing dot-blot hybridization assays and cloned LTV DNA fragments labeled with digoxigenin. These procedures were shown to be highly sensitive for detection of LTV in acutely infected chickens, as well as convalescent chickens when detection was no longer possible using virus isolation and ELISA. These procedures also were shown to provide rapid methods for detection of

chickens latently infected with LTV. Abbas *et al.* (2) described a dot-blot hybridization procedure using a biotinylated DNA probe generated by PCR procedures. In situ hybridization procedures were described by Nielsen *et al.* (134) for detection of LTV DNA in tissues.

Polymerase chain reaction (PCR) procedures for detection of LTV DNA have been described by a number of research groups (2, 4, 31, 38, 42, 92, 138, 164, 170, 188). These procedures include a multiplex PCR (138) that allows detection of multiple avian respiratory pathogens, including LTV, and real-time PCR (42) that markedly improves speed of diagnosis. These procedures have been shown to be more sensitive than virus isolation. Additionally, PCR procedures allow detection of LTV in samples contaminated with other microorganisms, such as adenoviruses, that may prevent LTV isolation due to overgrowth in culture (188).

Serology

A variety of techniques for demonstration of LTV-specific antibodies in serum have been described, including agar-gel immunodiffusion (AGID), virus neutralization (VN), indirect fluorescent antibody (IFA) test, and ELISA. These procedures also may be utilized for identification of LTV in infected cell cultures and CAMs.

Burnet (29) first described a VN test to detect LTV-specific antibodies in chicken serum using embryonated chicken eggs inoculated by the CAM route with subsequent enumeration of CAM lesions. The use of cell cultures has greatly simplified these procedures, and VN antibodies may be measured by assay in cell cultures seeded in tubes, petri dishes, or microwell plates (36, 153, 157).

Enzyme-linked immunosorbent assay systems have been developed for detection and quantitation of LTV-specific antibodies using LTV-coated plates (131, 135, 194). Direct comparison of the AGID, VN, IFA, and ELISA demonstrated that all were valid systems for detecting and quantifying LTV-specific antibodies (3). Although ELISA was shown to possess slightly greater sensitivity than VN, it was comparable to IFA; AGID was the least sensitive. Both ELISA and IFA have the advantages of speed and sensitivity; however, ELISA lacks the subjectivity inherent to IFA and is more suitable for testing large numbers of sera (13).

Recently, an ELISA for detection of LTV-specific antibodies was developed that utilized a recombinant *Escherichia coli* that expressed LTV glycoproteins, gE and gp60 (32). It was shown that this recombinant-based ELISA differentiated between LTV-vaccinated and unvaccinated/unexposed chickens, but sensitivity and specificity were not reported.

Differential Diagnosis

Respiratory disease associated with LT must be distinguished from other respiratory pathogens of poultry that may cause similar clinical signs and lesions. These include the diphtheritic form of avian poxvirus and infections caused by Newcastle disease virus, avian influenza virus, infectious bronchitis virus, fowl adenovirus, and *Aspergillus* spp.

Intervention Strategies

Management Procedures

Laryngotracheitis virus infections resulting from field exposure or vaccination will result in latently infected carrier birds; thus, it is extremely important to avoid mixing vaccinated or recovered birds with susceptible chickens. Special precautions should be taken to obtain a complete history when mixing breeding stock. Use of sound biosecurity measures will avoid exposing susceptible chickens via contaminated fomites.

The importance of site quarantine and hygiene in preventing the movement of potentially contaminated personnel, feed, equipment, and birds is central to successful prevention and control of LT. Measures to control dogs, cats and rodents also should be in place (113). The persistent LT disease threat posed by backyard and exhibition poultry flocks (125, 128) should be recognized and guarded against.

Cooperative control of LT outbreaks by collaboration between government and industry is most desirable. Correctly implemented (125), this approach may obviate the need for widespread use of LT vaccine. Where outbreaks have been contained, recovered flocks should be moved for processing under quarantine as soon as possible. Experience with LT outbreaks in Pennsylvania (45, 46) indicates that this interval can be as short as 2 wk after the last clinical signs of LT are observed on a site.

For control of an LT outbreak, the most effective approach is a coordinated effort to obtain a rapid diagnosis, institute a vaccination program, and prevent further virus spread (9). Vaccination in the face of an outbreak effectively limits virus spread and shortens the duration of disease. Spread of LTV between sites can be prevented by appropriate biosecurity measures.

Laryngotracheitis virus infectivity is readily inactivated outside the host chicken by disinfectants and warm temperatures, thus carryover between successive flocks in a house can be prevented by adequate cleanup. It is recommended that all potentially contaminated carcasses, feathers, feed, water and litter should be kept within the poultry house, and the house heated to 38 °C for 100 hours. Buildings and equipment should be washed and then sprayed with disinfectants such as phenolics, sodium hypochlorite, iodophors, or a quarternary ammonium compound. All disinfectants should be used only at the dilutions recommended by the manufacturer.

Vaccination

Vaccination has proven to be a satisfactory method for developing resistance in susceptible chicken populations (see "Immunity"). Since vaccination can result in latently infected carrier birds, it is recommended for use only in geographic areas where the disease is endemic. The appropriate regulatory agency should be contacted to determine approved vaccines and vaccine application procedures.

Modified-Live Virus Vaccines

Successful immunization against LT was first accomplished by application of virulent virus to the cloaca (26). Subsequently, it was demonstrated that immunity could be provided by vaccina-

tion of chickens with attenuated (modified-live) viruses via infra-orbital sinuses (169), intranasal instillation (20), feather follicles (132), eye drop (172), and orally through drinking water (161). Field strains of LTV have been attenuated by sequential passage in cell cultures (62, 95, 96) and embryonated chicken eggs (160), and via feather follicle inoculation of chickens (93).

Careful attention must be given to procedures of vaccine administration to ensure adequate immunization. Care must be taken to ensure that virus dose is sufficient to provide effective immunization. Raggi and Lee (149) found that LT vaccine must contain greater than 10^2 plaque-forming units/mL to induce satisfactory immunity when administered by routes other than the oral route. A virus concentration of 10^5 embryo infective doses was necessary for satisfactory oral vaccination (80). Modified-live LT vaccines must be handled with care in order to ensure adequate concentrations of infective virus; manufacturers' instructions for storage, resuspension, dilution, and application should be closely followed.

Administration of modified-live LT vaccine in drinking water or by spray are desirable methods for rapid, mass application of these vaccines; however, several problems have been associated with these routes of inoculation. Robertson and Egerton (154) demonstrated that administration of LT vaccines by the drinking water route can result in a high proportion of chickens that fail to develop protective immunity. Successful vaccination via the drinking water is dependent upon the vaccine virus making contact with susceptible nasal epithelial cells; this occurs via aspiration of virus through external nares or choanae. The studies of Robertson and Egerton (154) showed that this occurred infrequently in chickens vaccinated by the drinking water route. Incorrect application of LT vaccines by spray may result in adverse reactions as a result of insufficient attenuation of vaccine virus, deep penetration of respiratory tract due to small droplet size of spray (148), or excessive dose (37).

Modified-live LT vaccines have been associated with a variety of adverse effects including spread of vaccine virus to nonvaccinates (6, 35, 77, 161), insufficient attenuation, production of latently infected carriers (8), and increased virulence as a result of in vivo (bird-to-bird) passage (72). Laryngotracheitis vaccine viruses have been shown to spread readily from vaccinated to nonvaccinated chickens (6, 35, 77, 161). Such spread should be avoided, as spread to nonvaccinates results in in vivo (bird-to-bird) passage and possible reversion of vaccine virus to virulence (72). Alternatively, vaccine virus may result in disease in unvaccinated chickens due to insufficient attenuation. Spread of vaccine viruses may be prevented by biosecurity measures that prevent flock-to-flock spread, and by using vaccination methods that ensure simultaneous infection with LT vaccine virus of all susceptible birds on a farm.

Guy et al. (70, 71, 72) provided evidence indicating involvement of modified-live LT vaccine viruses in field outbreaks. They suggested that modified-live LT vaccine viruses increase in virulence as a result of vaccine virus spread and in vivo (bird-to-bird) passage. In studies comparing six modified-live LT vaccine viruses and field LTV isolates, vaccine viruses were shown to be indistinguishable from field isolates based on DNA-restriction endonuclease analyses (70), but the virulence of all vaccine viruses was low compared with field isolates (71). Two modified-live vaccine viruses, a chicken embryo-origin (CEO) virus and a tissue culture-origin (TCO) virus, were sequentially passaged in specific-pathogen-free chickens to determine whether virulence of vaccine viruses could increase after sequential in vivo passage (72). Sequential passage of modified-live LT vaccine viruses resulted in increased virulence of the CEO virus but not the TCO virus. After 10 sequential passages in chickens, the CEO virus possessed virulence comparable to that of a highly virulent reference strain (Illinois N71851 strain, ATCC VR-783). Guy et al. (72) suggested that increased virulence of modified-live LT vaccine viruses may occur in field situations as a result of drinking-water vaccination and poor biosecurity, conditions that allow uncontrolled spread of vaccine viruses to nonvaccinates, and sequential in vivo passage of vaccine viruses.

Inactivated Vaccines

Experimental vaccines have been prepared from inactivated whole LTV (12, 52) or affinity-purified preparations of LTV glycoproteins (193). These vaccines have been shown to stimulate immune responses in chickens and varying degrees of protection to LTV challenge. Practical field use of these types of vaccines, however, is unlikely due to high cost of preparation and delivery.

Vaccines Based on Recombinant DNA Technology

A variety of strategies for development of LT vaccines based on recombinant DNA technology recently were reviewed by Bagust and Johnson (10). They suggested that this type of vaccine could be used in conjunction with quarantine and hygiene measures for the development of regional LTV eradication programs.

Vaccines based on recombinant DNA technology have been developed for LTV control. These include recombinant, live LTV vaccines constructed by insertion of LTV genes into virus-vectors, and by alteration or deletion of viral genes. Recombinant, virus-vectored vaccines for immunization of chickens against LTV have been produced and evaluated (47, 159, 175). Saif et al. (159) evaluated the protective efficacy of a recombinant herpesvirus of turkeys (HVT) containing LTV genes; they reported that this recombinant vaccine produced protection against LTV challenge similar to that induced by modified-live virus vaccines. Tong et al. (175) constructed a recombinant fowlpox virus containing LTV gB gene; they reported that this vaccine produced protection against LTV challenge similar to that induced by modified-live vaccines. Davison et al. (47) evaluated a fowlpox virus recombinant containing LTV gB and UL-32 genes; they reported that this vaccine provided adequate immunity against LTV challenge.

Recombinant, live LTV vaccines have been constructed by alteration or deletion of viral genes, producing LTV mutants that lack genes coding for virulence factors. These mutants may then be capable of inducing protective immunity, without the capability to induce disease. Several LTV deletion mutants have been developed for potential use in the control of LTV (57, 58, 69, 124, 137, 163, 181, 182). Guo et al. (69) described the construction of a recombinant LTV expressing the β-galactosidase

marker gene by insertion of this gene into an open reading frame of the LTV DNA. Okamura *et al*. (137) and Schnitzlein *et al*. (163) developed recombinant LTV lacking thymidine kinase, a herpesvirus virulence factor, by inserting *Lac-Z* marker genes into the thymidine kinase gene of the viral DNA. The green fluorescent protein (GFP) also has been utilized as a marker to produce recombinant LTV. Fuchs *et al*. (57) produced a UL50 gene deletion mutant expressing GFP and concluded that the LTV UL-50 gene codes for a viral dUTPase enzyme, a virulence factor that is not required for replication of the virus in the respiratory tract of birds. Laryngotracheitis virus mutants lacking the gJ (58), gG (49), and UL0 genes (181) were shown to have minor growth defects in cell culture and showed an attenuated phenotype in chickens while maintaining their immunogenicity. Deletion mutant vaccines composed of gene deletions in the thymidine kinase gene (137, 163), UL0 gene (181), and gJ gene (58) are considered to be suitable candidates for vaccine use. The gJ gene mutant is of particular interest because antibodies against the gJ are present during a natural infection; therefore, the lack of this glycoprotein in the vaccine strain potentially allows identification of LTV-infected birds by detection of gJ-specific antibodies (58). Laryngotracheitis virus deletion mutants also have been used as a vector to express the H7 and H5 genes of avian influenza virus, and the application of these mutants as bivalent vaccines to induce protection against LTV and avian influenza infections has been proposed (124, 181). A variety of other LTV deletion mutant viruses have been evaluated in birds; these include LTV mutants lacking five unique open reading frames (ORF A–ORF E) (182), and mutant viruses having deletions of the UL49.5 gene that codes for gN, and the UL10 gene, which codes for the non-glycosylated membrane protein M (55, 56).

An LTV deletion mutant was constructed by deletion of adjacent genes US7 and US8 by insertion of a gene coding for green fluorescent protein; US7 and US8 genes code for gI and gE, respectively (48). This LTV deletion mutant could not be propagated in cell culture suggesting that these glycoproteins are essential for LTV replication.

Field Vaccination Protocols and Regimens
Chickens may be successfully vaccinated as early as 1 day of age (145); however, chickens less that 2 weeks of age do not respond as well as older birds (5, 40, 62). Additionally, severe reactions are more likely in younger chickens.

In chickens older than 2 wk of age, LT vaccination using modified-live vaccines or field exposure confers protection against challenge, which is partial by 3–4 days postvaccination and complete by 6–8 days (20, 61, 81). Waning of immunity has been detected as early as 8–15 wk postvaccination (83), but substantial flock immunity generally is observed for 15–20 wk after vaccination (5, 62, 139). Vaccine breaks in the field are most commonly observed after 15–20 wk postvaccination, but the value of revaccination is questionable (102). Revaccination with modified-live vaccines may be ineffectual in maintaining protection levels because the infectivity of vaccine virus may be neutralized and replication prevented by existing immunity (51, 196).

Laryngotracheitis can be well controlled in multiple-age layer flocks by vaccination with modified-live vaccines. Layer flocks generally are vaccinated twice before the onset of egg production; vaccines typically are administered by eye drop at approximately 7 weeks of age and again at approximately 15 weeks of age by eye drop, spray, or drinking water. Studies by Fulton *et al*. (59) demonstrated the importance of two vaccinations for development of protection against challenge. Two vaccinations resulted in superior protection compared with a single vaccination, regardless of route (eye drop, spray, water) and vaccine source. Vaccine application by eye-drop route was shown to provide more uniform protection following a single dose compared with spray and drinking water routes. Single dose vaccination by the drinking water route was dependent upon the proximity of birds to the water source, and some vaccines failed to provide protection when a single dose was administered by spray (59).

For intensive broiler production, the short growth cycle, all in-all out production, and a high level of biosecurity can reduce the need for prophylactic vaccination. However, vaccination of broiler flocks may be necessary when these flocks are in the vicinity of LT outbreaks or when disease has previously occurred on the farm. Under these circumstances, broiler chickens generally are vaccinated at 10–21 days of age, usually via the drinking water route.

A recombinant fowl pox virus-vectored vaccine for immunization of chickens against LTV is commercially available in the United States (47). This vaccine is used for immunization of multi-age layer flocks. It is administered by wing-web inoculation to chickens that are at least 8 weeks of age and at least 4 weeks prior to onset of egg production.

Treatment
No drug has been shown to be effective in reducing the severity of lesions or relieving disease signs. If a diagnosis of LT is obtained early in an outbreak, vaccination of unaffected birds may induce adequate protection before they become exposed.

Eradication
Eradication of LTV from intensive poultry production sites appears to be highly feasible owing to several biologic and ecologic properties of the virus, which have been reviewed in detail by Bagust and Johnson (10). These properties include the high degree of host specificity of LTV, fragility of virus infectivity outside the chicken, and antigenic stability of the LTV genome. The chicken is the primary host species and reservoir host; wildlife reservoirs are believed either to be nonexistent or of minor importance in LTV ecology. Backyard and fancier chicken flocks are likely reservoirs of LTV; thus, any eradication effort would require identification and inclusion of these birds (125). Laryngotracheitis virus strains are antigenically homogeneous; thus, a single LTV vaccine produces cross-protective immunity for all LTV strains.

Eradication of LTV will require a change in current LT vaccination practices. This will entail the replacement of conventional, modified-live vaccines in vaccination programs with vaccines produced by recombinant DNA technology; vaccines produced by this technology induce protective immunity without development of latently infected carrier chickens (10).

Chapter 6

Influenza

D. E. Swayne and D. A. Halvorson

Introduction

The term "influenza" originally referred to epidemics of acute, rapidly spreading catarrhal fevers of humans caused by viruses in the family *Orthomyxoviridae* (142). Today, orthomyxoviruses are recognized as the cause of significant numbers of natural infections and disease, usually of the upper respiratory tract, in humans, horses, domestic pigs, and various bird species and sporadic cases of naturally occurring disease in mink and a variety of marine mammals (88,172,333). Since 2003, isolated natural cases of H5N1 high pathogenicity avian influenza (HPAI) have been reported in leopards, tigers, domestic cats, dogs, stone martins, civets, and domestic pigs, which were exposed to H5N1 HPAI-infected birds, but these avian influenza (AI) virus infections have not become endemic in these species (62,138,153, 223,260,356). Infection of domestic poultry by AI viruses typically produces syndromes ranging from asymptomatic infection to respiratory disease and drops in egg production to severe, systemic disease with near 100% mortality (80). The latter form of disease is the result of infection by high pathogenicity or highly pathogenic (HP) AI viruses. Disease is usually absent with AI virus infection in most free-flying waterfowl species.

For more detail, see reviews on HPAI (308), outbreaks of AI in the 1990s (212), immunology of AI (278), AI in different bird species (10), epidemiology and control (8), and evolution and ecology of AI viruses (283,333).

Definitions and Synonyms

Avian influenza initially was recognized as a highly lethal, systemic disease (i.e., highly pathogenic or highly virulent AI). From the late 1870s to 1981, HPAI was known by various names including fowl plague (most common), fowl pest, peste aviaire, Geflugelpest, typhus exudatious gallinarium, Brunswick bird plague, Brunswick disease, fowl disease, and fowl or bird grippe (272,273). In 1981 at the First International Symposium on Avian Influenza, the terminology "highly pathogenic avian influenza," was adopted as the official designation for the highly virulent form of AI (21). "High pathogenicity" is an equivalent grammatical variant of "highly pathogenic" and can be used interchangeably.

Milder forms of AI were first recognized in various domestic poultry species between 1949 and the mid-1960s and have been termed low pathogenic, pathogenic, non-highly pathogenic and low pathogenicity AI (6,83,238). Their impact on poultry production and trade has been much less severe than with HPAI. At the Fifth International Symposium on Avian Influenza in 2002, the terminology "low pathogenicity (LP)" was adopted as the official designation for low virulence AI (i.e., any AI that does not meet the criteria for HPAI (95)).

The World Organization for Animal Health (Office International des Epizooties [OIE]) is an intergovernmental organization charged by the World Trade Organization to set the sanitary and health standards for animal diseases. The OIE uses the designation of notifiable AI (HP notifiable AI [HPNAI] and LP notifiable AI [LPNAI] for international animal health regulatory purposes (9,199). HPNAI encompasses all HPAI while LPNAI encompasses only H5 and H7 LPAI. Prior to 2004, OIE Terrestrial Animal Health Code covered only HPAI, which was on the OIE's most serious disease list, List A; however, since then, the List A and B system has been eliminated.

Economic Significance

Economic losses from AI have varied depending on the strain of virus, species of bird infected, number of farms involved, control methods used, and the speed of implementation of control or eradication strategies. In most developed countries, HP and LPAI have not been endemic diseases in the commercial poultry industries. Most outbreaks and economic losses have occurred from epidemics of HP or LPAI in commercially raised poultry, predominately chickens and turkeys. In some developing countries LPAI has been endemic in commercially raised poultry—especially viruses of the H9N2 subtype in the 1990s. In some developed countries, LPAI has been endemic in backyard and live poultry market (LPM) systems that serve ethnic populations of large metropolitan areas. Since 2003, H5N1 HPAI has become endemic in village poultry, especially domestic ducks in some parts of the world.

Generally, the most accurate reports on losses have resulted from HPAI eradication programs (Table 6.1). Direct losses in HPAI outbreaks have included depopulation and disposal costs, high morbidity and mortality losses, cleaning and disinfection, quarantine and surveillance costs, and indemnities paid for the birds. However, indirect costs such as uncompensated losses to the poultry industry including temporary or permanent loss in poultry exports, income lost by farmers and communities during the production down time, increased consumer costs from reduced supply of poultry products, and losses from decreases in consumer purchases can easily escalate losses by 5–10 fold. The economic costs for eradication of HPAI have varied greatly, but eradication costs have been very high and appear to be proportional to the number of birds that died and were culled

Table 6.1.   Examples of economic losses from HPAI and LPAI epidemics as reported in US dollars.

Year	Outbreak	Birds dead or culled	Cost item	Original cost	Cost in 2007 $US	Cost/farm in 2007 $US	Reference
HPAI							
1924–25	USA—Fowl Plague	unknown	Direct losses	$1M	$12.2M	—	(273)
1983–84	USA—H5N2 HPAI	17M (449 farms)	USDA eradication	$63M	$126M	$280,000	(94,161)
			Non-indemnified industry losses	$15M	$30M	$66,500	
			Increased customer costs	$349M	$700M	$1.5M	
1985	Australia—H7N7 HPAI	238,518 (1 farm)	Eradication cost	$1.4M	$2.7M	$2.7M	(68)
1999–2000	Italy—H7N1 HPAI	13M (413 farms)	Compensation	$100M	$121M	$298,000	(298)
			Indirect costs	$500M	$605M	$1.5M	
1997	Hong Kong—H5N1 HPAI	1.5 M	Eradication	$13M	$17M	—	(298)
Late 2003–mid-2005	Asia—H5N1 HPAI	220M	Losses to the poultry industries	>$10B	>$10B	—	(353)
LPAI							
1978	Minnesota USA—various LPAI	141 farms	Losses to the poultry industries	$5M	$16M	$113,000	(110)
1995	Minnesota USA—H9N2 LPAI	178 farms	Losses to the poultry industries	$6M	$8.2M	$46,000	(110)
1978–1995	Minnesota USA—various LPAI	1058 farms	Losses to the poultry industries	$22M		$21,000	(110)
1995	Utah USA—H7N3 LPAI	2M (60 farms)	Losses to the poultry industries	$2M	$2.7M	$45,000	(110,208)
2002	Virginia USA—H7N2 LPAI	4.7M (197 farms)	USDA eradication	$81M	$94M	$477,000	(3)
			Losses to the poultry industries	$130M	$150M	$761,000	
			State government	$1M	$1.2M	$6000	

(Table 6.1). However, in the 1983–84 USA H5N2 HPAI epidemic, the projected cost of not implementing an eradication program was $500 million for losses to poultry farmers and $5.5 billion in increased customer costs (161).

Low pathogenicity AI outbreaks have caused significant economic losses for producers of chickens, turkeys and ducks, especially when accompanied by secondary bacterial or viral pathogens, but accurate documentation of such costs are generally not available. In general, losses have been less than with HPAI outbreaks because infected flocks have typically been eliminated through a controlled marketing program, the mortality rates have been lower, no federal eradication costs were incurred, and national and international trade usually have not been disrupted (Table 6.1). Losses from LPAI epidemics include mortality losses, condemnations at slaughter, medication against secondary bacteria, cleaning and disinfection, and delayed placements of new birds. Poorly documented but more costly have been the endemic H9N2 LPAI poultry infections in much of Asia and the Middle East and H5N2 LPAI poultry infections in Mexico and Central America. Since LPAI is usually not dealt with by traditional stamping-out programs, the costs of LPAI are unknown. However, when a stamping-out program was undertaken in the Virginia 2002 H7N2 LPAI outbreak, the eradication program had similar costs as previous HPAI outbreaks (Table 6.1).

Public Health Significance

In general, influenza viruses exhibit host species adaptation with transmission occurring most frequently and with ease between individuals of the same species; occasionally interspecies transmission to closely related species occurs (283). On rare occasions, AI viruses have exhibited interspecies transmissibility to humans (80). Although rare, AI viruses or their genes have been transferred to humans: 1) transfer of complete AI viruses (*in toto*) with individual sporadic infections, and 2) appearance of individual AI viral gene segments in pandemic human influenza viruses (i.e., reassortment of gene segments).

Transfer of Complete AI Virus

Sporadic cases of transmission of whole AI viruses to humans have been documented (42,283). However, such cases have been rare compared to the hundreds of millions of human infections by H1N1 and H3N2 human-adapted influenza viruses that occur each year. Variations in cell receptor specificity on the respiratory tract epithelium may account for some of the differences in influenza virus transmission and efficient replication. AI viruses have preferential binding to N-acetylneuraminic acid-$\alpha 2$, 3-galactose linkage on sialoligosaccharide ($\alpha 2,3$ linkage) receptors, and human influenza viruses preferentially bind to N-acetylneuraminic acid-$\alpha 2,6$-galactose linkage on sialoligosac-

Table 6.2.   Listing of confirmed human cases of infection with avian influenza viruses (modified from (214,346)).

Year	Virus	Location	Symptoms	Exposure	Cases	Deaths	Reference
1959	H7N7 HPAI	USA	Hepatitis	Unknown	1	0	(72)
1977	H7N7 HPAI	Australia	Conjunctivitis	Laboratory accidental exposure	1	0	(314)
1978–79	H7N7 LPAI	USA	Conjunctivitis	Seals with respiratory disease	Not reported	0	(335,337)
1996	H7N7 LPAI	United Kingdom	Conjunctivitis	Tending domestic ducks that mixed with wild ducks on a pond	1	0	(23,155)
1998, 2003	H9N2 LPAI	Hong Kong and Mainland China	3 = respiratory symptoms; 5 = influenza-like illness	1 = contact with live poultry in LPM, 7 = not reported	8	0	(105,210,346)
2002–03	H7N2 LPAI	USA	1 = asymptomatic, 1 = respiratory symptoms	1 = outbreak crew, 1 = unknown	2	0	(56,57)
2003	H7N7 HPAI	Netherlands	Conjunctivitis > influenza-like illness > other symptoms	Depopulation crews, poultry workers and farmers from poultry H7N7 HPAI outbreak	89	1	(150)
2004	H7N3 HPAI	Canada	Conjunctivitis, coryza and headache	Depopulation crews for poultry H7N3 HPAI outbreak	2	0	(323)
1997–2006	H5N1 HPAI	Asia, Africa[1]	Respiratory symptoms < gastro-intestinal	Exposure to live or dead infected poultry in LPM or villages	348	207	(187,209,347)

charide (α2,6 linkage) receptors (128). Avian respiratory epithelium has predominantly α2,3 linkage while human respiratory epithelium has predominately α2,6 linkage (128). Although the human respiratory tract does have α2,3 receptors on cells deep in the respiratory tract—non-ciliated cuboidal bronchiolar and alveolar type II cells—which provide a site for potential AI virus replication (243), but the deep location of these receptors make exposure unlikely and the resulting human AI virus infections rare. In addition, other AI viral genes—e.g., polymerase complex—may confer inefficient replication in humans (243).

Nine incidents of limited natural human infection with *in toto* transfer of AI viruses have been reported over the past 50 years (Table 6.2). Most consistently, human AI cases presented with conjunctivitis (predominantly H7 cases), respiratory illness (predominantly H5 cases) or flu-like symptoms, but some cases presented with atypical signalment such as gastrointestinal symptoms (346). Six incidents involved 15 cases while the 2003 Netherlands H7N7 and 1997–2006 H5N1 HPAI viruses account for 207 of the 208 human infections and the H5N1 HPAI virus for 437 of 452 fatalities (Table 6.2). The H5N1 HPAI cases have occurred across a broad geographic area involving cases in multiple countries including Azerbaijan, Cambodia, Djibouti, Hong Kong, and Mainland China, Egypt, Indonesia, Iraq, Thailand, Turkey, and Vietnam, but the infecting viruses have all been direct descendants of a single AI H5 hemagglutinin gene. Most of the H5N1 HPAI cases have been linked to direct exposure to H5N1 HPAI

virus infected live or dead poultry within LPM or villages (213,245). Two cases are exceptions with presumed exposure through consumption of raw duck blood and organs, and defeathering H5N1 infected dead swans (345,348). Finally, in a study in Cambodia, villagers with close frequent contact to H5N1 HPAI virus infected poultry did not become infected which suggests transmission potential from poultry to individual humans is low (331). The cases listed in Table 6.2 and experimental data in animal models and humans suggest that some AI viruses, such as the H5N1 HPAI virus, have a greater potential to infect humans than other HPAI viruses and most LPAI viruses (33,77).

Transfer of AI Virus Gene Segments
Wild waterfowl and other aquatic birds are the primordial reservoir of all influenza viral genes (333). Although the probability of an AI virus entering the human population, reassorting and establishing a new lineage of human influenza virus has been extremely rare, which is consistent with the long time spans between the emergence of new human pandemic influenza viruses (23). For example, analysis of nucleotide sequence data has determined that the 1957 (H2N2) and 1968 (H3N2) human pandemic influenza viruses resulted from the reassortment of three (HA, NA, and PB1) and two (HA and PB1) AI viral genes with five and six human influenza viral genes, respectively (135,222,228,229). In theory, swine have been proposed as the "mixing" vessel for co-infection by influenza viruses from birds

and mammals with development of "new" strains (reassortants) having the ability to infect people and other mammals (230). However, in view of the human H5N1 HPAI virus infection and lack of H2N2 and H3N2 virus infections in pigs during 1957 and 1968 pandemics, reassortment of gene segments between a human adapted influenza virus and AI virus could have occurred in dually infected humans. Some recent evidence suggests that the 1918 pandemic virus was not derived by reassortment but arose by adaptation of a complete AI virus (313).

History

The history of avian influenza can be divided into three general periods: 1) early reports of HPAI, 2) recognition of less severe AI disease (LPAI) in domestic poultry, and 3) identification of AI viruses from asymptomatic wild bird reservoirs. Avian influenza was first reported as HPAI ("fowl plague") in 1878 by Perroncito in Italy (273). Initially, the disease was confused with the acute septicemic form of fowl cholera until 1880 when Rivolto and Delprato differentiated the two based on clinical and pathological features. In 1901, Centanni and Savonuzzi determined the cause was a filterable agent, but the virus was not identified nor classified as an influenza virus until 1955 (227,228,273).

In 1894, a severe outbreak of HPAI occurred in northern Italy and was disseminated via transport of chickens to eastern Austria, Germany, Belgium, and France (176,272). HPAI was spread throughout Germany as the result of the 1901 Brunswick Fowl Exposition (272). By the early part of the twentieth century, HPAI was reported in Switzerland, Romania, Russia, Netherlands, Hungary, Great Britain, Egypt, China, Japan, Brazil, and Argentina (152,182,273). By the mid-twentieth century, HPAI had been diagnosed in most of Europe, Russia, North Africa, Middle East, Asia, South America, and North America (82). In many parts of Europe, HPAI was endemic until the mid-1930s (11). HPAI was reported in the United States in 1924–1925 and 1929 (273). The HPAI outbreak began in 1924 with severe losses in the LPM system of New York and later New Jersey and Philadelphia, Pennsylvania (273). In 1925, infected farms or markets were identified in Connecticut, West Virginia, Indiana, Illinois, Michigan, and Missouri. The 1929 outbreak involved a few flocks in New Jersey (273). Quarantine, depopulation, cleaning, and disinfection were used to eradicate HPAI from the United States.

The outbreaks of HPAI between 1901 and the mid-1950s involved isolates that today have been classified as H7N1 and H7N7 subtypes (see Strain Classification) (80). However, an outbreak during 1959 in chickens of Scotland and during 1961 in common terns (*Sterna hirundo*) of South Africa involved new subtypes of AI viruses, H5N1 and H5N3, respectively (308). This led to the establishment of the erroneous dogma that all H5 and H7 AI viruses were highly pathogenic. Table 6.3 lists the summaries of HPAI outbreaks between 1955 and 2007. Of the 26 epidemics, 23 have involved domesticated poultry, principally chickens and turkeys, one involved exclusively wild birds (i.e., common terns) and one involved both domestic poultry, including ducks and geese, and wild birds. Details on individual outbreaks can be obtained from the references listed in Table 6.3.

Table 6.3. Twenty-six documented epidemics of HP AI since discovery of AI virus as cause of fowl plague in 1955, modified from (11,298,308).

Dates	Prototype AI Virus	Subtype	Number Affected with High Mortality or Were Depopulated(a)	Specific References
1959	A/chicken/Scotland/59	H5N1	2 flocks of chickens (*Gallus gallus domesticus*)—total number of birds affected not reported	215) (D.J. Alexander, (personal communication, 2000)
1961	A/tern/South Africa/61	H5N3	1300 common terns (*Sterna hirundo*)	(35)
1963	A/turkey/England/63	H7N3	29,000 breeder turkeys (*Meleagridis gallopavo*)	(343)
1966	A/turkey/Ontario/7732/66	H5N9	8,100 breeder turkeys	(160)
1975-76	A/chicken/Victoria/75 or A/chicken/Victoria/76	H7N7	25,000 laying chickens, 17,000 broilers, and 16,000 ducks (*Anas platyrhyncos*)	(18,322)
1979	A/chicken/Germany/79	H7N7	Unknown (formerly East Germany)	(11)
1979	A/turkey/England/199/79	H7N7	3 commercial farms of turkeys—total number of birds affected not reported	(4,16)
1983–84	A/chicken/Pennsylvania/1370/83	H5N2	17 million birds in 452 flocks; most were chickens or turkeys, a few chukar partridges (*Alectoris chukar*) and guinea fowl (*Numida meleagris*)	(80,84,325)
1983	A/turkey/Ireland/1378/83	H5N8	800 meat turkeys died on original farm; 8,640 turkeys, 28,020 chickens and 270,000 ducks were depopulated on original and 2 adjacent farms	(7,178)
1985	A/chicken/Victoria/185	H7N7	24,000 broiler breeders, 27,000 laying chickens, 69,000 broilers and 118,518 unspecified-type of chickens	(24,68)
1991	A/turkey/England/50–92/91	H5N1	8000 turkeys	(14)
1992	A/chicken/Victoria/192	H7N3	12,700 broiler breeders, 5,700 ducks	(234,344)
1994	A/chicken/Queensland/477/94	H7N3	22,000 laying chickens	(344)

Table 6.3. Twenty-six documented epidemics of HP AI since discovery of AI virus as cause of fowl plague in 1955, modified from (11,298,308). (*continued*)

Dates	Prototype AI Virus	Subtype	Number Affected with High Mortality or Were Depopulated(a)	Specific References
1994–95	A/chicken/Puebla/8623–607/94 A/chicken/Queretaro/14588–19/95	H5N2	Chickens(b)	(80,330)
1994–95, 2004	A/chicken/Pakistan/447/95 A/chicken/Pakistan/1369-CR2/95	H7N3	Two incursions: 1) 3.2 million broilers and broiler breeder chickens (northern part of country—1994–5), 2) 2.52 million layers (Karachi—2004) (c)	(80,190)
1996–2007	A/goose/Guangdong/1/1996 A/chicken/Hong Kong/220/97	H5N1	Over 220 million birds dead or culled, mostly chickens, but also ducks, geese, Japanese quail and some wildbirds(d)	(91,248,249)
1997	A/chicken/New South Wales/ 1651/97	H7N4	128,000 broiler breeders, 33,000 broilers, 261 emu (*Dromaius novaehollandiae*)	(213)
1997	A/chicken/Italy/330/97	H5N2	2116 chickens, 1501 turkeys, 731 guinea fowl, 2322 ducks, 204 quail (species unknown), 45 pigeons (*Columbia livia*), 45 geese (species unknown) and 1 pheasant (species unknown)	(51)
1999–2000	A/turkey/Italy/4580/99	H7N1	413 farms—8.1 million laying chickens; 2.7 million meat and breeder turkeys; 2.4 million broiler breeders and broilers; 247,000 guinea fowl; 260,000 quail, ducks and pheasants; 1,737 backyard poultry and 387 ostriches	(49)
2002	A/chicken/Chile/184240–1/2002	H7N3	Two farm, multiple houses; 617,800 broiler breeders, unspecified number turkey breeders (2 houses)	(226)
2003	A/chicken/Netherlands/ 621557/ 2003	H7N7	255 infected flocks, 1381 commercial and 16,521 backyard/smallholder flocks depopulated. 30 million died or depopulated—majority were chickens	(85)
2004	A/Chicken/Canada/AVFV2/04	H7N3	42 commercial and 11 backyard flocks infected (1.2 million poultry)—approximately 16 million commercial poultry depopulated, most were chickens	(123,195)
2004	A/chicken/Texas/298313/2004	H5N2	1 non-commercial farm and 2 live poultry markets, 6600 chickens	(168,197)
2004, 2006	A/ostrich/South Africa/2004	H5N2	2004—11 ostrich farms with depopulation of 23,625 ostriches and 3,550 other poultry (chickens, turkeys, geese, ducks and pigeons); 2006—7342 ostriches dead or culled	(196,200,201)
2005	A/chicken/North Korea/1/2005	H7N7	3 farms, 218,882 chickens culled; number dead not reported.	(197,198)
2007	Not available	H7N3	1 farm, 48,560 broiler breeders culled; 540 roosters died	(201a)

(a) Most outbreaks were controlled by "stamping out" or depopulation policies for infected and/or exposed populations of birds. Chickens, turkeys and birds in the order *Galliformes* had clinical signs and mortality patterns consistent with HPAI while ducks, geese and other birds lacked or had low mortality rates or infrequent presence of clinical signs.

(b) "Stamping-out" policy was not used for control. The AI outbreak had concurrent circulation of LP and HPAI virus strains. However, HPAI virus strains were present only from late 1994 to mid-1995. Estimates of number of birds infected with HP AI strains are unavailable but 360 commercial chicken flocks were "depopulated" for AI in 1995 through controlled marketing.

(c) "Stamping-out" policy was not used for control. Surveillance, quarantine, vaccination and controlled marketing were used as the control strategy. The numbers affected are crude estimates from 2 separate time periods of clinical disease outbreaks, but the virus lineage is the same between the outbreaks.

(d) The H5 and N1 gene lineages have been maintained among the HPAI viruses from outbreaks in various Asian, African and European countries (1996–2007). The six internal gene segments have undergone reassortment. The initial H5N1 HPAI outbreaks were reported in China (1996) with three incursions in Hong Kong (1997, 2001 and 2002). This was followed by regional extension with outbreaks in 2003–2005 within Southeast Asia (South Korea, Vietnam, Japan, Indonesia, Thailand, Cambodia, Laos, China and Malaysia). In mid-late 2005, outbreaks occurred in both wild birds and poultry in central Asia with extension to Eastern Europe and Middle East by fall of 2005. In 2006, outbreaks were reported in Africa. Initially, chickens were the main species affected with disease and death, but in many of the outbreaks, domestic ducks have emerged to be a major species in maintenance and epidemiology of the viruses. Various wild birds have succumbed to infections.

Milder diseases caused by AI viruses were recognized beginning in the middle of the twentieth century (82). Today, these AI viruses are termed low pathogenicity AI (LPAI) (see "Strain Classification" and "Pathogenicity"). The oldest existing LPAI virus, the Dinter strain from Germany, was isolated from chickens in 1949, but its identification as AI virus was not until 1960 (A/chicken/Germany/49 [H10N7]). Similarly, LPAI viruses were isolated from domestic ducks with respiratory disease between 1953–1963 in Canada, Czechoslovakia, England, and the Ukraine (82). Low pathogenicity avian influenza viruses emerged as a cause of respiratory disease and drops in egg production in turkeys in Canada and the United States during the early 1960s. Of notable significance was the identification of LPAI viruses of the H5 subtype in Canada during 1966 and the United States (Wisconsin) during 1968 (5,82,258). In 1971, a turkey flock in Oregon experienced mild respiratory disease with diarrhea, and an H7N3 AI virus was isolated (31). Since 1971, numerous H5 and H7 LPAI viruses have been isolated and characterized, thus dispelling the myth that subtypes H5 and H7 equate with HP (5,80,119).

Many AI viruses have been isolated from asymptomatic infections in wild aquatic birds. Initially, serologic surveys of migratory waterfowl showed evidence of infection by AI viruses (81). During 1972, AI viruses were isolated from migratory ducks as part of a Newcastle disease virus surveillance program (254) and in Australia from a pelagic seabird (shearwater) (75). Since then, large surveys have demonstrated that healthy wild aquatic birds, principally in the orders *Anseriformes* and *Charadriiformes*, have been asymptomatic reservoirs of AI viruses (265). AI viruses from wild birds have been mostly LP for domestic poultry. However, a few HPAI viruses have been isolated from wild birds: 1) during an epidemic with high mortality in common terns (A/tern/South Africa/61 [H5N3]); 2) single isolations of A/finch/Germany/72 (H7N1), A/gull/Germany/79 (H7N7) and A/Peregrine Falcon/UAE/2384/98 (H7N3); and 3) during the H5N1 HPAI outbreak in Asia, Europe and Africa with multiple isolations from wild birds (7,61,170,174).

Since AI is an international concern, global interest in AI resulted in the convening of international symposia in 1981, 1986, 1992, 1997, 2002 and 2006 to deal with AI issues (22,78,79,287, 307,309). Because influenza is an international problem, solutions will require international efforts and cooperation (80).

Etiology

Classification

Avian influenza viruses are classified in the family *Orthomyxoviridae*, genus *Influenzavirus A* (67).

Morphology

Virions are typically spherical to pleomorphic but can be filamentous (67). Individual virions range in diameter from 80–120 nm, but the filamentous forms can have lengths up to several hundred nm (Fig. 6.1) (67). The surface is covered by two types of glycoprotein projections (10–14 nm in length and 4–6 nm in diameter): 1) rod-shaped trimers of hemagglutinin (HA), and 2)
6.1. Purified A/WSN/33 influenza A virus. Negative stain with 2% phosphotungstic acid. ×282,100. (Gopal Murti)

mushroom-shaped tetramers of neuraminidase (NA). Virus buoyant density is 1.19 g/cm^3 in aqueous sucrose and single virion molecular weight (Mr) is 250×10^6 (67).

The nucleocapsid is helical. The viral genome is composed of eight segments of single-stranded, negative-sense RNA that code for 10 proteins. Their size and function are listed in Table 6.4. Eight proteins are constituents of the virus (HA, NA, NP, M1, M2, PB1, PB2, and HA), and the two nonstructural proteins (NS1 and NS2) are located in the host cell cytoplasm. Recently, NS2 has been shown to also be a minor constituent of virions (156).

Chemical Composition

Influenza virions are composed of 0.8–1.0% RNA, 5–8% carbohydrate, 20% lipid and 70% protein (156). The carbohydrates are contained within glycolipids and glycoproteins and include galactose, mannose, fucose, and glucosamine (144). Ribose is contained in the RNA genome. Lipids are present in the viral envelop and are derived from the host cell. Most of the lipids are phospholipids, but small amounts of cholesterol and glycolipid are present. The viral genome specifies the proteins and their potential glycosylation sites.

Virus Replication

The stages of virus replication have been reported by various investigators in great detail (156,203) or in brief (67,80). In brief, AI virus HA adsorbs to host cell receptors containing sialic acid bound to glycoproteins, thus initiating receptor-mediated endocytosis. In the endosomes, low-pH-dependent fusion occurs via HA-mediated fusion of viral envelope with the endosome membrane. Proteolytic cleavage of HA into HA1 and HA2 is an essential prerequisite for fusion and infectivity. The viral nucleocapsids are transported to the nucleus where viral transcriptase complex synthesizes mRNA. Transcription is initiated with 10–13 nucleotide RNA fragments generated from host heterogenous nuclear RNA via viral endonuclease activity of PB2. Six monocistronic mRNAs

[a]Number of nucleotides based on human influenza strain A/PR/8/34 (H1N1)

are produced in the nucleus and transported to the cytoplasm for translation into HA, NA, NP, PB1, PB2, and PA proteins. The mRNA of NS and M gene segments undergo splicing with each producing two mRNAs, which are translated into NS1, NS2, M1, and M2 proteins. The HA and NA proteins are glycosylated in the rough endoplasmic reticulum, trimmed in the Golgi and trans-ported to the surface where they are embedded in the plasma mem-brane. The eight viral gene segments along with internal viral pro-teins (NP, PB1, PB2, PA, and M2) assemble and migrate to areas of the plasma membrane containing the integrated HA, NA, and M2 proteins. The M1 protein promotes close association with the plasma membrane and budding of the virions.

Susceptibility to Chemical and Physical Agents
Avian influenza viruses are relatively unstable in the environ-ment. Physical factors such as heat, extremes of pH, hypertonic conditions, and dryness can inactivate AI viruses. Because AI viruses have lipid envelopes, they are inactivated by organic sol-vents and detergents, such as sodium desoxycholate and sodium dodecylsulfate. In the presence of organic matter, AI virus can be destroyed by chemical inactivants such as aldehydes (formalde-hyde or glutaraldehyde), beta-propiolactone, and binary ethylen-imine. After removal of organic matter, chemical disinfectants such as phenolics, ammonium ions (including quaternary ammo-nium disinfectants), oxidizing agents (such as sodium hypochlo-rite), dilute acids, and hydroxylamine can destroy AI viruses (99,165).

Laboratory Situation
The AI viruses are relatively stable in protein-containing solu-tions, but long-term storage should be at –70°C or following lyophilization. Egg grown virus can be maintained for several

weeks at 4°C without loss of infectivity, but hemagglutinating and NA activities can be maintained even longer even when the virus is no longer infectious. Inactivation with retention of hemagglutinating and NA activities can be achieved with various concentrations of formalin, binary ethylenimine, and beta-propiolactone (143). These compounds have been used as inactivants in vaccine production. Most commonly used detergents and disinfectants (such as phenolics, quaternary ammonium surfactant compounds, and sodium hypochlorite) inactivate AI viruses.

Field Situation

Influenza viruses are protected by organic material such as nasal secretions or feces, which increase resistance to physical and chemical inactivation (80). Cool and moist conditions favor long survival of AI viruses in the environment. AI viruses have been viable in liquid manure for 105 days in the winter and in feces for 30–35 days at 4°C and for 7 days at 20°C (28,94,342). Recent work on the H5N1 HPAI virus in Thailand indicated the virus could survive 4 days in chicken feces held at 25–32°C in the shade (261). In water at 28°C, the concentration of A/whooping swan/Mongolia/244/05 (H5N1) (Mongolia/05) and A/duck meat/Anyang/01 (H5N1) (Anyang/01) were reduced by 1 log in 4 and 5 days, respectively, and no virus was detected after 26 and 30 days, respectively. However, at 17°C, Mongolia/2005 and Anyang/2001 virus could persist until 158 and 94 days, respectively (38). The H5N1 HPAI virus had shorter environmental survival times compared to LPAI viruses obtained from wild waterfowl.

Proper inactivation and elimination of AI viruses shed in the environment is essential in the control of field infection and can be accomplished through integrated approaches including heating of buildings to 90–100°F for one week, thorough removal and proper disposal of manure and litter, cleaning and disinfecting of buildings and equipment, and allowing a 2–3 week vacancy period before restocking (106). Virus in manure and litter must be inactivated or disposed of by burial, composting, or incineration. Composting was effective at killing HPAI viruses within poultry carcasses in less than 10 days (237). Effective disinfectants against AI viruses on clean surfaces include 5.25% sodium hypochlorite, 2% sodium hydroxide (lye), phenolic compounds, acidified ionophor compounds, chlorine dioxide disinfectants, strong oxidizing agents, and 4% sodium carbonate/0.1% sodium silicate (65). However, organic material must be removed before disinfectants can work properly.

Pasteurization and cooking are effective means of inactivating AI viruses. USDA standard cooking times for poultry meat, which achieves an internal temperature of 165°F, and pasteurization (55.6–63.3°C, 210–372s) are adequate to kill AI viruses (286,290,315).

Strain Classification

Antigenicity

Influenza viruses are classified to genus ("type") based on serologic reactions of the internal proteins, principally NP and M1 proteins. This is typically done by an immunoprecipitation test (i.e., agar gel immunodiffusion test [AGID]) (302). All AI

viruses are *Influenzavirus A* or type A. *Influenzaviruses B* and *C* (i.e., types B and C) occur in humans and rarely in seals and pigs, but neither have been isolated from birds.

Influenzavirus A is further subtyped based on serologic reactions of the HA and NA surface glycoproteins. Sixteen subtypes of HA and nine subtypes of NA are recognized (Table 6.5). Serologic subtyping of HA is done by the hemagglutinin inhibition (HI) test and subtyping of neuraminidase by neuraminidase inhibition (NI) test (96,302). Most combinations of the 16 HA and 9 NA AI virus subtypes have been reported in domestic and wild birds, but distribution varies by year, geographic location, and host species. Since 1980, subtyping of HA and NA has been standardized for all type A influenza viruses from birds, pigs, horses, and humans (Table 6.5) (349). Prior to 1980, subtypes of HA and NA were classified according to the species of origin.

Convalescent sera from chickens and ferrets and monoclonal antibodies have been used for determining antigenic relatedness of influenza viruses within the individual subtype (80). Such studies typically have used HI, enzyme-linked immunosorbent assays (ELISA), and/or virus neutralization tests. Monoclonal antibodies have been useful for the detailed study of individual antigenic epitopes such as comparing the HA of H1N1 viruses from turkeys and pigs to establish antigenic relatedness of their HAs (19,115).

Strain Nomenclature

Standard international nomenclature for the designation of influenza virus strains has been established (349). The naming of the influenza virus strains includes the type (A, B, or C), host of origin (except for human where the "host of origin" is omitted), geographic site, strain number (if any), and year of isolation followed by the antigenic subtype designating HA (H) and NA (N)

in parentheses (80). For example, a type A influenza virus isolated from chickens in Pennsylvania during 1983 and classified as H5N2 is designated "A/chicken/Pennsylvania/1370/83 (H5N2)."

Antigenic Variation of Strains—Drift and Shift

Human influenza viruses have a high frequency of antigenic variation in the surface glycoproteins (HA and NA) because of two phenomena, drift and shift. Such concepts were developed to explain the antigenic change that arose in influenza viruses within the human population over time (188). Some have proposed similar phenomena for AI viruses (115), but differences in the epidemiological nature of AI viruses and the lack of endemic infections in commercial poultry populations in developed countries makes complete extrapolation to all bird populations of doubtful scientific foundation.

Antigenic drift in influenza viruses arises from point mutations in the HA and/or NA genes that results in minor antigenic changes in the coding proteins (188). In mammals, immune pressure plays a role in selection of antigenic variants, but impact of immune pressure on antigenic change of AI viruses is less well documented. In vaccinated poultry populations, immune pressure may play a role in selecting antigenic variants (166), but for most commercial poultry in developed countries, infrequent exposure to AI viruses, short life spans, and the rare use of vaccines raise doubt about the importance of vaccine pressure for selecting variants. However, in areas where LPAI viruses are endemic, such as H9N2 LPAI viruses in the Middle East and Asia, infection by field viruses is widespread with the appearance of drift variants in the field. It is unclear whether such immunological pressure is from vaccine use or infections by circulating field viruses.

Antigenic shift arises from genetic reassortment between the gene segments of two influenza viruses that infect the same cell and results in the acquisition of new HA and/or NA antigens in a population with endemic influenza (188). The lack of endemic influenza in most commercial poultry raises doubt as to the importance of antigenic shift in generating new strains, but in LPM, antigenic shift in HA and/or NA subtypes has been documented. In addition, genetic reassortment has resulted in the exchange of viral genes other than those coding for the HA and NA, as reported for the Hong Kong H5N1 virus of chickens and geese (54,275,277). In wild ducks, mixed infections have been reported based on antigenic and molecular testing (119).

Immunogenicity or Protective Characteristics

The HA is the major antigen that elicits antibodies which protect against death and clinical signs. Such antibodies are HA subtype specific (i.e., neutralize influenza virus of homologous HA subtype in *in vitro* assays). *In vivo* protection is also HA subtype specific and can last for periods greater than 35 weeks (43). Antibodies produced against the NA provide protection against homologous NA subtypes in birds (177), but such protection is inferior to HA-induced protection.

Antibodies against the internal proteins, principally nucleoprotein, do not confer protection from death or clinical signs fol-

lowing challenge by HPAI viruses (340). However, some reports suggest immunization with NP can reduce titers of influenza virus replication in lungs during the late stages of the infectious process (149). This protection may be mediated by cytotoxic T lymphocytes. In addition, prior exposure of chickens to live H9N2 LPAI virus conferred some level of protection in chickens against H5N1 HPAI virus in Hong Kong markets through cell mediated immunity (240). However, such heterotypic immunity has not been of sufficient length and level for use in the field.

Genetic or Molecular

In the 1980s, individual AI virus strains and reassortant viruses were differentiated by examining migration patterns of RNA segments in polyacrylamide gel electrophoresis (80). In addition, mutations within gene segments of closely related viruses were identified by oligonucleotide mapping (25). However, in the 1990s, the technical ease of obtaining and analyzing genetic sequence data has resulted in an explosion of genomic information about AI viruses. Such information has included partial sequence data for most gene segments, frequent reporting of full-length sequence for some gene segments (HA, NA, M, and NS) and, in some situations, the complete nucleotide sequence of all eight gene segments (277). This has resulted in detailed phylogenetic comparisons of strains for purposes of molecular epidemiology, identification of reassortant gene segments, and identification of specific mutations and their correlation with biological properties. With development of high throughput sequencers in later 1990s and early 2000s, full length genome sequencing has become a common laboratory tool.

Pathotype

Based on pathogenicity (i.e., the ability to produce disease), AI viruses from poultry are classified into two pathotypes: 1) HP, and 2) LP (i.e., non-HP). This terminology was originally based on lethality in experimentally inoculated chickens, but in 1994, molecular and *in vitro* criteria were added to the definition (326). Previously, OIE-specified HPAI viruses on List A and LPAI viruses were not reported, but this system of categorization on Lists A and B has been eliminated and new AI categorization developed for international trade purposes. Because some H5 and H7 LPAI viruses have been shown to change to HPAI viruses during circulation in chicken or turkey populations, OIE has added H5 and H7 LPAI viruses to the International Animal Health Code (199). The OIE Terrestrial Code now lists "notifiable" AI (HPNAI and LPNAI) as follows (199):

1. HPNAI viruses have an IVPI in 6-week-old chickens greater than 1.2 or, as an alternative, cause at least 75% mortality in 4-to-8-week-old chickens infected intravenously. H5 and H7 viruses which do not have an IVPI of greater than 1.2 or cause less than 75% mortality in an intravenous lethality test should be sequenced to determine whether multiple basic amino acids are present at the cleavage site of the hemagglutinin molecule (HA0); if the amino acid motif is similar to that observed for other HPNAI isolates, the isolate being tested should be considered as HPNAI.

2. LPNAI are all influenza A viruses of H5 and H7 subtype that are not HPNAI viruses.

In addition, the OIE code creates by default a third category of AI viruses—non-H5 and non-H7 LPAI viruses—which are not reported to OIE, but may be reportable to national and state/provincial authorities. However, based on pathobiological criteria (e.g., disease, lesions and signalment), LPAI viruses are indistinguishable irrespective of the H and N subtype. Although the pathogenicity classification is specific for chickens, similar *in vivo* test results have been obtained for related birds in the order *Galliformes* (12,216). However, most AI viruses that are HP for chickens have been LP for domestic ducks except for some strains of the recent Asian H5N1 HPAI virus, which are also highly lethal for young domestic ducks, but not highly lethal in older ducks (12,129). Pathogenicity test results are specific for the host used in the test.

Prior to 1959, HPAI viruses ("fowl plague" viruses) were thought to be associated only with H7 viruses. Then H5 was found to cause the same disease in 1959 and 1961. Furthermore, the discovery of low virulence H5 AI viruses in turkeys during 1966–1968 (5,82,258) and H7 during 1971 (30) established that antigenic subtyping was not a predictor of high pathogenicity. Only a small percentage of H5 and H7 AI viruses have been HP. By contrast, all H1–4, H6, and H8–16 AI viruses have been of low virulence (i.e., LP) for birds. Although non-H5 and non-H7 subtypes have been LP by the OIE definition, in some cases they can cause severe and economically important disease in the field where secondary infection and other stressors impact disease development.

Laboratory Host Systems

The preferred method for isolation and propagation of AI viruses has been 9–11-days-old embryonating chicken eggs inoculated via the chorioallantoic sac (CAS) (302), but with some isolates, inoculation by the yolk sac route or inoculation onto the chorioallantoic membrane resulted in isolation where CAS route failed (352). In embryonating chicken eggs, AI viruses grow to high titers and have a cleaved HA (80). Most inactivated vaccines have been produced by cultivation in embryonating eggs.

Avian influenza viruses replicate in a limited number of cell culture systems (80). Primary cultures of chicken embryo fibroblasts (CEF) or kidney cells are most commonly used for plaque assays and virus neutralization tests. Madin-Darby canine kidney cell cultures have also been used. However, in CEF and some other cells, LPAI viruses require the addition of exogenous trypsin to the medium or agar overlay in order to cleave the HA and produce infectious virus (80). Absence of exogenous trypsin will produce plaques less than 1 mm in size or no plaques depending on the virus strain. The HPAI viruses do not require the addition of exogenous trypsin for cleavage of HA and the subsequent production of infectious virus.

The chicken (*Gallus gallus domesticus*) has been the most frequently used animal in laboratory studies to determine pathogenicity and study pathogenesis. Other commonly used laboratory species include the turkey (*Meleagridis gallopavo*),

domestic duck (*Anas platyrhynchos*), house mouse (*Mus musculus*) and ferret (*Mustela putorius furo*). The mouse and ferret have been used as models to assess the risk of interspecies transmission of AI viruses to mammals (77), and the other species provide assessment of infections in natural hosts.

Pathogenicity
Clinical Groups in the Field
Although only two pathotypes of AI viruses can be demonstrated in the laboratory (HP and LP), natural infection by AI viruses results in a wide range of clinical outcomes which are dependent on virus strain, host species, host age, and environmental factors. From mortality patterns, clinical signs, and lesions in the field, AI can be categorized into four clinical groups: 1) highly virulent, 2) moderately virulent, 3) mildly virulent, and 4) avirulent. First, the highly virulent clinical group results from infection by HP H5 or H7 AI viruses usually in chickens or closely related gallinaceous birds and is expressed as a severe, highly fatal systemic disease that affects most organ systems including the nervous and cardiovascular systems. Morbidity and mortality approach 100%. Experimentally, the HPAI viruses reproduce the lesions and high mortality rates seen in the field (308). Second, the moderately virulent clinical group results from infection by LPAI viruses, of any HA or NA subtype, but also with co-infection by secondary pathogens (48,194). The mortality rates vary but range from 5–97% with the highest mortality occurring in young birds, reproductively active hens, or severely stressed birds (39,48,130). Lesions usually have been in the respiratory tract, reproductive organs, kidney, or pancreas (48,125,358). Some of these cases may have involved concurrent infection with bacteria that secreted proteases which cleaved HA of LPAI viruses, thus exacerbating the AI virus infection (252). Third, the mildly virulent clinical group results from infection by LPAI virus with low mortality and mild respiratory disease or drops in egg production. Mortality is usually less than 5%, and is typically in older birds. Fourth, the avirulent clinical group results from infections by LPAI viruses without any increased mortality or clinical signs. This has been most frequent with infections by LPAI viruses in wild birds of orders *Anseriformes* and *Charadriiformes* (283). In poultry, this has been seen following the introduction of a poorly host-adapted LPAI virus. Such an example would be the first cases of AI in range turkeys following exposure to wild waterfowl AI viruses that resulted in sero-conversion detected at slaughter without any previously noted clinical signs (283). Occasionally HP and LP viruses may appear together and this causes confusion in the field and the laboratory. In individual field situations, the clinical outcomes can be a mixture of the four clinical groups. For example, during the changing of a H5 or H7 LP to HPAI virus, gross lesions consistent with highly virulent AI will be seen in some dead birds, but the mortality rates will be low, similar to mildly virulent AI.

Effect of the Hemagglutinin Protein on Pathogenicity
The HA gene is the primary determinant of high pathogenicity in chickens, but a proper constellation of all eight gene segments is required for the maximal expression of virulence potential (36).

[1]Mechanisms: 1) substitutions of non-basic with basic amino acids; 2) insertions of multiple basic amino acids from codons duplicated from hemagglutinin cleavage site; 3) short inserts of basic and non-basic amino acids from unknown source; 4) non-homologous recombination with inserts which lengthen the proteolytic cleavage site; 5) loss of the shielding glycosylation site at residue 13.
[2]30 nucleotides from nucleoprotein of same virus gene coding 10 amino acid insert
[3]21 nucleotides from matrix of same virus gene coding 7 amino acid insert

In brief, the cleavage of the HA protein into the HA1 and HA2 proteins is essential for the virus to be infectious and produce multiple replication cycles. With LPAI viruses, only the trypsin-like proteases found in restricted anatomical sites, such as respiratory and intestinal epithelial cells or within secretions of the respiratory lumen, which are required to cleave the HA and thereby produce infectious virus, recognize the HA proteolytic cleavage site sequence. The HA proteolytic cleavage site of LPAI viruses has two non-consecutive basic amino acids at the carboxy-terminus of the HA1 and a glycosylation site at amino acid residue 13 that shields the proteolytic cleavage site. In contrast, H5 and H7 HPAI viruses have HA with a proteolytic cleavage site that is recognized and cleaved by ubiquitous furin proteases present in many cells of numerous visceral organs, the nervous system, and the cardiovascular system (268). Trypsin-like enzymes will also cleave the HA of HPAI viruses. These viruses have an altered HA proteolytic cleavage site structure at the carboxy-terminus of HA1 as compared to LPAI viruses (Table 6.6): 1) substitutions of non-basic with basic amino acids, 2) insertions of multiple basic amino acids from codons duplicated at the hemagglutinin cleavage site; 3) short inserts of basic and non-basic amino acids from unknown source; or 4) non-homologous recombination with inserts that lengthen the proteolytic cleavage site but which may or may not contain additional basic amino acids (Table 6.6) (48,101,126,211–213). In addition, loss of the shielding glycosylation site at residue Asn-11 may confer HP to some AI viruses if they have intermediate numbers of basic amino acids at the cleavage site (Table 6.6) (101,136).

In vitro tests have been used to predict pathogenicity potential and are based on structural variations in the proteolytic cleavage site of the hemagglutinin and its susceptibility to cleavage by different enzymes in various tissues. For example, the ability to pro-duce large plaques in tissue culture, such as chicken embryo fibroblast cultures, without trypsin supplementation correlates with furin cleavage of HA and HP in chickens in *in vivo* tests, but LPAI viruses require the addition of exogenous trypsin to cleave the HA and produce large plaques (36). Detection of a cleaved HA in tissue cell cultures without trypsin by radioimmunoprecipitation correlates with HP (238). All HP and LPAI viruses produce cleaved HA in embryonating chicken eggs. Detection of multiple basic amino acids at the HA proteolytic cleavage site correlates with HP or potential to become HP (292,341)

An issue separate from HA cleavability is receptor binding between the receptor-binding site of the HA and the receptor on the host cells. This is a poorly understood phenomenon but impacts both host specificity (host-adaption) and cell or tissue tropism within the host. This may restrict virus replication to specific cells, tissues, and organs. Changes in the receptor-binding site of the HA have been shown to change the host range of an influenza virus (191). Both the virus and host impact receptor binding.

Mechanisms of Cellular Pathobiology
Based on morphologic and biochemical evidence, AI viruses exert pathological effect on avian cells by two mechanisms: necrosis or apoptosis (118,231,277). Necrosis has been identified in many cell types including kidney tubule cells, pancreatic acinar epithelium, cardiac myocytes, adrenal cortical cells, and pulmonary epithelial cells in chickens (277). Necrosis has been associated with intense virus replication and demonstration of abundant AI viral nucleoprotein in the nucleus and cytoplasm (303). Apoptotic cell death has been demonstrated in various cell culture systems and involved several cytokines including interferon-beta and transforming growth factor-beta (118,231,232, 311). *In vivo*, apoptotic cell death has been identified most often

in lymphocytes, especially in the absence of direct AI viral replication (277). However, apoptosis has been demonstrated in neurons, respiratory epithelium, and pulmonary alveolar cells of mice infected with mouse-adapted influenza viruses (185,186). In chicken embryos, apoptosis and necrosis may share similar biochemical features and indicate that differentiation morphologically and biochemically between them is not always easy nor clear (93).

Pathobiology and Epidemiology

Incidence and Distribution

Avian influenza viruses have a worldwide distribution with reports of isolations from Africa, Asia, Australia, Europe, and North and South America and serologic evidence of infection in penguins from Antarctic (80,184,264,308). Proceedings of the International Symposia on Avian Influenza have tabulated LP and HPAI outbreaks and incidences since 1981 (22,78,79,287, 307,309).

The most frequent reports of AI viruses has been free-flying aquatic birds, especially of the orders *Anseriformes* (ducks and geese) and *Charadriiformes* (shorebirds, gulls, terns, and auks), which are considered the biological and genetic reservoirs of all AI viruses (265). In these species, AI virus infections usually have caused no disease (LPAI viruses) with the exception of high mortality in common terns of South Africa during 1961 and infections and mortality in a variety of wild birds with H5N1 HPAI virus that originated from Asia in 1996 (Table 6.3). Dabbling ducks, especially mallards (*Anas platyrhynchos*), have the highest reported isolation rates of AI viruses with up to 60% of juvenile ducks being infected prior to migration in the late summer (122). This frequency decreases during migration with the lowest rate (0.4–31%) being seen in ducks on the wintering grounds (267). However, the frequency of infection in native, nonmigratory ducks increases when migratory ducks arrive in the wintering grounds (113,267). The H3, H4, H6, N2, N6, and N8 subtypes have been dominant among AI viruses isolated from free-flying ducks (122,151,225,255,265). For shorebirds (Order: *Charadriiformes*), the greatest number of isolations have been in the spring with a second peak during the fall migration (134). The dominant AI virus subtypes have been H3, H9, H11, H13, N2, N4, N8, and N9 (104,134,151). However, most combinations of the 16 HA and 9 NA subtypes have been reported in free-flying aquatic birds. AI viruses are infrequently isolated from wild terrestrial birds because they occupy non-aquatic ecosystems that do not favor maintenance of AI viruses (265).

AI viruses have been isolated sporadically from domestic poultry, most frequently chickens, turkeys, and ducks and captive wild birds held as caged pets, or in quarantine stations, private collections/reserves, and zoological parks (5,7). However, incidence and distribution vary greatly with geographic region, species, age of bird, time of year, and the environmental or agricultural system occupied.

Turkeys and other gallinaceous birds (including chickens) are not natural reservoirs of AI viruses (213,278). Humans have altered the natural ecosystems of birds through captivity, domestication, industrial agriculture, national and international commerce and nontraditional raising practices (283). This has created new niches for AI viruses and variations in the incidence and distribution of AI infections. Five distinct man-made ecosystems have been identified that have impacted AI virus ecology (283): 1) integrated indoor commercial poultry; 2) range-raised commercial poultry; 3) live poultry markets (LPM); 4) village, backyard and hobby flocks; and 5) bird collection and trading systems. The frequency of AI infections within each system has varied. For example, in most integrated commercial poultry systems in developed countries, AI has been a rare occurrence considering the 25–30 billion chickens raised each year (324). However, when AI infections do occur, they sometimes spread rapidly throughout the integrated system from farm to farm resulting in epidemics of HP (Table 6.3) or LPAI. In commercial poultry, outbreaks have been most frequently reported in turkeys, slightly less frequently in laying chickens, and rarely in other domesticated poultry. A vaccination and controlled marketing strategy has reportedly eliminated H5N2 HPAI virus from Mexico, but H5N2 LPAI virus continues to circulate in commercial chickens of Mexico (330). In some developing countries of Asia and the Middle East during the middle to late 1990s, H9N2 LPAI became endemic in commercial chickens. Since 2003, H5N1 HPAI has become endemic in many Asian countries, being maintained in village or rural poultry, especially domestic ducks.

In Minnesota, influenza outbreaks in turkeys have been associated with range rearing and the introduction of AI viruses from migratory waterfowl (112). However, the number of farms with infected turkeys has varied from year to year with a minimum of two infected flocks in 1983 and peak infections of 141 (1978), 258 (1988), and 178 (1995) flocks (110). In 1998 the industry decided to eliminate range rearing of turkeys and as a result, only 33 flocks were infected from 1996 to 2000 and most were infected from H1N1 swine influenza (109). However, migratory waterfowl exposure alone does not adequately explain year-to-year variations in LPAI outbreaks in turkeys. Individual virus strain and the host species (chicken versus turkey) impact interspecies transmission of AI viruses from migratory waterfowl. For example, the H7N2 LPAI virus in Virginia during 2002 produced a higher proportion of affected turkey then chicken farms and, in experimental laboratory tests, this virus was more contagious for turkeys than chickens as evident by requiring 100–250 times less virus to infect turkeys than chickens (319).

Prior to the advent of modern vertically integrated commercial poultry systems in the 1950s combined with common use of refrigeration for storage and shipping, most meat and egg type stock were raised locally in backyard and hobby flocks or small commercial farms with immediate slaughter and consumption (103). Such small local production and slaughter still exist today as the LPM system in developed countries, but total production is dwarfed by the vertically integrated commercial system. In both developed and developing countries, village and rural poultry and LPM systems have some of the highest AI virus infection rates (245). Historically, poorly controlled movement and lack of biosecurity caused AI to become endemic in some poultry populations, especially between 1900–1930 in Europe and some areas

of Asia (273). The 1924–1925 HPAI outbreak in the United States occurred in a LPM-type system but was eliminated by depopulation before becoming endemic (152). Endemic HPAI disappeared from in Europe by the mid-1930s (11). Recent surveys of poultry in LPM of Hong Kong, New York, and other large cities have indicated LPAI viruses have become endemic in these agricultural systems (239,244,245,318,334). LPMs were the site of a 1997 H5N1 AI outbreak in Hong Kong and a 1997 H5N2 HD outbreak in Italy, and the LPM was most likely the source of HPAI viruses that caused the 1983–1984 outbreak in the United States (51,245,277,334). Low pathogenicity H7N2 AI has become endemic in poultry of the Northeast USA LPM (1993–2006), but since the implementation of a control program, the rate of infection has declined. These LPMs were the source of H7N2 LPAI that crossed over to infect 24 commercial poultry farms in Pennsylvania between 1996–1998, 7 farms in Pennsylvania during 2001–2002, 197 farms in Virginia during 2002, a large layer company in Connecticut during 2003, a small layer farm in Rhode Island during 2003, and 3 broiler farms in Delmarva during 2004 (3,76,87,235,276,288,358).

Most influenza infections in domestic poultry have been from avian-origin influenza viruses. However, H1N1, H1N2 and H3N2 swine influenza viruses have infected turkeys, especially turkey breeders, causing significant disease problems (80,181, 281,312),

Natural and Experimental Hosts

Avian influenza viruses have been shown to naturally infect a wide variety of wild and domestic birds, especially free-living birds occupying aquatic habitats. Some AI infections have involved wild terrestrial birds, but these birds do not represent a major source or reservoir of AI viruses (265). In brief, AI viruses have been isolated from more than 90 species of free-living birds representing 13 different orders: *Anseriformes* (ducks, geese, and swans), *Charadriiformes* (e.g., shorebirds [turnstones and sandpipers], gulls, terns, puffins, and guillemots), *Ciconiiformes* (herons and ibis), *Columbiformes* (doves), *Falconiformes* (raptors), *Galliformes* (partridge and pheasant), *Gaviiformes* (loons), *Gruiformes* (coots and moorhen), *Passeriformes* (perching birds—e.g., mynahs, finches, and weaverbirds), *Pelecaniformes* (cormorant), *Piciformes* (woodpecker), *Podicipediformes* (grebe), and *Procellariiformes* (shearwater) (5,7,13,174,266). This represents 61% of known avian species, but the actual number of naturally infected species is most likely much greater (7). Most AI infections have not produced recognizable disease in free-living birds.

In man-made ecosystems (agriculture, caged, hobby flocks, and exhibition systems), infections have been reported in *Psittaciformes* (parrots, cockatoos, and parakeets), *Casuariiformes* (emu), *Struthioniformes* (ostrich), *Rheiformes* (rhea), and most domesticated *Galliformes* and *Anseriformes*. The latter two groups include chickens, turkeys, Japanese quail (*Coturnix japonica*), helmeted guineafowl (*Numida meleagris*), bobwhite quail (*Colinus virginianus*), pheasants (various species), chukar partridges (*Alectoris chukar*), geese (*Anser anser domesticus*) and ducks (mallards [*Anas platyrhynchos domesticus*] and Muscovy [*Cairina moschata domesticus*]) (80). Birds of the or-

ders *Psittaciformes* probably are infected after capture and during mixing with infected birds at holding sites or in quarantine (80). Some infections of free-living *Passeriformes* (perching birds—starlings and sparrows) have been associated with outbreaks on poultry farms where they may have acquired infections from close contact with poultry (169,183).

Low pathogencity avian influenza viruses have caused epidemics of respiratory disease in mink, seals, and whales (45,88,102,116,158,172,337). Recently, the H5N1 HPAI virus has caused sporadic infections in tigers, leopards, house cats, Owston's palm civets, a stone martin and pigs (90). Most of these cases involved close contact or consumption of infected birds. A few cases of natural infections by AI viruses in humans have been reported (see "Public Health Significance").

In experimental studies, AI viruses have been shown to infect pigs, ferrets, rats, rabbits, guinea pigs, mice, cats, mink, nonhuman primates, and humans (33,80,82,120,142,246).

Transmission and Carriers

AI virus is excreted from the nares, mouth, conjunctiva, and cloaca of infected birds into the environment because of virus replication in the respiratory, intestinal, renal, and/or reproductive organs. In intranasally inoculated 3-to-4-week-old chickens, peak levels of HPAI virus recovery have been greatest from the oropharynx (swabs—$10^{4.2–7.7}$ EID$_{50}$/mL mean chicken embryo infective doses of respiratory secretions), and peak levels from the cloaca have been lower (swabs—$10^{2.5–4.5}$ EID$_{50}$/gm of feces) (291,297); LPAI viruses typically produce lower oropharynx (swabs—$10^{1.1–5.5}$ EID$_{50}$/mL) and cloacal (swabs—$10^{1.0–4.3}$ EID$_{50}$/mL) titers (291). With HPAI viruses, high virus levels in tissues of infected birds make consumption of carcasses through predation or cannibalism another source of virus transmission to susceptible birds. Titers in meat vary with virus strain, bird species and clinical stage of infection: 1) titers from dead chickens infected with 1983 H5N2 HPAI Pennsylvania virus had $10^{2.2–3.2}$ EID$_{50}$/gm of meat while 2003 H5N1 HPAI S. Korean virus had $10^{5.5–8.0}$ EID$_{50}$/gm of meat, and 2) H5N1 HPAI viruses produced different titers in clinically normal ($10^{2.0–3.4}$ EID$_{50}$/gm) or sick ($10^{4.0–6.0}$ EID$_{50}$/gm) domestic ducks (291,315).

The virus is transmitted by direct contact between infected and susceptible birds or indirect contact through aerosol droplets or exposure to virus-contaminated fomites (80). Aerosol generation from the respiratory tract is a significant mode of transmission because of high virus concentrations in the respiratory tract, but the large volume of lower concentration AI virus in infected feces makes fomites a major mode of transport. Thus, AI viruses are readily transported to other premises by people (contaminated shoes and clothing) and equipment shared in production, live-haul, or live-bird marketing (80).

Influenza viruses exhibit varying degrees of adaptation to individual host species with frequent and easy intraspecies transmission (283). However, interspecies transmission does occur, especially between closely related host species in the same taxonomic family, such as chickens, turkeys, guinea fowl, and quail of the order *Galliformes*, family *Phasianidae*. Interspecies transmission can occur across different orders within the same class

such as with free-flying duck-(Order: *Anseriformes*)-to-turkey (Order: *Galliformes*), but this is less frequent than occurs with closely related host species (283). Furthermore, interspecies transmission between different phylogenetic classes is even less frequent as has occurred rarely with chicken-to-human (283). One exception to the preceding rule has been the ease and frequency of transfer of swine H1N1 and H3N2 viruses to turkeys when the two species were raised in close geographic proximity (181,280,283,312). Obviously, many factors such as geographic restriction of host distribution, intermixing of species, age and density of birds, weather, and temperature also impacted the ability of the AI virus to move within and between host species and affected the overall incidence of infections (283).

Sources of infection for the initial introduction of the influenza virus into commercial poultry flocks (i.e., primary infections) include: 1) other domestic and confined poultry, 2) migratory waterfowl and other wild birds, 3) domestic pigs, and 4) companion or pet birds (5,7). The relative risk associated with each of these sources varies depending on the likelihood of direct or indirect contact with commercial poultry. First, the LPM system poses a significant risk to the introduction of LP and HPAI viruses into the commercial integrated poultry systems. Theoretically, transmission could occur by airborne dissemination as proposed in some AI outbreaks (69). However, high volume air sampling during the 1983–1984 H5N2 HPAI outbreak in the United States failed to yield influenza virus when samples were taken more than 45 meters downwind from an infected house (41). This suggests airborne transmission may have a limited role in most inter-flock dissemination of AI virus as compared to mechanical movement of fomites on equipment, clothing, or shoes (41). Especially high risk is movement of dead infected birds from farms through a shared rendering system or from the farm for burial without adequate sealing and decontamination of transport vehicles (37). Second, introduction of AI viruses (especially LPAI viruses) from wild birds, especially waterfowl, has been documented (112). The source is suspected to be contaminated feces from the ducks either through direct contact with poultry or indirectly through contamination of feed or water (121). The transmission potential of AI viruses from wild waterfowl emphasizes the need for producers of domestic, commercial poultry to provide separation between domestic and wild bird populations (80). Third, turkeys can be infected by introduction of H1N1, H1N2 or H3N2 and, potentially other subtypes of swine-origin influenza viruses, either by mechanical methods or potentially via humans infected with swine-origin influenza viruses (80). Fourth, AI viruses have been recovered from caged birds, usually during quarantine, but transmission for this source to poultry has not been documented as has occurred with Newcastle disease virus (80). To minimize the risk of introduction and dissemination of AI viruses, producers should raise only one species of bird in an individual operation, have an all-in-all-out production system, or add new birds only after testing and quarantine and practice high degree of biosecurity.

Secondary dissemination of AI viruses during an outbreak can be by mechanical transmission of virus on fomites, movement of infected poultry, or in some situations possibly airborne dissem-

ination,. Wild birds may play a major role in initial introduction of AI viruses in domestic poultry, but once established or adapted in commercial or LPM poultry, wild birds have had a very limited or no role in secondary dissemination (117,193). However, with the recent H5N1 HPAI viruses, wild birds have been infected and could serve a role in flock to flock spread in village or rural poultry systems.

Although horizontal transmission of AI viruses commonly occurs, proof of vertical transmission is lacking (80). However, HPAI virus infection of hens has resulted in virus recovery from the eggshell surface and the internal contents of the eggs (46). In experimental studies with HP H5N2 AI virus from Pennsylvania, most eggs laid on days 3 and 4 post-inoculation contained virus (28). However, AI viruses are embryo lethal, and hatching of internally contaminated eggs has never been demonstrated. Cleaning of fecal material and disinfection of eggshells may be necessary to prevent hatchery-associated dissemination of AI viruses. Most LPAI and HPAI viruses cause reduction or cessation, respectively, of egg production further limiting the potential for vertical transmission of AI virus.

Successful experimental routes of exposure include aerosol, intranasal, intrasinus, intratracheal, oral, conjunctival, intramuscular, intraperitoneal, intracaudal air sac, intravenous, cloacal, and intracranial administration of the various viruses (80).

In experimental studies, AI virus has been shown to replicate and be excreted from individual chickens for up to 36 days (304), and turkeys for up to 22 days (83,124). However, on a population basis, AI virus can be maintained for much longer time periods in agricultural operations or can re-emerge after a significantly stressful event. For example, a LP H7N2 AI virus in Pennsylvania during 1997–1998 was recovered from dead chickens collected from a layer flock with normal mortality six months after the initial AI infection on the farm and in another flock eight weeks after the induction of a molt (358). Once a flock is infected, it should be considered a potential source of virus for life. In wild waterfowl, AI viruses are maintained by passage in susceptible birds throughout the year, with peak prevalence in migratory waterfowl being in juvenile birds prior to fall migration (80). Prevalence of AI in migratory waterfowl AI is low as they arrive in the wintering grounds, but upon arrival, they infect susceptible resident waterfowl which go through their own cycle of infection (113,267). Thus, resident ducks contribute to the generation of virus during the winter and this source might reinfect migrating waterfowl prior to the spring migration.

Incubation Period
The incubation periods for the various diseases caused by these viruses range from as short as a few hours in intravenously inoculated birds to 3 days in naturally-infected individual birds and up to 14 days in a flock (80). In timed studies, intranasally inoculated chickens with H5N1 HPAI virus from Mongolia produced clinical signs within 24 hrs. The incubation period is dependent on the dose of virus, the route of exposure, the species exposed, and the ability to detect clinical signs (80). However, for international regulatory purposes, OIE recognizes 21 days as the

incubation period (199) where incubation period is defined as: the time from exposure to the onset of clinical signs, however this criteria may not be applicable to all AI viruses, especially LPAI viruses. Many infections by LPAI viruses do not cause clinical disease in all ages and all species of birds. "Infectious period", as defined as the time from exposure or detection of the virus to when the virus is no longer detected, may be more applicable for control and eradication purposes, especially in dealing with LPNAI viruses.

Clinical Signs

The pathotype of AI virus (LP or HP) has a major impact on the clinical manifestation of the disease. However, clinical signs of disease are extremely variable and depend on other factors including host species, age, sex, concurrent infections, acquired immunity, and environmental factors (80).

Low Pathogenicity Avian Influenza Viruses

Most infections by LPAI viruses in wild birds produce no clinical signs. However, in experimental studies in mallard ducks, LPAI virus infections suppressed T-cell function and produced a one week depression in egg production (163,164).

In domestic poultry (chickens and turkeys), clinical signs reflect abnormalities in the respiratory, digestive, urinary, and reproductive organs. The most frequent signs represent infection of the respiratory tract and include mild to severe respiratory signs such as coughing, sneezing, rales, rattles, and excessive lacrimation. In layers and breeders, hens may exhibit increased broodiness and decreased egg production. In addition, domestic poultry will exhibit generalized clinical signs including huddling, ruffled feathers, depression, decreased activity, lethargy, decreased feed and water consumption, and occasionally diarrhea. Emaciation has been reported but is infrequent because AI is an acute, not a chronic disease.

In ratites, LPAI viruses produced similar respiratory signs as with poultry and in some cases green diarrhea or "urine" (17,52, 131,173,202,205,295).

High Pathogenicity Avian Influenza Viruses

In wild birds and domestic ducks, most HPAI viruses either do not replicate or replicate to a limited degree and produce few clinical signs because of poor adaptation to non-gallinaceous species. There are two major exceptions to this rule: 1) the 1961 H5N3 HPAI outbreak in common terns in South Africa, which produced sudden death without any other clinical signs (35), and 2) some of the recent H5N1 HPAI viruses in wild birds and non-gallinaceous poultry produced mostly neurological signs, depression, anorexia and sudden death (167,320). Occasional sporadic, isolated cases of mortality have been reported in wild birds with HPAI viruses.

In domestic chickens, turkeys, and related galliformes, clinical signs reflect virus replication and damage to multiple visceral organs and cardiovascular and nervous systems. However, clinical manifestations vary depending on the extent of damage to specific organs and tissues (i.e., not all clinical signs are present in every bird). In most cases in chickens and turkeys, the disease is fulminating with some birds being found dead prior to observation of any clinical signs. If the disease is less fulminating and birds survive for 3–7 days, individual birds may exhibit nervous disorders such as tremors of head and neck, inability to stand, torticollis, opisthotonus, and other unusual positions of head and appendages. The poultry houses may be unusually quiet because of decreased activity and reduction in normal vocalizations of the birds. Depression is common as are significant declines in feed and water consumption. Precipitous drops in egg production occur in breeders and layers with typical declines including total cessation of egg production within six days. Respiratory signs are less prominent than with LPAI viruses but can include rales, sneezing, and coughing. Other galliforme birds have similar clinical signs but may live longer and have evidence of neurologic disorders such as paresis, paralysis, vestibular degradation (torticollis and nystagmus), and general behavior aberrations (216).

In ostriches (*Struthio camelus*), reduced activity and appetite, depression, ruffled feathers, sneezing, hemorrhagic diarrhea and open mouth breathing have been reported (47,52,63,64,173). In addition, some birds were uncoordinated, exhibited torticollis, and had paralysis of the wings and tremors of the head and neck.

Morbidity and Mortality

In chickens, turkeys, and related gallinaceous birds, morbidity and mortality rates are as variable as the signs and are dependent on virus pathogenicity and the host as well as age, environmental conditions, and concurrent infections (80). For the LPAI viruses, high morbidity and low mortality rates are typical. Mortality rates are usually less than 5% unless accompanied by secondary pathogens or if the disease is in young birds. For example, in the 1999 Italian H7N1 LPAI outbreak, mortality rates as high as 97% were observed in turkey poults less than 4 weeks of age when accompanied by secondary pathogens (48).

With the HPAI viruses, morbidity and mortality rates are very high (50–89%) and can reach 100% in some flocks. Typically, the virus spreads rapidly among poultry housed on the floor with peak mortality (70–100%) occurring in 3–5 days of first clinical signs, but in poultry housed in cages, the virus spreads slower through the house with peak mortality taking 10–15 days. With the H5N1 HPAI viruses, the mean death times in experimental studies (intranasal inoculation) are much shorter for chickens and turkeys than for other gallinaceous birds (219). In domestic ducks, the mortality from H5N1 HPAI viruses is dependent on virus strain and the age of the ducks. The H5N1 HPAI viruses from 1997–2001 did not cause illness or death in intranasally-inoculated ducks but many viruses from 2001–2006 caused varying mortality rates in 2–3 week old ducklings (60,60,167,274, 320). With specific viruses from Hong Kong in 2002, intranasal inoculation caused mortality, but in 5–6-week-old ducklings, either no deaths or low mortality was observed (299). This experimental variation based on age explains why mortality rates in domestic ducks and geese in the field have been low (247,355).

In ostriches, LP and HPAI viruses usually produce moderate morbidity and low mortality rates (47). Typically, the morbidity and mortality have been highest in young birds (<3 months) with mortality of 30% being seen (47), but mortality rates as high as

80% have been reported for LPAI viruses in chicks less than one month of age (17).

In wild birds, particularly waterfowl, neither LPAI or HPAI viruses usually produce mortality or morbidity. Occasionally, dead wild birds (passerines) have been identified on farms with HPAI outbreaks. High mortality was reported in the outbreak in South African terns during 1961. Mortality has been reported in a variety of wild birds associated with the recent H5N1 HPAI viruses in Asia, Africa and Europe. In some instances, the mortality has been sporadic involving individual birds such as pigeons (*Columbia livia*), or with some species such as swans and geese, large numbers of birds have died (61,86,247,336). Experimental studies have demonstrated great variation in the production of illness and death in wild birds, especially ducks (38,219). However, the exposure, morbidity and mortality rates are unknown since adequate surveys have not been conducted to determine the impact of H5N1 HPAI viruses on wild bird populations.

Pathology

Numerous reviews have been published on the pathology of AI virus (5,7,125,182,219,272,273). Details of field outbreaks and experimental studies have been published and are summarized in this section (2,22,31,47,48,50,52,66,80,82,132,145,146,152, 162–164,180,202,205,213,216–218,220,242,256,257,277, 282,289,295,296,301,303–306,308,320). The lesions in wild birds have been reported for some H5N1 HPAI viruses, but such information is beyond the scope of this chapter.

Gross

Gross lesions have been extremely variable with regard to their location and severity, depending greatly on the host species, pathogenicity of the infecting virus, and presence of secondary pathogens. Most frequently, descriptions of gross lesions have been provided for naturally occurring or experimental infections in chickens and turkeys. Until the late 1990s, few descriptions were available for other host species such as quail, ducks, geese and ratites.

Low Pathogenicity Avian Influenza Viruses. In gallinaceous poultry, the most frequent lesions are in the respiratory tract, especially sinuses, and are characterized as catarrhal, fibrinous, serofibrinous, mucopurulent, or fibrinopurulent inflammation. The tracheal mucosa can be edematous with congestion and occasionally hemorrhages. Tracheal exudates may vary from serous to caseous, with occasional occlusion of airways and resulting asphyxiation. Fibrinous to fibrinopurulent air sacculitis may be present. The fibrinopurulent inflammation usually is accompanied by secondary bacterial infections. The infraorbital sinuses may be swollen with mucous-to-mucopurulent nasal discharge. Fibrinopurulent bronchopneumonia can result when accompanied by secondary pathogens such as *Pasteurella multocida* or *Escherichia coli.*

Catarrhal to fibrinous inflammation may be noted in the air sacs and coelomic cavity ("peritoneal cavity"), and "egg yolk peritonitis" may be observed. Catarrhal to fibrinous enteritis may be observed in the ceca and/or intestine, especially in turkeys.

Inflammatory exudates may be found in the oviducts of laying birds, and the last few eggs laid will have reductions in calcium deposition within the eggshells. Resulting eggs may be misshapen and fragile with loss of pigmentation. Ovaries will undergo regression, beginning with hemorrhage in the large follicles and progressing to colliquation. The oviduct may be edematous and contain catarrhal to fibrinous luminal exudates before undergoing involution. In a few cases in laying hens and intravenous inoculated chickens, swollen kidneys occurred and were accompanied by visceral urate deposition ("visceral gout").

Sporadically, other lesions have been reported including firm pancreas with pale mottling and hemorrhage, usually in turkeys.

In domestic ducks and geese, LPAI viruses may produce lesions in the respiratory tract such as sinusitis, conjunctivitis, and other respiratory lesions. Co-infections with bacteria are common.

In rheas (*Rhea americana*) and emus (*Dromaius novaehollandiae*), LPAI virus infection produced ocular discharge; fibrinous sinusitis, tracheitis, and air sacculitis; interstitial pneumonia; congested visceral organs; hemorrhage in trachea; and occasional fibrinous perihepatitis and pericarditis.

Highly Pathogenic Avian Influenza Viruses. In gallinaceous poultry, HPAI produce a variety of edematous, hemorrhagic and necrotic lesions in visceral organs and the skin (see Fig. 6.2). Although, when death is peracute, no gross lesions may be observed. In chickens, swelling of the head, face, upper neck, and feet may be observed which results from subcutaneous edema and may be accompanied by petechial-to-ecchymotic hemorrhages. Periorbital edema may be seen. Necrotic foci, hemorrhage, and cyanosis of the non-feathered skin have been reported, especially wattles and combs. Lesions in visceral organs vary with virus strain but most consistently are represented by hemorrhages on serosal or mucosal surfaces and foci of necrosis within parenchyma of visceral organs. Especially prominent are hemorrhages on the epicardium, in pectoral muscles, and in mucosa of the proventriculus and ventriculus. With the H5N1 HPAI viruses, necrosis and hemorrhage in Peyer's patches of the small intestine were common as was reported with outbreaks of fowl plague in the early 1900s. In addition, these strains of HPAI viruses tend to produce more severe hemorrhage and edema in the lungs.

With most HPAI viruses, necrotic foci are common in pancreas, spleen, and heart, and occasionally in liver and kidney. The kidney lesions may be accompanied by urate deposits. Lungs have focal ventral to diffuse interstitial pneumonia with edema. The lungs can be congested or hemorrhagic. The cloacal bursa and thymus are usually atrophic.

In ostriches, HPAI viruses produced edema of head and neck, severe hemorrhagic enteritis, enlarged and firm pancreas, mild to severe air sacculitis, hepatitis, peritonitis, renomegaly, and splenomegaly.

Microscopic

Low Pathogenicity Avian Influenza Viruses. In poultry, LPAI viruses produce pneumonia varying in character from ventromedial, fibrinocellular-to-peribronchiolar lymphocytic. In severe cases, the pneumonia may be diffuse with air capillary edema.

Heterophilic to lymphocytic tracheitis and bronchitis have been common. On intravenous (IV) or intranasal inoculation and in field cases in chickens, nephrosis and nephritis have been reported. However, this renal tropism is virus-strain specific and most consistently produced with IV inoculation. In turkeys, experimental and natural cases of pancreatitis with acinar necrosis have been seen, especially with the 1999 Italian H7N1 AI virus. Pancreatitis is less common in chickens than turkeys. Birds that die from LPAI have lymphocyte depletion and necrosis or apoptosis of lymphocytes in the cloacal bursa, thymus, and spleen, whereas other tissues such as trachea and nasal cavity have lymphocyte accumulations. Viral antigen is rarely seen in lymphocytes but is commonly demonstrated in necrotic respiratory epithelium, renal tubule epithelium, and pancreatic acinar epithelium. The latter is primarily in IN inoculated chickens.

In rheas (*Rhea americana*), the LPAI viruses produce heterophilic to pyogranulomatous sinusitis, bronchitis, and pneumonia with necrosis of respiratory epithelium. In ostriches, lesions of splenic and hepatic necrosis, enteritis, and sinusitis were seen.

Highly Pathogenic Avian Influenza Viruses. Lesions in natural outbreaks have been reported and have been reproduced in experimental studies with chickens. Histologic lesions are most consistent in tissues having gross lesions. Specific histopathologic descriptions for experimental studies vary with individual viruses as a result of variations in inoculum doses, strain of chicken, route of inoculation, and passage history. Basically, the histologic lesions consist of multi-organ necrosis and/or inflammation. The most consistent and most severely affected tissues are brain, heart, lung, pancreas, and primary and secondary lymphoid organs. Lymphocytic meningoencephalitis with focal gliosis, neuronal necrosis, and neuronophagia are common, but edema and hemorrhage may be seen. Focal degeneration to multifocal-diffuse coagulative necrosis of cardiac myocytes has been reported, usually with accompanying lymphohistiocytic inflammation. Lesions in the brain and heart have abundant associated influenza virus proteins in neurons and myocytes, respectively. Other common lesions associated with AI virus replication include necrosis in skeletal myofibers, kidney tubules, vascular endothelial cells, corticotrophic cells of adrenal, and pancreatic acinar cells. If the birds survive for 3–5 days, the quantity of necrosis is reduced and the intensity of lymphohistiocytic inflammation is increased. In lymphoid tissue, necrosis, apoptosis, and depletion are common in cloacal bursa, thymus, and spleen, but AI viral antigen is rarely seen in lymphocytes. The lesions in respiratory tract vary widely from minimal to severe. The non-feathered skin contains numerous microthrombi within dermal and hypodermal capillaries and small blood vessels. This is accompanied by vasculitis, perivascular to generalized edema, subcutaneous edema, and necrosis of capillary endothelium. The epidermis has various stages of vesicle formation progressing to full-thickness necrosis.

In gallinaceous species other than chickens and turkeys, lesions are similar to above, but in general, since the birds survive longer than chickens or turkeys, the necrosis and inflammation are more common and prominent in tissues.

In ostriches, HPAI viruses produced coagulative necrosis in spleen, kidney, and liver. Fibrinoid necrosis was common in the arterioles of the brain and spleen. The pancreas had necrosis of acinar cells with mild mononuclear cell inflammation and fibrosis. Foci of malacia and neuronophagia were present in brains, and necrotic and hemorrhagic lesions were in the intestine.

Pathogenesis of the Infectious Process

First, in poultry, the process begins by inhalation or ingestion of infectious LP or HPAI virions. Because trypsin-like enzymes in respiratory and intestinal epithelial cells allow cleavage of the surface hemagglutinin, multiple replication cycles occur in respiratory and/or intestinal tracts with release of infectious virions. In gallinaceous poultry, the nasal cavity is a major site of initial replication.

Second, with HPAI viruses, after initial replication in respiratory epithelium, the virions invade the submucosa, entering capillaries. The virus replicates within endothelial cells and spreads via the vascular or lymphatic systems to infect and replicate in a variety of cell types in visceral organs, brain, and skin. Alternatively, the virus may become systemic before having extensive replication in vascular endothelial cells. The virus is present in the plasma, red and white blood cell fractions. Macrophages appear to play a role in systemic virus spread. The presence of a hemagglutinin proteolytic cleavage site that can be cut by ubiquitous furin-like cellular enzymes is responsible for this pantropic replication. Clinical signs and death are due to multiple organ failure. Damage caused by AI viruses is the result of one of four processes: 1) direct virus replication in cells, tissues, and organs; 2) indirect effects from production of cellular mediators such as cytokines; 3) ischemia from vascular thrombosis, and 4) cardiovascular collapse from coagulopathy or disseminated intravascular coagulation.

Third, for the LPAI viruses, replication usually is limited to the respiratory or intestinal tracts. Illness or death is most often from respiratory damage, especially if accompanied by secondary bacterial infections. Sporadically in some species, the LPAI viruses spread systemically, replicating and causing damage in kidney tubules, pancreatic acinar epithelium, oviduct and other organs with epithelial cells having trypsin-like enzymes.

Pathogenesis of the infection process is less well understood in non-gallinaceous birds.

Immunity

Active

Infection with AI viruses as well as immunization with vaccines elicits a humoral antibody response at both the systemic and mucosal levels (278). This includes a systemic IgM response by 5 days post-infection, followed shortly by an IgG response. The mucosal immune response is poorly characterized (278). The intensity of the antibody response varies with bird species (i.e., chickens > pheasant > turkeys > quail > ducks) (114,278). However, reports of serological response in ducks varies from poor antibody response and no hemagglutination inhibition (HI) antibodies (140,316) to 29.5% HI positive ducks on a farm near the 1992 H7N3 outbreak in Australia (344).

Antibodies against the surface proteins (HA and NA) are neu-

tralizing and protective (278). Protection has been primarily associated with antibodies directed against the HA protein. However, antibodies directed against either HA, NA, or both prevent clinical signs and death following challenge with HPAI viruses with homologous HA or NA subtypes. The level of protection against mucosal infection and subsequent shedding of challenge virus may depend on the degree of antigenic (or proteins sequence) similarity between HA of vaccine and challenge virus (293,297,300). Duration of protection is unknown, but in layers, protection against clinical signs and death has been demonstrated to at least 30 weeks following a single immunization (43). Birds that have recovered from field exposure are protected from the same HA and NA subtypes. Some birds, such as waterfowl, turkeys and long-lived chickens (layers and breeders) may require multiple vaccinations to maintain adequate protection.

Immune response against viral internal proteins has not been shown to prevent clinical signs or death but may shorten the period of virus replication and shedding (149). However, the mechanism of this limited protection is unknown but may be the result of cell-mediated immunity. A recent experimental study with inactivated H9N2 AI virus demonstrated short-term protection in chickens against HP H5N1 AI challenge virus, but immunization did not totally block virus replication in the digestive tract (240). Cell-mediated immunity was responsible for the protection.

Passive

Studies on protection by maternal antibodies to homologous HA or NA have not been reported, but based on evidence available for other avian pathogens, protection against clinical signs and death from homologous AI viral challenge is probable for the first two weeks after hatching.

Diagnosis

A definitive diagnosis of AI is established by 1) direct detection of AI viral proteins or genes in specimens such as tissues, swabs, cell cultures, or embryonating eggs; or 2) isolation and identification of AI virus. A presumptive diagnosis can be made by detecting antibodies to AI virus. During outbreaks of HPAI, mortality rates, clinical signs and lesions may be useful as part of the case definition in deciding which farms to quarantine and possibly for depopulation of birds for eradication purposes.

Sample Selection and Storage

Avian influenza viruses are commonly recovered from tracheal, oropharyngeal or cloacal swabs of either live or dead birds, because most HP and LPAI viruses replicate in the respiratory and intestinal tracts. The swabs should be placed in a sterile transport medium containing high levels of antibiotics to reduce bacterial growth (302). Tissues, secretions, or excretions from these tracts are appropriate for virus isolation or detection. Tissues can be collected and placed into sterile plastic tubes or bags. In the examination of organs for virus, efforts should be made to collect and store internal organs separately from the respiratory and intestinal tract tissues because isolation of virus from internal organs may be an indication of systematic spread and is most often

associated with the HPAI viruses. In the case of systemic infections produced by HPAI viruses, virtually every organ can yield virus because of the high levels of viremia or replication in parenchymal cells.

If the samples for virus detection can be tested within 48 hours after collection, they may be kept at 4°C; however, if the samples must be held for additional time, storage at –70°C is recommended. Before testing for virus, tissues should be ground as a 5–10% suspension in the transport medium and clarified by low-speed centrifugation.

Direct Detection of AI Viral Proteins or Nucleic Acids

The direct demonstration of influenza virus RNA or viral proteins in samples from animals is routinely used as a diagnostic screening test. Several commercial and laboratory specific antigen detection kits are available for detection of influenza A nucleoprotein and have been used to detect influenza viral antigen in avian specimens and allantoic fluid of inoculated embryonating chicken eggs (70,148,251,351). These antigen capture immunoassays vary in sensitivity with the best tests being 3–4 log less sensitive than virus isolation (351). Polyclonal and monoclonal antibodies are useful for localizing viral antigen in tissues by immunofluorescent or immunoperoxidase staining methods (250,256,328), and radiolabeled gene probes for *in situ* hybridization can locate cells involved in viral replication in tissues of infected birds (327). Reverse transcriptase polymerase chain reaction (RT-PCR) and real-time RT-PCR (RRT-PCR) methods have been developed and used in some laboratories for experimental studies and field case diagnosis of AI (3,262,354). The RRT-PCR has a 3 hour test time and a sensitivity and specificity comparable to virus isolation procedures (97). This technology has accelerated influenza diagnosis and field monitoring. In the USA, screening of tracheal or oropharyngeal samples is done using a matrix gene RRT-PCR test and if positive, the samples are tested with H5 and H7 subtype specific RRT-PCR tests (263)

Virus Isolation

Methods for the isolation and identification of influenza viruses have been described in detail (55,80,302). Chicken embryos, 9–11 days old, are inoculated via the allantoic cavity with approximately 0.2 mL of sample. In some cases, yolk sac inoculation has yielded viruses when allantoic cavity inoculation has failed (352).

The death of inoculated embryos within 24 hours after inoculation usually results from bacterial contamination or inoculation injury, and these eggs should be discarded. A few viruses may grow rapidly and kill the embryos by 48 hours; however, in most cases the embryos will not die before this time. After 72 hours, or at death, the eggs should be removed from the incubator, chilled, and allantoic fluids collected. The presence of virus is demonstrated by hemagglutinating activity using chicken erythrocytes, however the presence of NDV must be excluded.

Generally, if virus is present in a sample, there will be sufficient growth in the first passage to result in hemagglutination, and repeated passage is unnecessary. Repeated passage of samples increases the risk of cross-contamination in the laboratory.

Long-term storage of viruses should be done at –70°C or below. Lyophilization of viruses is also appropriate for long-term storage; however, these stocks should be tested periodically to ensure infectivity.

Virus Identification

Standardized methods for testing the egg fluids for the presence of hemagglutinating activity using chicken erythrocytes by macro- or micro-techniques are employed (58,80,302). Allantoic fluid positive for hemagglutination is used for virus identification.

It is important to determine whether the hemagglutinating activity detected in the allantoic fluid is due to influenza virus or other hemagglutinating viruses, such as paramyxoviruses like Newcastle disease virus (NDV). Thus, the isolate is tested in HI assays against Newcastle disease and other antiseram. If negative, the virus then is tested for the presence of the type A specific antigen to establish that an influenza A virus is present. The type-specific NP (nucleoprotein) or matrix protein may be detected by the double immunodiffusion test (26,74), the single-radial-hemolysis test (74) or commercial antigen capture immunoassay. Monoclonal antibodies that react with the nucleoprotein or matrix proteins have proven useful in identifying these antigens in ELISA (332).

The next step in the identification procedure is to determine the antigenic subtype of the surface antigens, HA and NA. The NA subtype is identified by a micro-NI assay with antisera prepared against the nine known NAs (204,302,329).

The HA is identified in the HI test (302) using a panel of polyclonal antisera prepared against whole virus representing the 16 distinct HA subtypes. Subtyping is facilitated by using antisera against the HA alone (i.e not the whole virus) or against reassortant viruses with heterologous NAs; this helps avoid steric inhibition due to antibodies against the NA (137,139). An influenza virus with a new HA would not be detected in tests using antisera to the known HA subtypes. Therefore, it is essential to confirm that the unknown hemagglutinating agent is an influenza virus using the type-specific test described previously.

Final identification is most commonly accomplished by state, federal, or OIE influenza reference laboratories.

Serology

Serologic tests are used to demonstrate the presence of AI-specific antibodies, which may be detected as early as seven days after infection. Several techniques are used for serologic surveillance and diagnosis. In serologic surveillance programs, a double immunodiffusion test (agar gel immunodiffusion or AGID) for the detection of anti-NP antibody is frequently used, because this detects antibodies to type A-specific antigens shared by all influenza A viruses. ELISA assays have been developed to detect antibodies to AI viruses (1,34,92,179,241,259,357). ELISAs are commercially available for detecting antibody to influenza from chickens and turkeys. Once influenza is detected by immunodiffusion or ELISA, HI tests can be used to determine the HA subtype.

In serologic assays, be aware that there is considerable variation in the immune response among the various avian species.

For example, antibodies to the NP are generally prominent in turkeys and pheasants but may be undetectable in ducks known to have been infected (253). In addition, antibodies may be induced in ducks, as well as other species, which fail to be detected in conventional HI tests performed with intact virus (141,171).

The sera of many species contain nonspecific inhibitors that may interfere with the specificity of the HI and other tests. Because these inhibitors are especially active against certain viruses, they present a very practical problem in serologic testing and the identification of viruses. Therefore, sera should be treated to reduce or destroy such activity, although it should be recognized that some treatments may lower specific antibody levels. The two most commonly used treatments for these inhibitors have been receptor destroying enzyme (RDE) and potassium periodate (58,74). In addition to the non-specific inhibitors of hemagglutination, sera from other bird species, such as turkey and goose, may cause non-specific agglutination of the chicken erythrocytes used in the HI test. This may mask low levels of HI activity. Such hemagglutinating activity can be removed by pretreatment of the serum with chicken erythrocytes (192). This problem may sometimes be avoided by using erythrocytes in the HI test of the same species as the serum being tested.

Differential Diagnosis

Because of the broad spectrum of signs and lesions reported with infections by AI viruses in several species, a definitive diagnosis must be made by virologic and serologic methods. For HPAI viruses, other causes of high mortality must be excluded such as Newcastle disease, septicemic fowl cholera, heat exhaustion, water deprivation and some toxins. For LPAI viruses, other causes of respiratory disease and drops in egg production must be investigated such as lentogenic Newcastle disease virus, avian pneumovirus and other paramyxoviruses, infectious laryngotracheitis, infectious bronchitis, chlamydia, mycoplasma, and various bacteria. Concurrent infections with other viruses or other bacteria have been commonly observed (80).

Intervention Strategies

Management Procedures

There are three different goals or outcomes in the control of AI: 1) prevention, 2) management, and 3) eradication (284). These outcomes are accomplished based on strategies using combinations of five specific components: 1) education, 2) biosecurity, 3) diagnostics and surveillance, 4) elimination of infected poultry, and 5) decreasing host susceptibility. How effective each strategy is at controlling AI is dependent upon how many of the five components are used and how thoroughly they are practiced in the field. The goals for individual LPAI and HPAI control strategies may be different depending on the country, subtype of the virus, economic situation and risk to public health.

There is no single control strategy for AI. In most developed countries, HPAI outbreaks have been eradicated within six months to a year by traditional stamping-out programs, but in some developing countries, the lack of indemnities, poor veteri-

nary infrastructure and high level of poultry production at the village or rural level, have made immediate eradication unachievable. In these situations, management of the disease to a low infection rate has been a realistic option. By comparison, control of LPAI has varied greatly among individual countries, and even between states and provinces within a single country (288). Notably good control programs have emerged from Minnesota (106, 221) and Pennsylvania (41) which have been successful in eradicating LPAI viruses on multiple occasions. Recommendations and responsibilities for containing influenza outbreaks have been described (92). The Minnesota plan has been the model for many other state plans and has five components: education, preventing exposure, monitoring, reporting, and a "responsible response" (221). The designation of H5 and H7 LPAI as LPNAI has increased the use of stamping out programs in dealing with these two AI subtypes as a means to prevent emergence of HPAI viruses. Historically HPAI viruses have emerged after LPAI H5 or H7 viruses circulated widely in susceptible poultry for several months.

Education

One critical aspect in control is the education of all poultry and allied industry personnel regarding how the viruses are introduced, how they spread, and how such events can be prevented. An individual's control of risky behaviors greatly reduces the spread of AI virus by controlling fomite or aerosol movement of the virus thus preventing AI virus movement on the farm and between farms.

Biosecurity

Biosecurity is the first line of defense (see Chapter 1) and is practiced as inclusion biosecurity, such as quarantine, to keep the virus on infected premises and exclusion biosecurity to keep the virus off of virus free premises. The most likely source of virus for poultry is other infected birds, so the basic means for the prevention of infection of poultry with influenza viruses is the separation of susceptible birds from infected birds and their secretions and excretions. Transmission can occur when susceptible and infected birds are in close contact or when infectious material from infected birds is introduced into the environment of susceptible birds. Such introductions are associated with the movement of cages, equipment, footwear and clothing, vehicles, insemination equipment, etc. The presence of virus in fecal material and respiratory secretions is a likely means for movement of the virus either by ingestion, contact with mucous membranes, or inhalation. Contaminated poultry manure is a high risk source for virus transmission between flocks. Certain things have been identified that contribute to spread after AI has been introduced into commercial flocks: unclean moving equipment and crews, partial flock marketing, marketing an actively infected flock, shared rendering pick-up of daily mortality, moving the birds, and inadequate cleaning and disinfection (106). Poultry raised outdoors or that have outdoor access have been infected following exposure to wild birds, primarily to infected ducks and shorebirds. In some countries, LPM and village poultry are an important reservoir of influenza virus and pose a risk for introduction to commercial poultry if adequate biosecurity is not practiced.

Swine may serve as a source of H1 and H3 swine influenza viruses to turkeys where the virus is transmitted mechanically or by infected pigs (80).

All biosecurity practices limit spread of influenza by preventing contamination; controlling the movement of birds or their products, people, and equipment; or reducing the amount of the virus (e.g., cleaning and disinfection) (106). Persons who have direct contact with birds or their manure have been the cause of most virus transmission events between houses or premises, but airborne transmission has served as a source to some farms in association with certain depopulation and cleaning activities during the peak of infection (37,69,233). Equipment that comes in direct contact with birds or their manure should not be moved from farm to farm without adequate cleaning and disinfection, and it is important to keep the traffic area near the poultry house free from contamination by manure. Visitors on farms should not be allowed or should be strictly controlled with mandatory disinfection of footwear and cleaning of clothing. Farm-to-farm spread of influenza virus must first be brought under control before the disease can be eradicated.

Special biosecurity procedures must be used when depopulating or marketing infected or dangerous-contact flocks, including re-routing trucks from infected farms away from other poultry farms and the sealing, cleaning, and disinfection of depopulation trucks before they leave farms. In addition, special biosecure practices are needed in repopulating within an infected zone or compartment during the recovery phase to prevent resurgence of the virus.

Diagnostics and Surveillance

Accurate and rapid diagnosis of AI is a prerequisite to early and successful control. The speed with which AI is controlled is largely dependent upon how rapid the first case or cases are detected, the existing biosecurity, and how quickly control strategies are implemented, especially if eradication is the goal. Passive surveillance is critical to differentiate LPAI virus as the cause of respiratory disease or drops in egg production from causes of endemic diseases with similar signs. Similarly, HPAI virus must be differentiated from other causes of high mortality events. Active surveillance is essential to determine where the virus is located within a country, zone, or compartment and can best be accomplished through either serological testing of birds for antibodies and/or random testing of daily mortality for the presence of AI virus. Surveillance is also crucial for on-going evaluation of the success of control strategies and for use in decision making as a prelude to improving control strategies. Serological testing has been used to certify a country, zone, or compartment as AI free, or during an AI outbreak to determine the extent of the infected zone for quarantine purposes.

Elimination of Infected Poultry

After identification of infected flocks, elimination of infected flocks, their eggs, and manure is essential to preventing future transmission. For HPAI, this has been typically accomplished through depopulation and disposal of carcasses, eggs, and manure by an environmentally sound method such as composting,

incineration, rendering, or landfill burial. For LPAI, orderly marketing of birds after recovery from infection has been an acceptable means for elimination, and eggs have been marketed if properly cleaned. Most influenza virus shedding occurs during the first 2 weeks of infection and usually by 4 weeks after the initiation of the infection, virus cannot be detected by sampling. Sero-positive flocks have not been associated with a high risk of transmission if maintained under biosecure practices. However, there should be no contact with recovered flocks because the length of time birds within a population shed virus is not clearly defined. Because the economic losses due to influenza may be severe, the control program should not unnecessarily penalize the growers. Indemnities by federal governments may be necessary for control and eradication of both HPNAI and LPNAI.

Decreasing Host Susceptibility

If poultry are at risk to AI virus exposure, increasing the resistance of birds to infection may be necessary to break the infection cycle. Theoretically, this can be achieved by genetic selection for resistant bird strains or breeds, but to date, only minor chicken breed resistant to LPAI virus has been identified and scientifically verified (301). Another method to increase resistance is through active or passive immunity to the AI viral hemagglutinin or neuraminidase proteins. This is predominantly done through vaccination, but antibody and immune cell transfer can be protective.

Vaccination

Various vaccine technologies have been developed in the laboratory and have shown efficacy in experimental studies, in mostly chickens and turkeys, to provide protection from LPAI and HPAI viruses (284). The most frequently licensed AI vaccine technology has been inactivated whole AI virus vaccines, typically made using LPAI field outbreak strains, and more recently reverse genetic generated AI vaccine strains, followed by chemical inactivation and oil emulsification (285). These vaccines have been used in a variety of poultry and other avian species, and their effectiveness in preventing clinical signs and mortality is well documented. However, protection is virus-subtype specific. Birds are susceptible to infection with influenza viruses belonging to any of the 16 hemagglutinin subtypes, and there is no way to predict their exposure to any particular subtype. It is not practical to use preventive vaccination against all possible subtypes. However, if a particular hemagglutinin subtype is at risk for introduction or after an outbreak occurs and the hemagglutinin subtype of the virus is identified, vaccination may be a useful tool in a control program (111). At this time, there is no substantive data to indicate vaccines based on conserved AI proteins (such as nucleoprotein, matrix proteins, or polymerase proteins) will provide any practical field protection.

Inactivated H5 and H7 AI vaccines, including those in the USDA Vaccine Bank, and a fowl pox-AI hemagglutinin (H5) recombinant vaccine (rFP-AI-H5) are licensed in the United States for potential emergency use in future HPAI or LPNAI eradication efforts. In addition, a conditional license has been granted for other LPAI viral hemagglutinin subtypes (non-H5 and non-H7) of

inactivated AI vaccines for limited use, particularly in turkeys (111,175). Numerous experimental studies (15,20,40,43,44,133, 140,270,271,338,350) have demonstrated that AI vaccines can induce antibody and provide protection against mortality, morbidity, and declines in egg production. In addition, properly administered vaccines increase resistance to AI virus infection, reduce the number of birds shedding virus, greatly reduce the titer of challenge virus shed, and prevent contact transmission. Carefully controlled use of vaccines in a H5 and H7 LPNAI outbreak may delay and reduce the chance of the emergence of HPAI viruses. Most frequently, inactivated vaccines are administered prior to anticipated exposure by subcutaneous administration. Chickens can be immunized successfully by the *in ovo* administration of inactivated oil emulsion vaccine (269). The rFP-AI-H5 vaccine is given by subcutaneous or wing web inoculation at 1 day post-hatch in chickens only. The rFP-AI-H5 vaccines cannot be used in chickens that have received a prior pox virus vaccine or have been infected by a field strain of fowl pox virus or AI protection will be inconsistent (294). In the case of many LPAI outbreaks in the United States, producers have been allowed to use USDA licensed inactivated AI vaccines following state veterinarian approval. The limitation of vaccination in this situation is that serologic surveillance is impeded, and viral infection can occur and persist in the absence of disease. However, circulation of natural infection with LPAI viruses in a poultry industry can also impede detection of HPAI infected flocks. To counter the problem, surveillance must be designed and used to identify infected birds within a vaccinated population (i.e., DIVA strategy). One method is surveillance for active infection by detection of AI virus among the daily mortality using antigen capture immunoassay or RRT-PCR. Another method is serological surveillance for antibodies in vaccinated flocks either using routine serological tests (AGID, ELISA, or HI) in non-vaccinated sentinel birds or use of appropriate serological tests for vaccinated birds. For example, with birds vaccinated with an inactivated vaccine, detection of antibodies to the NS1 protein (321) may be used, or if using a heterologous NA vaccine, detection of anti-NA antibodies against the NA of the field AI virus (53) is indicative of infection in vaccinated birds. If using recombinant vaccines with only the AI virus hemagglutinin (such as rFP-AI-H5), detection of antibodies against AI virus NP or M proteins (AGID or ELISA) indicates infection in vaccinated chickens. Vaccinated flocks cannot be considered influenza virus-free without adequate surveillance. Vaccinated flocks must be identified and monitored for the presence of AI virus until slaughtered.

Additional considerations that influence decisions on vaccination for H5 or H7 LPNAI viruses have been discussed (27,107, 108). Previously, the lack of a government indemnity program for LPNAI resulted in some industry segments (e.g., egg layers) being subject to severe economic damage from LPNAI virus. By withholding vaccine availability, regulatory agencies have provided the producer with an incentive to intentionally expose his/her flock to reduce the economic impact of LPNAI on egg production or air sac condemnations. Intentional exposure is likely to contribute to the spread of the disease. Controlled, effective vaccine use will reduce the population of susceptible poultry

and reduce the quantity of virus shed if infection occurs. Recent examples where inactivated H5 or H7 vaccine has been used as an aid in controlling LPNAI include Minnesota (108,288), Utah (98,110), Italy (89), and Connecticut (288). A national U.S. program for control of H5 and H7 LPNAI has been approved under the National Poultry Improvement Plan. This plan provides for indemnities, surveillance guidelines, federal-state-industry partnership and the ability to use vaccines under appropriate conditions (http://www.aphis.usda.gov/vs/npip/, lpai_interim_final_rule[1].pdf).

Approaches to AI vaccines, which are alternatives to the use of inactivated virus and rFP-AI-H5 vaccines, are the use of other vectored vaccines (Rous sarcoma virus, vaccinia, infectious laryngotracheitis, Venezuelan equine encephalitis virus, and adenoviruses) or DNA vaccines incorporating hemagglutinin genes, which have provided protection (32,59,71,100,127,154, 189,224,285,317). These different experimental approaches have been used successfully to immunize and protect birds. Hemagglutinin-based vaccines have been shown to provide protection against a broad array of homologous hemagglutinin subtype viruses (147,293,297). Recently developed vaccine technologies show promise for application by mass immunizing methods that are not possible with current AI vaccine technology, such as Newcastle disease virus vectored AI hemagglutinin vaccine (206,285,310), AI-NDV chimera vaccine (206), and others. Recently, NDV-AI-H5 vectored vaccines have been licensed for use in China and Mexico. These vaccines provide dual protection against ND and AI, but, similar to the pox vectored vaccine, preexisting immunity to ND might interfere with AI protection.

It is clear that opportunities to develop a variety of effective vaccines exist. The ensuing debate (27) centers on the role they should play in controlling influenza viruses of varying pathogenicity in different domestic bird populations in different geographic regions. Based on the multitude of influenza A viruses in wild bird populations, it is reasonable to expect that these viruses will continue to cause serious disease problems when introduced into the LPM, rural or village poultry, and commercial poultry industries. Therefore, judicious use of vaccines may be appropriate to reduce influenza transmission and decrease susceptibility of poultry to the viruses, so eradication methods can be implemented before the disease spreads and becomes endemic.

Treatment

Presently, no practical, specific treatment exists for AI virus infections in commercial poultry. Amantadine has been shown experimentally to be effective in reducing mortality (29,73,80, 159,339), but the drug is not approved for food animals, and its use rapidly gives rise to amantadine-resistant viruses. Supportive care and antibiotic treatment have been employed to reduce the effects of concurrent bacterial infections. The use of human anti-influenza drugs is strongly discouraged.

Chapter 7
Infectious Bursal Disease

N. Eterradossi and Y. M. Saif

This chapter is an updated version of the chapter originally authored by Drs. Phil D. Lukert and Y. M Saif for the 11th edition of *Diseases of Poultry*.

Introduction

Infectious bursal disease (IBD) is an acute, highly contagious viral infection of young chickens that has lymphoid tissue as its primary target with a special predilection for the bursa of Fabricius (cloacal bursa). It was first recognized as a specific disease entity by Cosgrove (42) in 1962 and was referred to as "avian nephrosis" because of the extreme kidney damage found in birds that succumbed to infection. Since the first outbreaks occurred in the area of Gumboro, Delaware, "Gumboro disease" was a synonym for this disease and is still frequently used. The economic importance of this disease is manifested in two ways. First, some virus strains may cause up to 20% or more mortality in chickens 3 weeks of age and older. The second, and more important, manifestation is a severe, prolonged immunosuppression of chickens infected at an early age. Sequelae that have been associated with immunosuppression induced by the virus include gangrenous dermatitis, inclusion body hepatitis-anemia syndrome, *E. coli* infections, and vaccination failures. Protection of young chicks from early infection is paramount, and this is usually accomplished by transfer of maternal antibodies to the newly hatched chick. The virus does not affect man and has no public health significance.

History

Early studies to identify the etiologic agent of IBD (avian nephrosis) were clouded by the presence of infectious bronchitis virus in the kidneys of field cases. Winterfield and Hitchner (290) described a virus isolate (Gray) that came from a field case of nephrosis not unlike the newly reported syndrome. Because of the similarity between kidney lesions induced by Gray virus and those seen in avian nephrosis as described by Cosgrove (42), it was believed that Gray virus was the causative agent. Later studies, however, revealed that birds immune to Gray virus could still be infected with the IBD agent and would develop changes in the cloacal bursa specific for the disease. In subsequent studies with IBD, Winterfield *et al.* (291) succeeded in isolating an agent in embryonating eggs. The mortality pattern was irregular, and the agent was difficult to maintain in serial passage. The isolate was referred to as "infectious bursal agent" and was identified as the true cause of IBD; Gray virus was identified as an isolate of infectious bronchitis virus with nephropathogenic tendencies. Hitchner (97) subsequently proposed the term *infectious bursal disease* as the name of the disease causing specific pathognomonic lesions of the cloacal bursa.

In 1972, Allan *et al.* (6) reported that IBD virus (IBDV) infections at an early age were immunosuppressive. The recognition of the immunosuppressive capability of IBDV infections greatly increased the interest in the control of these infections. The existence of a second serotype was reported in 1980 (166). Control of IBD viral infections has been complicated by the recognition of "variant" strains of serotype 1 IBDV, which were found in the Delmarva poultry producing area (220, 227). These strains were breaking through maternal immunity against "standard" strains, and they also differed from standard strains in their biological properties (224, 225). These variants, or subtypes, were either already present in nature but unrecognized or were new mutants that have arisen, possibly due to immune pressure. In the late 1980s, very virulent strains of IBDV (vvIBDV) were isolated in the Netherlands (32), and these strains quickly spread to Africa, Asia, and more recently to South America (52). The vvIBDV strains were not reported from Australia, New Zealand, or the United States.

Etiology
Classification
Infectious bursal disease virus is a member of the *Birnaviridae* family (26, 55, 177). The family has 3 genera designated *Aquabirnavirus* whose type species is infectious pancreatic necrosis virus (IPNV), which infects fish, molluscs, and crustaceans; *Avibirnavirus* whose type species is IBDV, which infects birds; and *Entomobirnavirus* whose type species is Drosophila X virus, which infects insects (51). Viruses in that family have genomes consisting of 2 segments of double-stranded RNA (dsRNA) (157, 177, 254), hence the name *birnaviruses*. Before the recognition of the *Birnaviridae* family and before there was adequate information on its morphology and physicochemical characteristics, IBDV was placed at times in the *Picornaviridae* (39, 155) or *Reoviridae* families (83, 133, 151, 205).

Morphology
The virus is a single-shelled, non-enveloped virion with icosahedral symmetry and a diameter varying from 55–65 nm (94, 191, 200) (see Fig. 7.1).
7.1. Electron micrograph of negatively stained infectious bursal disease (IBD) viral particles. ×200,000.

Buoyant density of complete particles in cesium chloride gradients has been reported to range from 1.31–1.34 g/mL (15, 64, 115, 175, 191, 205, 264). Lower density values were reported for incomplete virus particles.

The capsid symmetry is askew, with a triangulation number of T = 13. Once believed to have a capsid with a dextro-handed symmetry (200), IBDV has been shown in recent structural studies to have a typical *laevo* icosahedral geometry (43, 214).

Chemical Composition

The dsRNA of the IBDV genome has two segments designated A and B (15, 55, 116, 177) as shown by polyacrylamide gel electrophoresis. It was reported that the two segments of 5 serotype 1 viruses migrated similarly when co-electrophoresed. The RNA segments from serotype 2 viruses migrated similarly, but differed from serotype 1 viruses when co-electrophoresed (16, 116).

Five viral proteins designated VP1, VP2, VP3, VP4, and VP5 are recognized (15, 53, 55, 182, 191, 264). The approximate molecular weights of the 5 proteins are 97 kD, 41 kD, 32 kD, 28 kD, and 21 kD, respectively. Additional proteins, such as VPX or pVP2, have been observed and have a precursor-product relationship (53). Becht *et al.* (16) compared isolates of serotypes 1 and 2 and reported viral proteins with molecular weights in the same range as those observed by Jackwood *et al.* and Kibenge *et al.* (116, 129). It was not possible to differentiate between strains of serotype 1 viruses based on differences in structural proteins (270). VP2 and VP3 are the major structural proteins of IBDV. In serotype 1 viruses, they constitute 51% and 40% of the virus proteins, respectively (55); whereas VP1 (3%) and VP4 (6%) are minor proteins. However, the exact amount of VP4 in purified IBDV particles is not known precisely, as it was later shown that VP4 is mainly a nonstructural protein that may be copurified with virus particles in cesium chloride gradients because it forms in infected cells type II tubules with the same buoyant density as mature virions (80). In addition to the structural viral proteins, mature virus particles also harbor at their surface four small peptides that are formed when VP2 is progressively matured (47).

VP1 is the viral RNA dependent RNA polymerase (RdRp) and exhibits an original organization as compared with other viral RdRps (77, 282). It is present in virus capsids both as a genome-linked and as a free protein (176). VP2 is the main capsid protein. It forms trimers which are the basic units of the virus shell, the crystal structure of which has been recently determined with a 7 Å resolution (43). VP3, the other major structural protein, interacts with itself, VP2, VP1, and the viral genome, thus playing a critical role in both virion morphogenesis and encapsidation (34, 146, 257). VP3 is most likely not exposed at the surface of the virion, as suggested by the fact that VP2 alone accounts for the capsid crystal structure, but is rather located inside the virus particle in an unordered position—hence undetected by X-ray cristallography (43). VP4 is a viral protease (103, 187) that exhibits an unusual Ser-Lys catalytic dyad (24, 140). VP4 plays a major role in the maturation of capsid protein VP2, by progressively trimming several peptides at the VP2 carboxy-terminal extremity during virus assembly (140). The crystal structure of a birnavirus protease has been recently determined in blotched snakehead virus (69). VP5 has no clearly established function, but it was suggested that it might have a regulatory function playing a role in virus release and dissemination, as well as an anti-apoptotic function at the early stages of infection (144, 147, 184). Two of the peptides that arise from the maturation process of pVP2 are crucial determinants that control the geometry of the virion assembly process (33, 47). One of these peptides also has a destabilizing effect on cellular membranes and has been proposed to be involved, after IBDV particles are bound to their cellular receptor, in the process of virus translocation across the cytoplasmic membrane (33, 47).

The small segment of the IBDV genome (B, approximately 2.9 kbp) codes for VP1, whereas the large segment (A, approximately 3.3 kbp) encodes the VP5 protein and, in another and partially overlapping reading frame, a 110 kDa polyprotein that will yield VP2, VP4, and VP3 upon co-translational cleavage by VP4 (9, 103, 173). A high degree of sequence homology was reported between the pathogenic serotype 1 and the non-pathogenic serotype 2 viruses in the coding region of segment B; whereas lower sequence identities were observed in the coding region of segment A of serotypes 1 and 2 viruses (186). In both genome segments, the coding regions are flanked by short 5′ and 3′ untranslated regions (79 to 111 nucleotide long) (181). The secondary structure of the 3′ untranslated region appears to be critical for an efficient replication (19).

The molecular basis for IBDV antigenicity is now better understood. The VP2 and VP3 proteins were identified in western-

blotting experiments with convalescent sera as important IBDV-derived antigens (64).

VP3 was first believed to represent IBDV major immunogen (65). However, although anti-VP3 neutralizing monoclonal antibodies have been occasionally described (217, 285), it was subsequently shown that VP3 mostly elicits non-neutralizing and non-protective antibodies (16, 67) whereas VP2 is an essential immunogen of IBDV (16, 66). Up to four VP3-located antigenic domains have been identified (122, 159, 198, 300). All contain epitopes common to both serotypes (group-specific epitopes), whereas two of these domains also contain serotype-specific epitopes (159).

Two antigenic domains were also identified in the VP2/pVP2 protein (10). One domain is conformation-independent, located at the carboxy-terminal end of VP2/VPX and elicits non-neutralizing monoclonal antibodies (10, 16, 67). Some of the VP2-specific non-neutralizing epitopes are group-specific (16), whereas others appear to be strain specific (279). The other major VP2 antigenic domain is conformation-dependent, is encoded by the AccI-SpeI fragment (mid-third) of the VP2 gene (10), and mainly groups serotype- or strain-specific epitopes that elicit neutralizing and passively protective antibodies (67, 250). This general pattern is not absolute, though, as Snyder et al. reported an anti-VP2 monoclonal antibody that neutralized both serotypes (248, 250). The largest panels of neutralizing monoclonal antibodies (60, 67, 250, 276, 300) detect as many as 6 VP2-located neutralizing epitopes, which co-locate in at least three overlapping antigenic sites. Comparison of the amino acid sequences of several IBDV strains showed that most amino acid changes were encoded within the AccI-SpeI region; this VP2 region has been known since as "VP2 variable domain" (14). Further analysis of IBDV strains with different Mab reactivities identified hot-spots for antigenically significant amino acid changes (61, 89, 137, 229, 272, 276). These are located within stretches of hydrophilic amino acids in the VP2 sequence: aa 212–224 and 314–324 are known as "VP2 major hydrophilic peaks" or "hydrophilic peaks A and B," respectively (229), whereas aa 248–252 and 279–290 are designated as "VP2 minor hydrophilic peaks 1 and 2," respectively (276). Recent structural studies demonstrated these amino acids to be located in the most exposed part of VP2 and to be displayed at the most external surface of the virus particle (43).

The molecular basis for pathogenicity of the virus has not been determined. The development of a reverse genetics system by Mundt and Vakharia (185) made it possible to manipulate the virus allowing for a better understanding of the molecular basis of important biologic activities of the virus. Using this approach, segment A was demonstrated to form the genetic basis for bursal tropism in serotype 1 IBDV (305). A genetically engineered chimeric virus expressing the VP2 gene of a vvIBDV within the genetic context of a classical serotype 1 virus was also shown not to exhibit the very virulent phenotype, thus demonstrating that VP2 is not the sole determinant of virulence (20). Some epidemiological and experimental studies further suggested that both genome segments might be required for the expression of the vvIBDV phenotype (22, 99, 105, 141, 143). It has been suggested

that reassortment phenomena might be involved in the emergence of vvIBDV (27, 99).

The chemistry of the virus was reviewed some years ago by Kibenge et al. (127).

Virus Replication

Kibenge et al. (127) and Nagarajan and Kibenge (186) reviewed this subject some years ago. Some progress has been made in the understanding of the biochemical events associated with replication of birnaviruses. Several laboratory hosts for IBDV are described later in this chapter. The virus was shown to attach to chicken embryo kidney cells maximally 75 minutes after inoculation (151). The multiplication cycle in chicken embryo cells is 10–36 hours, and the latent period is 4–6 hours (15, 116, 151, 191). In Vero and BGM-70 cells, a longer (48-hour) multiplication cycle was described (119, 128, 154).

The cell receptor of the virus is not known. Nieper and Müller suggested that serotype 1 and serotype 2 IBDV may use several receptors on different cell types, these receptors being either common to both serotypes or serotype specific (192). Ogawa et al. demonstrated that the receptor for virulent IBDV is a N-glycosylated membrane protein expressed in the IgM-bearing immature B lymphocytes (194). Translocation across the cytoplasmic membrane of the receptor-bound IBDV particles could be mediated by pep46, one of the VP2-derived peptides that are present in the virus particle (33, 47).

The mechanism of viral RNA synthesis has not been clearly determined. A dsRNA-dependent RNA polymerase, VP1, was described (253, 282). Genome-linked proteins have been demonstrated, indicating that the virus replicates its nucleic acid by a strand displacement mechanism (253). Von Einem et al. showed that a baculovirus expressed IBDV RdRp specifically used the 3′ untranslated region of an IBDV positive strand template to initiate the synthesis of a complementary strand by a "copy-back" mechanism (282). RNA polymerase activity could be demonstrated without the pretreatment of the virus, indicating that transcription and replication occur following cell penetration without the uncoating of the virus (253). It has been hypothetized that non-polyadenylated mRNAs are extruded through pores possibly located at the 5-fold symetrical axis in IBDV capsid (43).

Becht (15) reported that synthesis of host proteins is not shut off in chicken embryo fibroblasts (CEFs) infected with IBDV. In chicken bursal lymphoid cells grown in vitro, the viral polypeptides were detected in the cells and their culture media at 90 minutes and 6 hours post-infection, respectively (175). Tacken et al. demonstrated an interaction between VP1 and eukaryotic translation initiation factor 4AII; this association suggests that VP1 could also be involved in the translation of IBDV RNA (258). The lack of accumulation of the polyprotein in infected cells suggests its co-translational cleavage (175). The model currently proposed for the assembly of IBDV particles involves most virus proteins: VP1 most probably first interacts with virus RNA, as described in IPNV, another birnavirus (54). VP3 then interacts with itself, pVP2, VP1 and the viral genome, thus playing a critical chaperone role in virion morphogenesis and encapsidation (34, 146, 257). The final maturation of pVP2 by serial cleavage

of its last carboxy-terminal peptides occurs within the virus capsid (33, 35).

Virus particles accumulate within the cytoplasm of infected cells (161). This could be favored by the fact that VP5 prevents apoptosis at the early stages of infection, by interfering with the caspases and NF-KB pathways (144). However, VP5 (301) and/or VP2 (70) have also been reported to induce apoptosis in infected cells. The VP5-mediated formation of pores in the membrane of the infected cells (147), would contribute to virus release.

Susceptibility to Physical and Chemical Agents

Infectious bursal disease virus is very stable. Benton *et al.* (17) found that IBDV resisted treatment with ether and chloroform was inactivated at pH 12 but unaffected by pH 2, and was still viable after 5 hours at 56°C. The virus was unaffected by exposure for 1 hour at 30°C to 0.5% phenol and 0.125% thimerosal. There was a marked reduction in virus infectivity when exposed to 0.5% formalin for 6 hours. The virus was also treated with various concentrations of three disinfectants (an iodine complex, a phenolic derivative, and a quaternary ammonium compound) for a period of 2 minutes at 23°C. Only the iodine complex had any deleterious effects. Landgraf *et al.* (138) found that the virus survived 60°C but not 70°C for 30 minutes, and 0.5% chloramine killed the virus after 10 minutes. Invert soaps with 0.05% sodium hydroxide either inactivated or had a strong inhibitory effect on the virus (236). Alexander and Chettle (5) detected a biphasic drop in infectivity of the virus in bursal homogenates at 70°, 75°, and 80°C, with initial rapid drop followed in the second phase with a gradual decline. A drop of 1 log 10 at 70°, 75°, and 80°C took 18.8, 11.4, and 3.0 minutes, respectively. Mandeville *et al.* (162) inoculated chicken parts or chicken products with the virus and then cooked them to an internal temperature of 71° and 74°C, respectively, followed by cooling and viable virus was recovered from both products.

Certainly, the hardy nature of this virus is one reason for its persistent survival in poultry houses even when thorough cleaning and disinfection procedures are followed.

Strain Classification

A variety of phenotypic and molecular genetic procedures have been developed and used to classify isolates of IBDV. Classification systems based on phenotypic traits, such as serotyping, have been used successfully since the discovery of the virus. Serotyping of IBDV isolates using polyclonal antibodies in cross virus neutralization (VN) tests has correlated very well with protection studies. The newer molecular genetic procedures have proved extremely useful for diagnostics and epidemiologic studies, but the use of these procedures at this point for classification of isolates has caused some confusion, mostly because of the lack of documented criteria for interpretation of the results and the lack of correlation between serogrouping and molecular grouping. Following are some of the procedures used to classify IBDV isolates.

Antigenicity

McFerran *et al.* (166), in Northern Ireland, were the first to report antigenic variations among IBDV isolates of European origin. They presented evidence for the existence of two serotypes, designated 1 and 2, and showed only 30% relatedness between several strains of serotype 1 and the designated prototype of that serotype. Similar findings were reported in the United States (115, 150), and the American serotypes were designated I and II. Later studies (167) indicated the relatedness of the European and American isolates of the second serotype, and use of the Arabic numerals 1 and 2 to describe the two serotypes of IBDV has been used since. Antigenic relatedness of only 33% between 2 strains of serotype 2 was reported (167), indicating an antigenic diversity similar to that of serotype 1 viruses.

The 2 serotypes are differentiated by virus-neutralization (VN) tests, but they are not distinguishable by fluorescent antibody tests or enzyme-linked immunosorbent assay (ELISA). Immunization against serotype 2 does not protect against serotype 1. The reverse situation cannot be tested because no virulent serotype 2 viruses are available for challenge (108, 118). The first isolates of serotype 2 (115) originated from turkeys, and it was thought that this serotype was host specific. Later studies showed, however, that viruses of serotype 2 could be isolated from chickens (109), and antibodies to serotype 2 IBDVs are common in both chickens and turkeys (113, 227).

Variant viruses of serotype 1 were described (221, 227). Vaccine strains available at the time they were isolated did not elicit full protection against the variants, which are antigenically different from the standard serotype 1 isolates. Jackwood and Saif (114) conducted a cross-neutralization study of 8 serotype 1 commercial vaccine strains, 5 serotype 1 field strains, and 2 serotype 2 field strains. Six subtypes were distinguished among the 13 serotype 1 strains studied. One of the subtypes included all of the variant isolates. Snyder *et al.* (249, 250), using monoclonal antibodies, suggested that a major antigenic shift in serotype 1 viruses had occurred in the field. Sequencing studies later identified several amino acid changes in "VP2 hydrophilic peaks" that correlated with the antigenic changes observed in the variant viruses (89, 137, 272). Sapats and Ignjatovic (230) similarly reported Australian antigenic variants. Australian variants seem to be generated by a similar genetic mechanism as the North American variants, but they differ genetically and antigenically— as detected with monoclonal antibodies—from these. The impact of antigenic variation on cross protection has been less documented for Australian variants.

The vvIBDV strains that were first described in Europe (32) were shown to be mostly antigenically similar to the classic serotype 1 viruses (2, 23, 59, 267, 275, 279). However, further characterization with monoclonal antibodies demonstrated one modified neutralizing epitope in typical vvIBDV, as compared with classic serotype 1 viruses (60). Some atypical vvIBDV with more extensive epitope changes have been occasionally identified (61, 62). Sapats *et al.* recently developed a chicken recombinant antibody (laboratory produced synthetic antibody derived from the lymphocytes of chickens immunized with vvIBDV, same use as monoclonal antibody) that positively recognizes vvIBDV (231).

In summary, there are currently 3 well-documented antigenic types. These are classic (often called standard) and variant

serotype 1 (possibly including an American and an Australian group) and serotype 2 viruses. Subtypes of the three antigenic types have also been described.

Immunogenicity or Protective Types

The term protective type was coined by Lohr (145) to describe a practical procedure to classify infectious bronchitis viruses (IBV) based on their protective potential. Classification of IBV has been problematic. This classification is based on cross protection studies in live birds. As indicated earlier, cross-challenge studies with IBDV has yielded results similar to those obtained by cross VN studies used for the antigenic classification (107). There are two serotype 1 protective types, classic/standard and variant groups. Serotype 2 viruses do not protect against challenge with serotype 1 viruses.

Molecular Genetic Types and Gene Sequencing

Molecular genetic techniques are increasingly used to group different isolates of IBDV (120). These techniques have become popular because of their sensitivity, the time they save, the ability to use them on crude samples or inactivated samples, and they do not require replication of the virus. The most commonly used procedure is the reverse transcriptase/polymerase chain reaction-restriction enzyme fragment length polymorphisms RT/PCR-RFLP, mostly applied to the characterization of the genomic region encoding "VP2 variable domain" (see above). A RT-PCR/RFLP approach has also been implemented for the molecular grouping of IBDV strains according to their segment B restriction profile (263). Currently described molecular groups do not always correspond to antigenic or protective groups, and one has to be careful in interpreting the significance of this classification.

A more thorough molecular characterization can be achieved by sequencing the virus genome and studying the phylogenetic relationships of the studied isolate with reference viruses. Care should be taken that for an optimum assessment of genetic relatedness both genome segments should be characterized (141). As no genetic marker for virulence has yet been defined, attempts to infer the phenotype from genetic data should still be considered as tentative.

Pathogenicity

Chickens are the only animals known to develop clinical disease and distinct lesions when exposed to IBDV. Care should be taken, when comparing experiments aimed at assessing the pathogenicity of different IBDV isolates, that these experiments do include relevant control IBDV strains with a well characterized pathogenicity. Major variables to be standardized in comparative trials are the breed or genetic lineage, age and immune status of the challenged chickens, the dose and route of inoculation of the challenge virus and the possible presence of contaminating viruses in the inoculum (294). Field viruses exhibit different degrees of pathogenicity in chickens. In the authors experience based on the experimental reproduction of acute IBD in specific pathogen free white leghorn chickens, "variant" IBDV induce little if any clinical signs and mortality, but marked bursal lesion, classical IBDV induce approximately 10–50% mortality with typical signs and lesions and vvIBDV induce approximately 50–100% mortality with typical signs and lesions (294). Comparative studies show that it may prove difficult to define cut off values, and that putative vvIBDV, when identified by the genetic sequence of their segment A only, may greatly vary in pathogenicity (141, 278). Vaccine viruses also have varying pathogenic potential in chickens, as discussed later in this chapter.

There has been interest in studying the potential pathogenicity of viruses belonging to serotype 2 in chickens and turkeys. Jackwood et al. (118) reported a lack of clinical signs and either gross or microscopic lesions in chickens inoculated with a serotype 2 isolate. Sivanandan et al. (240), however, observed typical IBDV lesions in chickens inoculated with the same isolate. In later studies (108), 5 isolates of serotype 2, 3 of chicken origin and 2 of turkey origin (including the isolate studied by Jackwood et al. and Sivanandan et al.), were found nonpathogenic in chickens.

In turkey poults inoculated at 1–8 days of age, an isolate of serotype 2 from turkeys failed to cause disease or gross or microscopic lesions in the cloacal bursa, thymus, or spleen (117); however, the virus was infectious, and the poults responded serologically to the infection. Nusbaum et al. (193) studied experimental infection in 1-day-old poults with isolates representing serotypes 1 and 2 that originated from turkeys. Virus-infected cells were detected by immunofluorescence in the bursa, thymus, spleen, and the Harderian gland of infected birds, but no clinical disease resulted. Only slight gross changes were observed, and no histologic differences were seen between infected and non-infected birds. In general, the distribution of fluorescing (infected) cells from these tissues seemed to indicate that the majority were not lymphocytes. The number of plasma cells in the Harderian gland was reduced at 28 days of age. As indicated earlier, the effect of the host system on pathogenicity of the virus may be profound (85, 265). In recent studies, the OH strain of serotype 2 virus that was back passaged 5 times in chicken embryos was shown to be pathogenic to the embryos. Nonetheless, that virus was not pathogenic for 2-week-old SPF chickens or turkeys (4).

Laboratory Host Systems

Chicken Embryos

Initially, most workers had difficulty in isolating virus or, if successful, in serially transferring virus using chicken embryos. Landgraf et al. (138) reported a typical experience using the allantoic sac route of inoculation. On the first passage, all inoculated embryos died; on the second, 30% died; and on the third, there was no embryo mortality.

Continued studies (97) uncovered 3 factors that could explain these difficulties: 1) Embryonating eggs that originated from flocks recovered from the disease were highly resistant to growth of the virus; 2) In early virus passage, the allantoamnionic fluid (AAF) had a very low virus content and the chorioallantoic membrane (CAM) and embryo each had a much higher and nearly equal virus content; 3) Comparison of the allantoic sac, yolk sac, and CAM as routes of inoculation showed the allantoic sac to be the least desirable, yielding embryo-infective dose—50% (EID_{50}) virus titers of 1.5–2.0 $\log_{10}$—lower than those obtained

after inoculation by the CAM route. The yolk sac route gave titers that were intermediate.

Winterfield (289) increased virus concentration in the AAF by serial passage in embryonating eggs. Hitchner (97) used isolate 2512, obtained from Winterfield in the 46th embryo passage, to perform a multi-step growth curve study. He found that virus concentration reached a peak 72 hours post-inoculation.

Injection of the virus into 10-day-old embryonating eggs resulted in embryo mortality from days 3–5 post-inoculation. Gross lesions observed in the embryo were edematous distention of the abdominal region; cutaneous congestion and petechial hemorrhages, particularly along feather tracts; occasional hemorrhages on toe joints and in the cerebral region; mottled-appearing necrosis and ecchymotic hemorrhages in the liver (latter stages); pale "parboiled" appearance of the heart; congestion and some mottled necrosis of kidneys; extreme congestion of lungs; and pale spleen, occasionally with small necrotic foci. The CAM had no plaques, but small hemorrhagic areas were observed at times. Lesions induced in embryos by IBDV variants differ from those induced by standard isolates. Splenomegaly and liver necrosis are characteristic of the lesions induced by the variants, but there is little mortality (224). Two vvIBDV strains were reported to constantly induce high mortality in chicken embryos, whereas, a classic strain induced erratic lower mortality (259). Similar to the situation with the classic strains, the CAM was the most sensitive route for infecting chicken embryos with the vvIBDV strains, but the yolk sac route was a good alternative (259).

Cell Culture

Many strains of IBDV have been adapted to cell cultures of chicken embryo origin, and cytopathic effects have been observed. Cell culture-adapted virus may be quantified by plaque assay or microtiter techniques. Rinaldi *et al.* (219) and Petek *et al.* (208) were able to culture egg-adapted strains of IBDV in CEFs, which proved more sensitive to the virus than either embryonating eggs or suckling mice.

Lukert and Davis (151) successfully adapted wild-type virus from infected bursas to growth in cells derived from the chicken embryo bursas. After 4 serial passages in chicken embryo bursa cells, the virus grew in chicken embryo kidney cells and produced plaques under agar. This virus was subsequently propagated in CEFs and used as an attenuated live virus vaccine (241). In addition to cells of chicken origin, the virus has been grown in turkey and duck embryo cells (168), mammalian cell lines derived from rabbit kidneys (RK-13) (219), monkey kidneys (Vero) (94, 154), and baby grivet monkey kidney cells (BGM-70) (119).

Jackwood *et al.* (119) compared three mammalian cell lines (MA-104, Vero, and BGM-70) for their ability to support several strains of IBDV serotypes 1 and 2, including serotype 1 variants. The viruses replicated in the 3 cell lines, but cytopathic effects were most pronounced in the BGM-70 cells. The growth curve of one strain tested in BGM-70 cells was similar to that in CEFs, and VN titers in BGM-70 cultures compared well with those in CEFs.

A continuous fibroblast cell line of Japanese quail origin (QT35) was found to support the replication of IBDV and several other viral pathogens of poultry (44). These viruses, already adapted to tissue culture, produced a cytopathic effect in the quail cells.

Hirai and Calnek (93) propagated virulent IBDV in normal chicken lymphocytes and in a lymphoblastoid B-cell line derived from an avian leukosis virus-induced tumor. The virus would not replicate in 6 T-cell lymphoblastoid cell lines initiated from Marek's disease tumors (MSB-1, RPL-1, GACL-1, JMCL-1, CVCL-1 and GBCL-1). Their work showed that IgM-bearing B lymphocytes were the probable target cells of IBDV. This was subsequently verified in a study on normal lymphocytes of chickens (188). Lymphocytes from the cloacal bursa and thymus were purified and separated into T cells, B cells, and null cells. The B cells bearing surface IgM were susceptible to IBDV, but the T cells and null cells were not.

Müller (174) enriched Ig-bearing cells by rosetting and cell sorting and observed that IBDV replicated preferentially in a population of proliferating cells and that susceptibility did not correlate with expression of immunoglobulins on their surface. A B-lymphoblastoid cell line from a chicken with lymphoid lesions (LSCC-BK3; 92) was found to be superior to CEF, chicken kidney cells, and BGM-70 cells in propagating several attenuated and pathogenic viruses (266).

Isolation of IBDV from field cases of the disease may be difficult. McFerran *et al.* (166) found it very difficult to isolate and serially propagate the virus in cell cultures of chicken embryo origin. Lee and Lukert (139) attempted isolations of IBDV from turkeys and chickens as well as from samples of challenge strains received from other laboratories. Turkey strains (5 of 5) were readily adapted to CEF cells after 3 to 10 blind passages. Only 2 of 9 chicken strains could be adapted to CEF cells; the other 7 strains could be grown only in chicken embryo bursa cells, even after 20 bursal cell passages.

BGM-70 cells were used successfully for isolation of IBDV from the bursas of naturally infected chickens (228). Usually, a cytopathic effect was detected after 2 or 3 blind passages.

One aspect that should be considered concerning *in vitro* replication of the virus is the possibility of development of defective particles. Müller *et al.* (179) reported that serial passages of undiluted virus in chicken embryo cells resulted in fluctuations in infectivity and the development of a stable small-plaque-forming virus that interfered with the replication of the standard virus and favored the generation of defective particles. The defective particles had lost the large segment of dsRNA. Passage of the virus 6 times in BGM-70 cells or CEF resulted in loss of pathogenicity, but similar passages in chicken embryos did not affect the pathogenicity of the virus (85).

Compared to classic and variant strains of serotype 1, adaptation of the vvIBDV viruses to cell culture has been very difficult (2). Site-directed mutagenesis (185) has been used to identify single amino acids that restrict propagation in cell culture (142, 180), but these amino acids could be strain specific. Later, it was reported (3) that adaptation of the virus to BGM-70 cells resulted in a significant reduction in the ability of the virus to replicate in the bursa of Fabricius. Tsukamoto et al (266) reported that LSCC-BK3 cells were superior to BGM-70 cells and CEF in an infectivity assay.

Pathobiology and Epidemiology

Incidence and Distribution

Infections with serotype 1 IBDV are of worldwide distribution, occurring in all major poultry producing areas. The incidence of infection in these areas is high; essentially, all flocks are exposed to the virus during the early stages of life, either by natural exposure or vaccination. Because of vaccination programs carried out by most producers, all chickens eventually become sero-positive to IBDV. Clinical cases are very rare in the United States because infections are either modified by antibodies or are due to variant strains that do not cause obvious clinical disease. These variant strains seem to be the predominate viruses that exist in the United States. Classical viruses and a local type of variants have been reported in Australia (230). In Europe, Africa, Asia, and South America, the vvIBDV strains seem to predominate.

In the United States, it was shown that antibodies to serotype 2 IBDV were widespread in chicken (113, 227) and turkey flocks (11, 37, 115), indicating the common prevalence of the infection.

Natural and Experimental Hosts

Chickens and turkeys are the natural hosts of the virus. A serotype 1 virus was isolated from two 8-week-old ostrich chicks that had lymphocyte depletion in the bursa of Fabricius, spleen, and/or thymus (293). Another serotype 1 isolate was obtained from healthy ducks (166). A serotype 2 IBDV was isolated from captive penguins that died without specific clinical signs (78). Van den Berg (277) inoculated pheasants, partridges, quails, and guinea fowl with vvIBDV. These authors did not report any clinical signs or lesions in these species, however quails replicated the virus in their bursa, shed it for five days in their feces and developed neutralizing antibodies. This contrasts with a previous study by Weisman and Hitchner, who could not infect Coturnix quail with a chicken-origin virus (284), but confirms an earlier report that IBDV-inoculated Guinea fowl did not develop lesions or antibody (196).

Several species of free-living and captive birds of prey were examined for antibodies to IBDV, and positive results were obtained from accipitrid birds (271). Antibodies to IBDV were also detected in rooks, wild pheasants, and several rare avian species (30); in Antartic penguins (74); in ducks, gulls and shearwaters (287); and crows, gulls and falcons (195).

For many years, the chicken was considered the only species in which natural infections occurred. All breeds were affected, and many investigators observed that white leghorns exhibited the most severe lesions and clinical signs and had the highest mortality rate. Meroz (170), however, found no difference in mortality between heavy and light breeds in a survey of 700 outbreaks of the disease.

The period of greatest susceptibility to clinical disease is between 3 and 6 weeks of age. Susceptible chickens younger than 3 weeks do not exhibit clinical signs but have subclinical infections that are economically important as a result of severe immunosuppression of the chicken. This immunosuppressive effect of IBDV was first recognized by Allan et al. (6) and Faragher et al. (68) and is discussed later in this chapter.

The reason for the apparent age susceptibility of chickens to IBDV has been the subject of several research publications regarding the pathogenesis of IBDV infections. Fadly et al. (63) treated 3-day-old chicks with cyclophosphamide and found that they were refractory to clinical signs and lesions when challenged at 4 weeks of age. Kaufer and Weiss (126) found similar results with birds surgically bursectomized at 4 weeks of age. When they were challenged immediately, or 1 week later, there was no clinical disease, whereas 100% of the control non-bursectomized chickens died. Bursectomized chickens challenged with virulent virus produced 1000 times less virus than control birds, produced VN antibodies by day 5, and had only very discrete and transient necrosis of lymphatic tissues.

Several studies on the pathogenesis of IBDV infections have been conducted. Skeeles et al. (242) attempted to demonstrate that the hemorrhagic lesions were a result of formation of immune complexes, as proposed by Ivanyi and Morris (111). Histologic lesions in the cloacal bursa resemble an Arthus reaction (necrosis, hemorrhage, and large numbers of polymorphonuclear leukocytes). This reaction is a type of localized immunologic injury caused by antigen-antibody-complement complexes that induce chemotactic factors, which cause hemorrhage and leukocyte infiltration. They found that 2-week-old and 8-week-old chicks produced rapid and high levels of antibody by 72 hours post-infection, but that 2-week-old chickens had very little complement compared with 8-week-old chickens. They postulated that the reason 2-week-old chickens did not develop Arthus-type lesions was a lack of sufficient complement. They also showed that complement was depleted in 8-week-old chickens at 3, 5, and 7 days post-infection compared with uninfected controls. A later study by Skeeles et al. (245) with another IBDV isolate failed to substantiate the depletion of complement at 3 days post-infection.

Kosters et al. (133) and Skeeles et al. (242, 245) found increased clotting times in IBDV-infected chickens and suggested that such coagulopathies would contribute to the hemorrhagic lesions observed with this disease. Skeeles et al. (245) found that 17-day-old chickens did not exhibit clotting defects, but at 42 days, they had greatly increased clotting times and became clinically ill; 4 of 11 died. The key to the pathogenesis of IBDV in birds of different ages may lie with the factors involved in the clotting of blood and/or an immunologic injury. The pathogenesis is certainly not straightforward and simple.

Naturally occurring infections of turkeys and ducks by serotypes 2 and serotype 1 viruses, respectively, have been recorded (125, 166, 168, 201). Serologic evidence and isolation of IBDV from these species indicate that natural infections do occur. McNulty et al. (168) examined turkey serums from several flocks and could not detect IBDV antibodies prior to 1978, suggesting that IBDV infections of turkeys were a relatively new occurrence. Owoade et al. reported the isolation of an IBDV strain with genetic relatedness to vvIBDV in a turkey flock in Nigeria (199).

Giambrone et al. (76) found that experimental IBDV infections of turkeys were subclinical in 3- to 6-week-old poults, producing microscopic lesions in the bursa. Virus-infected cells in the bursa were detected by immunofluorescence. Neutralizing

antibody was detected 12 days post-infection, and the virus could be reisolated after 5 serial passages in chicken embryos. Weisman and Hitchner (284) could not reisolate virus from their 6- to 8-week-old IBDV-infected poults, but they observed an increase in VN antibody. Infection was subclinical, and no damage to the bursa was evident.

Transmission, Carriers, and Vectors

Infectious bursal disease is highly contagious, and the virus is persistent in the environment of a poultry house. Benton *et al.* (18) found that houses from which infected birds were removed were still infective for other birds 54 and 122 days later. They also demonstrated that water, feed, and droppings taken from infected pens were infectious after 52 days.

No evidence suggests that IBDV is transmitted through the egg or that a true carrier state exists in recovered birds. Resistance of the virus to heat and disinfectants is sufficient to account for virus survival in the environment between outbreaks. Snedeker *et al.* (246) demonstrated that the lesser mealworm (*Alphitobius diaperinus*), taken from a house 8 weeks after an outbreak, was infectious for susceptible chickens when fed as a ground suspension. In another study (165), the virus was isolated from several tissues of surface-sterilized lesser mealworm adults and larvae that were fed the virus earlier.

Howie and Thorsen (100) isolated IBDV from mosquitoes (*Aedes vexans*) that were trapped in an area where chickens were being raised in southern Ontario. The isolate was non-pathogenic for chickens. Okoye and Uche (197) detected IBDV antibodies by the agar-gel precipitin (AGP) test in 6 of 23 tissue samples from rats found dead on 4 poultry farms that had histories of IBDV infection. There has been no further evidence to support a conclusion that either mosquitoes or rats act as vectors or reservoirs of the virus.

Pagès-Manté *et al.* reported that a dog fed chickens that had died of acute IBD shed viable vvIBDV in its feces for two but not for three days after ingestion (202).

As indicated earlier in this chapter, several avian species were shown to be susceptible to the infection or to have antibodies against the virus.

Incubation Period and Clinical Signs

The incubation period is very short, and clinical signs of the disease are seen within 2–3 days after exposure.

One of the earliest signs of infection in a flock is the tendency for some birds to pick at their own vents. Cosgrove (42), in his original report, described soiled vent feathers, whitish or watery diarrhea, anorexia, depression, ruffled feathers, trembling, severe prostration, and finally, death. Affected birds became dehydrated, and in terminal stages of the disease, had a subnormal temperature.

Morbidity and Mortality

In fully susceptible flocks, the disease appears suddenly, and there is a high morbidity rate, usually approaching 100%. Mortality may be nil but can be as high as 20–30%, exceptionally higher with vvIBDV, usually beginning on day 3 post-

7.2. Hemorrhages of leg muscle typical in IBD.

infection and peaking and receding in a period of 5–7 days. In the late 1980s, strains of vvIBDV became a problem in Europe. Several of these isolates caused mortality rates of 90% (32) to 100% (275) in 4-week-old susceptible leghorn chickens. A 1970 isolate (52/70) (29) was compared with 2 vvIBDV isolates in a study; it caused 50% mortality compared with 90% for the vvIBDV strains (32). In another such study, the vvIBDV isolates caused lower mortality, however percent mortality was again at least twice as much as caused by the 52/70 isolate (59).

Initial outbreaks on a farm are usually the most acute. Recurrent outbreaks in succeeding broods are less severe and frequently go undetected. Many infections are silent, owing to age of birds (less than 3 weeks old), infection with avirulent field strains, or infection in the presence of maternal antibody.

Pathology

Gross Lesions

Birds that succumb to the infection are dehydrated, with darkened discoloration of pectoral muscles. Frequently, hemorrhages are present in the thigh and pectoral muscles (Fig. 7.2). There is increased mucus in the intestine, and renal changes (42) may be prominent in birds that die or are in advanced stages of the disease. Such lesions are most probably a consequence of severe dehydration. In birds killed and examined during the course of infection, kidneys appear normal.
7.3. Edematous (*right*) and hemorrhagic *(center)* cloacal bursas typical in acute IBD at 72–96 hours post-infection. The bursa on the left is normal.

The cloacal bursa appears to be the primary target organ of the virus. Cheville (36) made a detailed study of bursal weights for 12 days post-infection. It is important that the sequence of changes be understood when examining birds for diagnosis. On day 3 post-infection, the bursa begins to increase in size and weight because of edema and hyperemia (Fig. 7.3). By day 4, it usually is double its normal weight, and the size then begins to recede. By day 5, the bursa returns to normal weight, but it continues to atrophy, and from day 8 forward, it is approximately one-third its original weight, or even less.

By day 2 or 3 post-infection, the bursa has a gelatinous yellowish transudate covering the serosal surface. Longitudinal striations on the surface become prominent, and the normal white color turns to cream color. The transudate disappears as the bursa returns to its normal size, and the organ may become gray during and following the period of atrophy.

Isolates of variant IBDV were reported not to induce an inflammatory response (221, 234), although one variant strain (IN) did so (86).

The infected bursa often shows necrotic foci and at times petechial or ecchymotic hemorrhages on the mucosal surface. Occasionally, extensive hemorrhage throughout the entire bursa has been observed (see Fig. 7.3); in these cases, birds may void blood in their droppings.

The spleen may be slightly enlarged and very often has small gray foci uniformly dispersed on the surface (218). Occasionally, hemorrhages are observed in the mucosa at the juncture of the proventriculus and gizzard.

Compared with a moderately pathogenic strain of the virus, the vvIBDV strains caused a greater decrease in thymic weight index and more severe lesions in the cecal tonsils, thymus, spleen, and bone marrow, but bursal lesions were similar. It was also shown that pathogenicity correlated with lesion production in non-bursal lymphoid organs, suggesting that pathogenicity may be associated with antigen distribution in non-bursal lymphoid organs (260).

Microscopic Lesions
Microscopic lesions of IBD occur primarily in the lymphoid tissues (i.e., cloacal bursa, spleen, thymus, Harderian gland, and cecal tonsil). Histopathology at the level of light microscopy has been originally studied by Helmboldt and Garner (91), Cheville

(36), Mandelli *et al.* (161), and Peters (209). Changes were most severe in the cloacal bursa. As early as 1 day post-infection, there was degeneration and necrosis of lymphocytes in the medullary area of bursal follicles. Lymphocytes were soon replaced by heterophils, pyknotic debris, and hyperplastic reticuloendothelial cells. Hemorrhages often appeared but were not a consistent lesion. All lymphoid follicles were affected by 3 or 4 days post-infection. The increase in bursal weight seen at this time was caused by severe edema, hyperemia, and marked accumulation of heterophils. As the inflammatory reaction declined, cystic cavities developed in medullary areas of follicles; necrosis and phagocytosis of heterophils and plasma cells occurred; and there was a fibroplasia in interfollicular connective tissue. Proliferation of the bursal epithelial layer produced a glandular structure of columnar epithelial cells containing globules of mucin. During the suppurative stage, scattered foci of lymphocytes appeared but did not form healthy follicles during the observation period of 18 days post-inoculation (91). Some of the histologic changes observed in the cloacal bursa are shown in Figure 7.4. A recent isolate (variant A) of IBDV was reported to cause extensive lesions in the cloacal bursa, but an inflammatory response was lacking (234).

A recent sequential study (292) of the recovery of the cloacal bursa after neonatal infection by classical IBDV demonstrated that the initial depletion of B lymphocytes was maximum during the first week, and combined with a transient massive influx of T cells and macrophages until three days post-infection. From 1 to 8 weeks post-infection, two distinct types of bursal follicles were then observed: large reconstituted functional follicles, most likely reconstituted from endogenous bursal stem cells that survived IBDV infection, and small poorly developed follicles lacking a discernible cortex and medulla. The structure of these small follicles suggested they were unable to produce functional peripheral B cells, which hypothesis was confirmed by the lack of active antibody responses in birds lacking large reconstituted follicles. After their initial influx in the bursa, T cells declined in number along with viral clearance and persisted mostly in the small follicles during the recovery phase. Inflammatory foci persisted during the recovery phase, possibly centered on antigen presenting cells. It is not known whether their presence was associated with persistent IBDV infection in some cells (292). Essentially similar but more severe and more persistent histolog-
7.4. Photomicrographs of 6-week-old birds affected with infectious bursal disease virus (IBDV). Tissues are cloacal bursa fixed in 10% buffered formalin and stained with H & E. A. Normal tissue. Large active follicles consist of lymphoid cells that form discrete follicles with little interfollicular tissue. Covering epithelium is simple columnar. ×40. B. Bursa approximately 24 hours post-infection. Note interfollicular edema mixed with phagocytic cells, many of which are heterophils. Follicles are already beginning to degenerate. ×40. C. Single follicle approximately 60 hours post-infection. Medullary portion is now a mass of cellular debris surrounded by cortical remnants. Only reticular cells exist in any number, but scattered among them are a few lymphocytes that will later regenerate. ×250. D. Terminal phase of severe infection. Only ghosts of follicles remain, and heterophils (scattered dark cells) are actively engaged in phagocytosis. Covering epithelium is plicated and grandular, with globules of mucins. ×40. (91).

ical lesions have been described following challenge with a vvIBDV, which however also induced thymic lesions (288).

The spleen had hyperplasia of reticuloendothelial cells around the adenoid sheath arteries in early stages of infection. By day 3, there was lymphoid necrosis in the germinal follicles and the periarteriolar lymphoid sheath. The spleen recovered from the infection rather rapidly, with no sustained damage to the germinal follicles.

The thymus and cecal tonsils exhibited some cellular reaction in the lymphoid tissues in early stages of infection, but, as in the spleen, the damage was less extensive than in the bursa, and recovery was more rapid. A variant virus (A) was reported

to cause milder lesions in the thymus than a standard isolate (IM) (234).

Survashe *et al.* (256) and Dohms *et al.* (57) found that the Harderian gland was severely affected following infection of 1-day-old chicks with IBDV. Normally, the gland is infiltrated and populated with plasma cells as the chicken ages. Infection with IBDV prevented this infiltration. From 1–7 weeks of age, the glands of infected chickens had populations of plasma cells 5–10-fold fewer than those of uninfected controls (57). In contrast, broilers inoculated with IBDV at 3 weeks of age had plasma cell necrosis in the Harderian gland 5–14 days post-inoculation, and the plasma cells were reduced by 51% at 7 days after inocu-

lation (58). Reduction in plasma cells, however, was transient, and the numbers were normal after 14 days.

Histologic lesions of the kidney are non-specific (209) and probably occur because of severe dehydration of affected chickens. Helmboldt and Garner (91) found kidney lesions in less than 5% of birds examined. Lesions observed were large casts of homogeneous material infiltrated with heterophils.

The liver may have slight perivascular infiltration of monocytes (209).

Ultrastructural

Naqi and Millar (189) followed the sequential changes in the surface epithelium of the cloacal bursa of IBDV-infected chicks by scanning electron microscopy. They observed a reduction in number and size of microvilli on epithelial cells at 48 hours post-inoculation. There was gradual loss of the button follicles normally seen at the surface, and by 72 hours, most had involuted. By 96 hours, there were numerous erosions of the epithelial surface. The surface was intact by day 9 post-inoculation, but follicles were involuted, leaving deep pits.

Pathogenesis of the Infectious Process

Helmboldt and Garner (91) detected histologic evidence of infection in the cloacal bursa within 24 hours. In sequential studies of tissues from orally infected chickens using immunofluorescence, viral antigen was detected in macrophages and lymphoid cells in the cecum at 4 hours after inoculation; an hour later, virus was detected in lymphoid cells in the duodenum and jejunum (178). The virus first reaches the liver, where it is detected 5 hours post-inoculation. It then enters the bloodstream, where it is distributed to other tissues including the bursa; the bursal infection is followed by a second massive viremia, however virus peak titer in the non-lymphoid organs is several log10 lower than in the bursa and limited to the viremic period.

Studies of gene expression during acute IBD demonstrated the activation of spleen macrophages (130) and of bursal T cells (131). Ruby *et al.* recently provided an extensive transcriptional study (226) of the early host responses to neonatal infection with a classical IBDV (F52/70). Changes in the expression levels of bursal genes closely mirrored the early histological changes discussed earlier in this chapter: low level of expression of B-cell-specific genes in relation with B-cell depletion, enhanced expression of numerous genes related with the activation of macrophages, T cells, and NK cells. Early upregulated genes included genes of the antiviral interferon system (IFN α/β and the IFN-induced genes), cytokines (IL-18, IL-6), and chemokines (IL-8, MIP-1β...); genes involved in the innate immune response (MD-1 and MD-2, complement components, heat shock proteins HSP70 and 47); some genes encoding cytoskeleton proteins; and genes involved in both the proinflammatory and inflammatory responses. Interestingly, the latter genes had significantly more expression at 24 hours PI in an IBD-resistant chicken line, as compared with a susceptible one. Another difference in the resistant line was a transient overexpression of p53 at 48 hours PI. On the other hand, a number of genes involved in B and T cell proliferation were down-regulated by IBDV infection. The authors propose that in resistant birds, a more rapid inflammatory response and more-rapid activation activation of apoptotic pathways in IBDV target cells would limit virus replication and its subsequent pathological effects (226).

The virus was shown to persist in bursal tissues of experimentally inoculated SPF chickens up to 3 weeks, but it persisted for shorter periods in the presence of maternal antibodies in commercial broilers (1).

Based on the fact that IBDV-induced pathology still progresses several days after the viral load starts to decline (5 days PI), Williams and Davison suggested that the disease mechanism is related to immunopathology as well as to virus-induced lysis (288).

Immunity

Viruses of both serotypes of IBDV share common group antigen(s) that can be detected by the fluorescent antibody test and ELISA (106, 115). Hence, it is not possible to distinguish serotypes or their antibodies by these tests. The common (group) antigens for both serotypes are on VP2 (40 kD) and VP3 (32 kD). VP2 also has serotype-specific group antigens that induce VN antibodies (10, 16). Becht *et al.* (16) reported that antibodies against VP3 do not have any protective effect. *In vivo* studies (107, 118) corroborated this observation, because chickens having antibodies to serotype 2 viruses were not protected against serotype 1 viruses. The current thought is that VP2 has the major antigens that induce protection (10, 16).

Traditionally, serotype 1 viruses have been used for studies of the immune response to IBDV. All known isolates of serotype 2 were reported to be non-pathogenic in chickens and turkeys (108, 117, 118) or of very low pathogenicity (40, 193, 207). The discovery of variant strains of serotype 1 has heightened interest in furthering the knowledge of the immune response to IBDV. It was interesting that variants were originally isolated from chickens that had VN antibodies to serotype 1 (221, 227). Inactivated vaccines and a live vaccine made from variant strains protected chickens from disease caused by either variant or standard strains, whereas inactivated vaccines made from standard strains did not protect, or only partially protected, against challenge with variant strains (107, 225).

Five different subtypes of serotype 1 IBDV were tested as inactivated vaccines against a variant strain of a different subtype (107). Vaccines made with 10^8 but not 10^5 tissue-culture-infective doses-50% were protective against a challenge dose of 10^2 EID$_{50}$. Even the higher vaccine dose did not protect against challenge with $10^{3.5}$ EID$_{50}$. Based on these results, it was suggested that all the subtypes of serotype 1 share a minor antigen(s) that elicits protective antibodies.

The contribution of humoral immunity to protection has been well documented as indicated by protection conferred by passive transfer of antibodies. Evidence is accumulating on the additive effect of cell-mediated immunity in protection from the disease (216, 235). Recent studies indicated the natural resistance of some breeds of chickens to the disease (84).

Active Immunity

Field exposure to the virus, or vaccination with either live or killed vaccines, stimulates active immunity. Antibody response

may be measured by several methods—VN, AGP, or ELISA tests. Antibody levels are normally very high after field exposure or vaccination, and VN titers greater than 1:1000 are common. Adult birds are resistant to oral exposure to the virus but produce antibody after intramuscular or subcutaneous inoculation of IBDV (98). However, partial protection against IBD was achieved in chickens in the absence of detectable neutralizing antibodies, as a result of experimental immunization with a fowlpox recombinant virus that expresses the VP2 protein (13), which finding is an indication that cell-mediated immunity may also play an important role in protecting against IBD.

Passive Immunity

Antibody transmitted from the hen via the yolk of the egg can protect chicks against early infections with IBDV, with resultant protection against the immunosuppressive effect of the virus. The half-life of maternal antibodies to IBDV is between 3 and 5 days (244). Therefore, if the titer of neutralizing antibodies in the progeny is known, the time that chicks will become susceptible can be predicted. Lucio and Hitchner (148) demonstrated that after antibody titers fell below 1:100, chicks were 100% susceptible to infection, and titers from 1:100 to 1:600 gave approximately 40% protection against challenge. Skeeles *et al.* (244) reported that titers must fall below 1:64 before chickens can be vaccinated effectively with an attenuated strain of IBDV. These figures should be considered as indicative that significant differences have been reported in the neutralizing titers determined by different laboratories (169). Use of killed vaccines in oil emulsions (including variant strains) to stimulate high levels of maternal immunity is extensively practiced in the field. Studies by Lucio and Hitchner (148) and Baxendale and Lutticken (12) indicated that oil emulsion IBD vaccines can stimulate adequate maternal immunity to protect chicks for 4–5 weeks, and progeny from breeders vaccinated with live vaccines are protected for only 1–3 weeks. As with many diseases, passively acquired immunity to IBDV can interfere with stimulation of an active immune response.

Immunosuppression

Allan *et al.* (6) and Faragher *et al.* (68) first reported immunosuppressive effects of IBDV infections. Suppression of the antibody response to Newcastle disease virus was greatest in chicks infected at 1 day of age. There was moderate suppression when chicks were infected at 7 days, and negligible effects when infection was at 14 or 21 days (68). Hirai *et al.* (95) demonstrated decreased humoral antibody response to other vaccines as well. Not only was response to vaccines suppressed, but chicks infected early with IBDV were more susceptible to inclusion body hepatitis (63), coccidiosis (7), Marek's disease (38, 232), hemorrhagic-aplastic anemia and gangrenous dermatitis (223), infectious laryngotracheitis (222), infectious bronchitis (206), chicken anemia agent (303), and salmonellosis and colibacillosis (295).

A paradox associated with IBDV infections of chickens is that although there is immunosuppression against many antigens, the response against IBDV itself is normal, even in 1-day-old susceptible chickens (243). It has been suggested that the ability of the

chickens to develop an active anti-IBDV antibody response correlates, after challenge at day-old, with the development of large bursal follicles during the recovery phase (292). This may not be the only mechanism, though, as older chickens that did not succumb to infection and exhibit an extreme bursal atrophy often develop high titers of neutralizing antibodies. It should hence be further investigated whether there is a selective stimulation of the proliferation of B cells committed to anti-IBDV antibody production.

The effect of IBD on cell-mediated immune (CMI) responses is transient and less obvious than that on humoral responses. Panigrahy *et al.* (203) reported that IBDV infections at a young age caused a delayed skin graft rejection; however, other workers (75, 102) found no effect from early IBDV infections on skin graft rejection or tuberculin-delayed hypersensitivity reaction. Sivanandan and Maheswaran (239) observed suppression of CMI responsiveness, using the lymphoblast transformation assay. They found that maximal depression of cellular immunity occurred 6 weeks post-infection. Nusbaum *et al.* (193) detected a significant suppression of T-cell response to the mitogen concanavalin A in poults from 3 days to 4 weeks post-infection. There was no reduction, however, in tuberculin reactions in IBDV-infected poults. In a sequential study of peripheral blood lymphocytes from chickens inoculated with IBDV, a transient depression of mitogenic stimulation was reported (41). Sharma and Lee (233) reported an inconsistent effect of IBDV infection on natural killer cell toxicity and a transient early depression of the blastogenic response of spleen cells to phytohemagglutinin. Craft *et al.* (45) demonstrated that a variant IBD virus strain (A) had a significantly more severe effect on the CMI response than a standard strain (Edgar) when given to 1-day-old chicks, and the CMI was suppressed for 5 weeks. A similar transient suppression of the CMI was observed in chickens infected at 3 weeks of age.

Another component of the immune system is the Harderian gland, which is associated with the local immune system of the upper respiratory tract. Pejkovski *et al.* (206) and Dohms *et al.* (57) reported that IBDV infection of 1–5-day-old chicks produced a drastic reduction in plasma cell content of the Harderian gland that persisted for up to 7 weeks. There have been similar observations with IBDV infections of poults (193). In other studies on broilers infected with IBDV at 3 weeks of age, extracts from the Harderian gland and serum had reduced antibody titers to *Brucella abortus* (a T-cell-independent antigen) and sheep red blood cells (SRBC, a T-cell-dependent antigen). Compared with SRBC antibody response, diminished antibody responses to *B. abortus* were evident at a later time period. A variant virus of serotype 1 produced a similar effect in chickens (56).

Chickens infected with IBDV at 1 day of age were completely deficient in serum immunoglobulin G and produced only a monomeric immunoglobulin M (IgM) (110, 111). The number of B cells in peripheral blood was decreased following infection with IBDV, but T cells were not appreciably affected (96, 237). The virus appears to replicate primarily in B lymphocytes of chickens (93, 110, 299). Apparently, IBDV has a predilection for actively proliferating cells (174), and it was suggested that the

virus affected "immature," or precursor, B lymphocytes to a greater extent than mature B lymphocytes (163).

Beside lymphocyte lysis, apoptosis is another mechanism of immunosuppression. Apoptosis is also a mechanism of lesion development and could occur in a variety of tissues and organs (6, 136, 261, 280, 281).

Although evidence is accumulating on the role of T cells in protection, there is also evidence of a role in immunopathogenesis (216, 235) resulting from tissue destruction enhancement mediated by cytokines.

Diagnosis

Acute clinical outbreaks of IBD in fully susceptible flocks are easily recognized, and a presumptive diagnosis can be readily made. The rapid onset, high morbidity, spiking mortality curve, and rapid recovery (5–7 days) from clinical signs are characteristics of this disease. Confirmation of the diagnosis can be made at necropsy by examination for characteristic grossly visible changes in the cloacal bursa. Remember that there are distinctive changes in size and color of the bursa during the course of infection (i.e., enlargement due to inflammatory changes followed by atrophy) (see "Gross Lesions").

Infections of very young chicks, or chicks with maternal antibody, are usually subclinical and are diagnosed retrospectively at necropsy with observations of macroscopic and microscopic bursal atrophy. Infections of chickens of any age with variant strains of IBDV will be detected only by histopathology of the cloacal bursa or by virus isolation.

Isolation and Identification of the Causative Agent

The cloacal bursa and spleen are the tissues of choice for the isolation of IBDV, but the bursa is the most commonly used for it contains the highest virus titers. Other organs contain the virus, but at a lower concentration and probably only because of the viremia. Tissues should be macerated in an antibiotic-treated broth or saline and centrifuged to remove the larger tissue particles. The supernatant fluid then is used to inoculate embryonating eggs or cell cultures.

Hitchner (97) demonstrated that the chorioallantoic membrane (CAM) of 9–11-day-old embryos was the most sensitive route for isolation of the virus. The virus subsequently could be adapted to the allantoic sac and yolk sac routes of inoculation. Death of infected embryos usually occurs in 3–5 days. Variant strains of IBD differ from standard viruses in that they induce splenomegaly and liver necrosis of embryos and produce little mortality (224). The embryonating egg may be the most sensitive substrate for isolation of IBDV. McFerran *et al.* (166) reported that 3 of 7 chicken isolates of IBDV failed to grow in chicken embryo fibroblast (CEF) cells; however, they could be propagated in embryonating eggs.

Isolation and propagation of IBDV in cell culture was discussed previously in this chapter (see "Laboratory Host Systems"). Because the virus has been shown to replicate in B lymphocytes, either primary cells derived from the cloacal bursa or continuous cell lines of B-cell origin would be the cells of choice for the isolation of the virus. It appears that some strains of virus are very fastidious, and although they may replicate in embryonating eggs or B lymphocytes, they cannot readily be adapted to CEF cells or cells from other organs such as the kidney and liver (139, 166). The use of immunofluorescence and electron microscopy of infected embryos and cell cultures has proven to be of tremendous value for the early detection and identification of IBDV. Cell cultures containing 50% bursal lymphocytes and 50% CEF have been used to successfully isolate and serotype IBD viruses (149). The fibroblasts serve as a matrix for the lymphocytes, and the infected lymphocytes are detected by immunofluorescence. BGM-70 cells may also be used for isolation of IBDV.

Identification of the virus by direct immunofluorescent staining of affected organs or direct examination by electron microscopy has proven to be an adjunct to the isolation and identification of IBDV (166). If antigen or virus is detected by these methods from field cases of disease, every effort should be made to isolate the virus using both embryonating eggs and cell-culture techniques. The isolation, antigenic analysis, and pathogenicity studies of viruses from field cases of IBD are needed continually so that changes in the wild virus population can be detected.

Nucleic acid probes (112) and antigen-capture enzyme immunoassays using monoclonal antibodies (248) to detect and differentiate IBD viruses directly in tissues may prove beneficial for rapid diagnosis and typing of field viruses. One study (87) compared antigen-capture enzyme immunoassay with cell cultures and determined that cell culture was more sensitive than antigen-capture and, in turn, that antigen-capture with polyconal antibody was more sensitive than with monoclonal antibody. A rapid monoclonal-antibody based antigen-capture test under a one-step strip format has been recently proposed (304). In a study using several procedures for detection of the virus in bursa of experimentally infected chickens, the RT-PCR was the most sensitive test (1, 4). Recent developments of the RT-PCR technique include multiplex RT-PCR (135) or real-time RT-PCR (171, 210) protocols aimed at detecting and differentiating the different strains of IBDV (classic, variant, and vvIBDV) directly from infected tissues. Provided an adequate dose effect curve is available, real-time RT-PCR may also be used to quantify the virus load in the studied sample (172, 210).

Differential Diagnosis

The sudden onset, morbidity, ruffled feathers, and droopy appearance of the birds in initial disease outbreaks are suggestive of an acute outbreak of coccidiosis. In some cases, there is blood in the droppings that would lead one to suspect coccidiosis. The muscular hemorrhages and enlarged edematous or hemorrhagic cloacal bursas would, however, suggest IBD.

Birds that die from IBD may show an acute nephrosis. Because of many other conditions that may cause nephrosis and the inconsistency of kidney lesions, such lesions should not be sufficient cause for a diagnosis of IBD. Again, involvement of the cloacal bursa usually will distinguish IBD from other nephrosis-causing conditions. Water deprivation will cause kidney

changes and possibly gray, atrophied bursas that closely resemble those associated with IBD infection. However, unless this occurs as a flock condition, such changes would be seen in relatively few birds. A history of the flock would be essential in aiding in the differential diagnosis of these cases.

Certain nephropathogenic strains of infectious bronchitis virus cause nephrosis (290). These cases can be differentiated from infectious bursal disease by the fact that there are no changes in the cloacal bursa, and deaths usually are preceded by respiratory signs. The possibility that the two diseases may occur simultaneously in a flock should not be overlooked.

The muscular hemorrhages and mucosal hemorrhages seen at the juncture of the proventriculus and gizzard are similar to those reported for hemorrhagic syndrome and could be differentiated on the basis of bursal changes that accompany IBDV infections. It is not unlikely that before IBD was recognized some cases were diagnosed as hemorrhagic syndrome.

Jakowski *et al.* (123) reported bursal atrophy in experimentally induced infection with 4 isolates of Marek's disease. The atrophy was observed 12 days post-inoculation, but the histologic response was distinctly different from that found in IBD (see Chapter 15).

Grimes and King (81) reported that experimental infections of 1-day-old, specific-pathogen-free (SPF) chickens with a type 8 avian adenovirus produced small bursas and atrophy of bursal follicles at 2 weeks post-infection. Several other organs such as the liver, spleen, pancreas, and kidneys were grossly affected, and intranuclear inclusion bodies were observed in the liver and pancreas.

Serology

The ELISA procedure is presently the most commonly used serological test for the evaluation of IBDV antibodies in poultry flocks. Marquardt *et al.* (163) first described an indirect ELISA for measuring antibodies, and since that time, several workers (25, 160, 247, 252, 262) have reported on the use of ELISA and its comparison to VN test results. The ELISA procedure has the advantage of being a rapid test with the results easily entered into computer software programs. With these programs, one can establish an antibody profile on breeder flocks that will indicate the flock immunity level and provide information for developing proper immunization programs for both breeder flocks and their progeny. To perform an antibody profile on a flock for the evaluation of the efficacy of vaccination programs, no less than 30 serum samples should be tested; many producers submit as many as 50–100 samples. The antibody profiles may be performed with serum collected either from the breeders or from 1-day-old progeny. If progeny serums are used, titers normally will be 60–80 percent lower than those in the breeders. It should be recognized that the indirect ELISA does not differentiate between antibodies to serotypes 1 and 2 (108) and that commercial kits may significantly detect antibodies to both serotypes (8). It should also be kept in mind that ELISA kits may also vary in sensitivity and specificity (50), and that being a very sensitive technique, ELISA may present both intra-laboratory and inter-laboratory variation (134). Thus, the introduction in the panel of

tested sera of a reference sentinel serum with a known reactivity is advisable.

Prior to the use of the ELISA, the most common procedure for antibody detection was the constant virus-diluting serum VN test performed in a microtiter system (243). The VN test is the only serological test that will detect the different serotypes of IBDV and it is still the method of choice to discern antigenic variations between isolates of this virus. The indicator virus used for VN can make a significant difference in test results due to the fact that within a given serotype there are several antigenic subtypes (114). Significant discrepancies in the determination of virus neutralizing titers in different laboratories are also not uncommon (169). Most chicken serums from the field have high levels of neutralizing antibody to a broad spectrum of antigenically diverse viruses owing to a combination of field exposure, vaccine exposure, and cross-reactivity from high levels of antibody.

The other method used for the detection of IBDV antibodies is the AGP test. In the United Kingdom, a quantitative AGP test is routinely used (46); however, as used in the United States, the test is not quantitative. This test does not detect serotypic differences; it measures primarily antibodies to group-specific soluble antigens.

Treatment

No therapeutic or supportive treatment has been found to change the course of IBDV infection (42, 204). Because of the rapid recovery of the affected flock, treatments might appear highly effective if non-treated controls were not maintained for comparison. There are no reports in the literature concerning the use of some of the newer antiviral compounds and interferon inducers for the treatment of IBD.

Prevention and Control

The epidemiology of this infection has not been studied extensively, but it is known that contact with infected birds and contaminated fomites readily causes spread of the infection. The relative stability of this virus to many physical and chemical agents increases the likelihood that it will be carried over from one flock to a succeeding flock. The sanitary precautions that are applied to prevent the spread of most poultry infections must be rigorously used in the case of IBD. The possible involvement of other vectors (e.g., the lesser mealworm, mosquitos, dogs and rats) already has been discussed; they could certainly pose extra problems for the control of this infection.

Management Procedures

At one time, before the development of attenuated vaccine strains, intentional exposure of chicks to infection at an early age was used for controlling IBD. This could be advised on farms that had a history of the disease, and the chicks normally would have maternal antibodies for protection. Also, young chicks less than 2 weeks of age did not normally exhibit clinical signs of IBD. When the severe immunosuppressive effect of early IBD infections was discovered, the practice of controlled exposure with virulent strains became less appealing. On many farms, the

cleanup between broods is not thorough (including buildings and all materials and equipments), and due to the stable nature of the virus, it easily persists and provides an early exposure by natural means.

Immunization

Immunization of chickens is the principal method used for the control of IBD in chickens. Especially important is the immunization of breeder flocks so as to confer parental immunity to their progeny. Such maternal antibodies protect the chick from early immunosuppressive infections. Maternal antibody will normally protect chicks for 1–3 weeks, but by boosting the immunity in breeder flocks with oil-adjuvanted vaccines, passive immunity may be extended to 4 or 5 weeks (12, 148).

The major problem with active immunization of young maternally immune chicks is determining the proper time of vaccination. Of course, this varies with levels of maternal antibody, route of vaccination, and virulence of the vaccine virus. Environmental stresses and management may be factors to consider when developing a vaccination program that will be effective. Monitoring of antibody levels in a breeder flock or its progeny (flock profiling) can aid in determining the proper time to vaccinate. It should be mentioned that although they produce correlated antibody titers, the ELISA and VN tests may result in predicting different dates for vaccine susceptibility in progeny chicks (49). It is therefore advisable that the formulae used for calculating the dates of vaccination be extensively evaluated.

Many choices of live vaccines are available based on virulence and antigenic diversity. According to virulence, vaccines that are available in the United States are classed as mild, mild intermediate, intermediate, intermediate plus, or "hot." Vaccines that contain Delaware variants, either in combination with "classic" strains or alone, are also available. Highly virulent (hot), intermediate, and avirulent strains break through maternal VN antibody titers of 1:500, 1:250, and less than 1:100, respectively (148, 244). Intermediate strains vary in their virulence and can induce bursal atrophy and immunosuppression in 1-day-old and 3-week-old SPF chickens (152). If maternal VN antibody titers are less than 1:1000, chicks may be vaccinated by injection with avirulent strains of virus. Some vaccine virus replicates in the thymus, spleen, and cloacal bursa where it persists for 2 weeks (153). After the maternal antibody is catabolized, there is a primary antibody response to the persisting vaccine virus. A vaccine made by mixing an intermediate plus vaccine strain with a measured amount of IBDV antibody before injection has been used with some success to immunize day-old chicks in the presence of maternal antibody (82).

Killed-virus vaccines in oil adjuvant are used to boost and prolong immunity in breeder flocks. It has been proposed that their antigenic content may be measured by quantifying in the AC-ELISA the amount of VP2 or VP3 contained in the vaccine (156). Killed-virus vaccines are usually not practical or desirable for inducing a primary response in young chickens, however, injection of a fraction of a dose in broiler or pullet chicks between 1 and 10 days of age has sometimes been reported (296, 298). Oil-adjuvant vaccines are most effective in chickens that have been "primed" with live virus either in the form of vaccine (297) or field exposure to the virus. Oil-adjuvant vaccines presently may contain both standard and variant strains of IBDV. Antibody profiling of breeder flocks is advised to assess effectiveness of vaccination and persistence of antibody.

A more recent concept for the vaccination of chickens for IBD and other agents is *in ovo* vaccination at 18 days of incubation (73, 286). *In ovo* is a labor-saving technique and may provide a way for vaccines to circumvent the effects of maternal antibody and initiate a primary immune response. The injected material is a live IBD vaccine, either alone (73) or in combination with an anti-IBDV antibody so as to form immune complexes (286). The working mechanism of *in ovo* vaccination is not yet fully elucidated: *In ovo* injection of an intermediate IBD vaccine alone experimentally resulted in a faster recovery of bursal lesions, as compared with post-hatch vaccination, and in similar protection against challenge (215). Jeurissen proposed the working mechanism of the immune complex vaccine to be related to its specific cellular interactions with follicular dendritic cells in spleen and bursa (124). *In ovo* and post-hatch vaccinations have been recently reviewed by Negash *et al.* (190).

Advances in biotechnologies also allowed the development of new generations of vaccines, most of which are still experimental.

Production of IBD subunit vaccines has been attempted mainly from baculovirus- (164, 251, 273, 274, 302) or yeast- (158, 213) expressed proteins, with a report of expression using a Semliki forest virus vector (211). Several studies reported that baculovirus-expressed recombinant VP2 confered good to very good protection against IBDV challenge (164, 212, 273). The efficacy of baculovirus-expressed recombinant vaccines was shown to critically depend on the conformation and assembly of the expressed proteins (164), which process is now better understood (34, 35). A baculovirus-expressed VP2 protein has been used commercially in broiler breeders, and immunity was transferred to their progeny (302). More recently, Pitcovski *et al.* (213) described an oil-adjuvanted vaccine based on a purified recombinant VP2 antigen expressed in the *Pichia pastoris* yeast. This vaccine induced a protection level similar to conventional inactivated IBD vaccine and has been used in broilers in the field in Israel (213).

DNA vaccination is another approach, still experimental, based on plasmids expressing either the polyprotein gene (71, 31) or the VP2 gene alone (132, 283). Significant levels of protection were observed provided high amounts of plasmid DNA were repeatedly injected. Attempts have been made to increase the efficacy of IBD DNA vaccines, by co-administrating interleukine genes (104, 255) or synthetic oligodeoxynucleotides containing unmethylated CpG dinucleotide motifs (283) with an adjuvant effect, or by changing the route of administration of the DNA vaccine (88).

Finally, live recombinant virus vectors expressing IBDV immunogens have been reported. These include fowlpox virus (13, 28, 90), herpes virus of turkey (HVT) (48, 269), Marek's disease virus (268), CELO virus (72) and Newcastle disease virus (101). Additional recombinant vaccine viruses include IBDV vaccines that have been modified to broaden their antigenic spectrum

(183) or to allow the differentiation of vaccine induced antibodies (21). The only recombinant vaccine that has been licensed so far is derived from HVT and induces an active anti-IBDV antibody response facing high levels of neutralizing maternally derived antibodies (79).

A universal vaccination program cannot be offered because of the variability in maternal immunity, management, and operational conditions that exists. If very high levels of maternal antibody are achieved and the field challenge is reduced, then vaccination of broilers may not be needed. Vaccination timing with attenuated and intermediate vaccines varies from as early as 7 days to 2 or 3 weeks. If broilers are vaccinated at 1 day of age, the IBDV vaccine can be given by injection along with Marek's disease vaccine. Priming of breeder replacement chickens may be necessary, and many producers vaccinate with a live vaccine at 10–14 weeks of age. Killed oil-adjuvant vaccines commonly are administered at 16–18 weeks. Revaccination of breeders may be required if antibody profiling should indicate a major drop in flock titers.

The use of restriction fragment length polymorphisms of the VP2 gene of IBDV can be a powerful tool from an epidemiologic point of view. The original work by Jackwood and Sommer (120) described 5 molecular groups from 13 vaccine viruses and 5 IBDV isolates from the United States. When the same workers (121) examined 81 strains from around the world, they identified 16 more molecular groups. This certainly should indicate that this technique will identify strains of virus but does not indicate antigenic differences in the virus and, therefore, would not be helpful in predicting the immunogenicity of a vaccine.

Chapter 8

Chicken Infectious Anemia Virus and Other Circovirus Infections

---

Introduction

Karel A. Schat and Leslie W. Woods

Classification

Circoviridae form a newly recognized family of viruses infecting mammalian and avian species (26). This family is related to a group of plant viruses known as nanoviruses (29). Porcine circovirus (PCV) was first described in 1974 as a picornavirus-like contaminant in PK15, a pig kidney cell line, without being linked to disease (23). This agent was named circovirus when it was shown that the genome consisted of circular, covalently linked single-stranded DNA. PCV had no similarities to any other known animal virus, but similar physicochemical properties were found in plant pathogens belonging to the geminiviruses (22). A second serotype of PCV (PCV2) has been described that is causing postweaning multisystemic wasting syndrome and perhaps other disease syndromes in piglets (reviewed in 1).

Viruses with similar physicochemical characteristics were detected in chickens and several psittacine species during the 1980s (20, 27). Notable viruses include psittacine beak and feather disease virus (PBFDV or BFDV) associated with feather dystrophy and loss, malformations of the beak and immunosuppression (16), chicken infectious anemia virus (CIAV) (31) and the recently recognized pigeon circovirus (PiCV) (30). These viruses as well as other avian circoviruses are described in detail in chapters 8.1 and 8.2.

Although these animal circoviruses have similar characteristics, there are major differences between CIAV on the one hand, and BFDV and PCV on the other hand. Based on the lack of DNA sequence similarities or common antigenic epitopes, replication strategies, and morphological differences, it was suggested that CIAV belongs to a separate virus group (12). Subsequent studies confirmed that the two groups are indeed different and that PCV, BFDV, and plant circoviruses are closely related (2, 11). The plant circoviruses are currently placed in the genus nanoviruses (9, 29). The vertebrate circoviruses may have evolved as the consequence of a recombinational event in which the N-terminus of the *rep* (replication initiator protein) gene came from a nanovirus and the C-terminal region came from a picorna-like virus (7).

The taxonomy of the *Circoviridae* was changed in 1999 during the XIth International Congress of Virology in Sidney, Australia to better reflect the differences between the different members of the *Circoviridae*. CIAV was assigned as the only member to a new genus, *Gyrovirus*, while PCV and BFDV remained as the only recognized members of the genus *Circovirus* (14). Since then, canary circovirus and goose circovirus were also recognized as species in the genus *Circovirus*, while duck circovirus, finch circovirus, and gull circovirus are listed as tentative species (24).

Viruses with a similar genomic structure but with very limited sequence similarity to CIAV have been described in humans: the so-called TT viruses (TTV) and mini-TT viruses (TTMV). TTV was originally named after the initials of a patient in Japan, in whom it was first identified (reviewed in 3). The working group on the nomenclature of circoviruses has renamed these viruses as torquetenovirus and torquetenominivirus, respectively. These viruses are currently placed in a new genus *Anellovirus*, which is a floating genus unattached to an existing virus family (4). Since the identification of TTV, many similar viruses have been detected in nonhuman primates and other animals, but the clinical relevance of these viruses remains unclear (4).

Avian Circovirus or Circovirus-like Infections

Circoviruses or circovirus-like agents that are distinct from PBFDV, CIAV, and PiCV have been described in other avian species, both free-ranging and domestic. Companion and free-ranging avian species in which circovirus infections have been described include canaries (13), finches (10), starlings (8), ravens (19), a jay (Woods, personal observation), doves (15), and a gull (28). Domestic/poultry avian species with circovirus infections include geese (17), ducks (18), pheasants (21), and ostriches (5). Most infections have been associated with putative immunosuppression with or without feather abnormalities. The primary histopathological changes were lymphocytic depletion in the primary lymphoid tissues in addition to changes associated with secondary infections. In most of these reports, circoviruses or circovirus-like agents have been identified by electron microscopic or molecular-based methods (PCR, *in situ* hybridization).

Antibodies against CIAV were found in Japanese quail (*Coturnix coturnix japonica*) (6). It is not known whether the presence of the antibodies reflects infection of Japanese quail with CIAV or with a related virus. Todd *et al.* (25) suggested that additional circoviruses will probably be discovered in the future—most likely as one of the components in multifactorial diseases.

Chicken Infectious Anemia
K. A. Schat and V. L. van Santen

Introduction

Chicken infectious anemia (CIA) was first recognized by Yuasa *et al.* (260) as a new disease in young chickens caused by a novel virus agent. The disease is characterized by aplastic anemia and generalized lymphoid atrophy with concomitant immunosuppression and is frequently complicated by secondary viral, bacterial, or fungal infections. The virus appears to play a major role in the etiology of a number of multifactorial diseases associated with hemorrhagic syndrome and/or aplastic anemia. Since the first description of this disease and subsequent isolation in cell culture of the virus in Japan (247), the virus has been isolated in virtually all countries with a poultry industry. In addition to anemia and associated syndromes, subclinical chicken infectious anemia virus (CIAV) infections, without anemia and increased mortality, are frequently observed in commercial flocks.

Definition and Synonyms
The terminology for the causative agent has varied over the years. The agent was originally designated chicken anemia agent (CAA) (260), but after morphologic and biochemical characterization (53, 123, 207), it was renamed chicken anemia virus (CAV) (53, 138). The name CAV has been accepted by the International Committee for the Taxonomy of Viruses (203). However, because the disease is commonly referred to as chicken infectious anemia, the causative virus is more logically referred to as chicken infectious anemia virus (CIAV) (239). This terminology will be used in this chapter.

CIA and closely associated syndromes have commonly been termed *hemorrhagic syndrome* (255), *anemia-dermatitis* (228), or *blue wing disease* (8, 48).

Economic Significance
Infection with CIAV has been confirmed as the cause of disease in chicken flocks between 2 and 4 weeks of age with syndromes suggestive of infectious anemia (12, 23, 28, 45, 63, 74, 101, 122, 162, 174, 192, 228, 241, 255). In these flocks growth was retarded and mortality was generally between 10 and 20%, but occasionally it reached 60%. In chickens 6 or more weeks of age, the etiologic significance of CIAV infection associated with aplastic anemia-hemorrhagic syndromes (64, 151, 257) has not definitely been established.

Infection with CIAV constitutes a serious economic threat, especially to the broiler industry and the producers of specific-pathogen-free (SPF) eggs. McIlroy *et al.* (112) reported a loss of net income of about 18.5% due to decreased weight at process-

ing and increased mortality around 3 weeks of age in 15 broiler flocks. Approximately 29% of these broilers were derived from a common breeder flock, which was free of CIAV antibodies at 20 weeks of age, making the offspring susceptible to CIAV infection at a very early age. Interestingly, feed conversion ratios were not affected in the broilers with CIA. Davidson *et al.* (35) documented 14–24% reductions in weight of meat sold, as well as changes in feed conversion ratios, from CIAV-infected flocks exhibiting clinical signs characteristic of CIA.

Studies addressing the impact of subclinical CIAV infection on broiler flock performance have yielded conflicting results. In one study subclinically infected flocks in Northern Ireland yielded a 13% lower net income than CIAV antibody-negative flocks, mostly due to decreased weight at processing and suboptimal feed conversion ratios (125). A Belgian study demonstrated a higher slaughterhouse condemnation rate in CIAV positive flocks compared to CIAV negative flocks, but was unable to detect differences in other performance criteria (38). However, others were unable to confirm the negative influence of subclinical infection on production in the United States (61) and Denmark (96). In a retrospective case-control study in the United States, although presence of CIAV was found to be a risk factor for disease (gangrenous dermatitis, coccidiosis or respiratory disease), and disease was associated with production losses, the detection of CIAV alone was not associated with statistically significant decreases in performance or losses in production (69). It is likely, however, that the impact of subclinical infection with CIAV is underestimated, especially because subclinical infection reduces the development of antigen-specific cytotoxic T lymphocytes (CTL) significantly (109) and also adversely affects macrophage function (110).

The economic importance for the SPF industry is difficult to estimate, but seroconversion frequently occurs during the laying period (55, 246). As a consequence of seroconversion the flock is considered positive and the eggs are no longer SPF. The importance of this depends on legislation for vaccine production. The European Union requires the absence of CIAV from eggs used for the production of all poultry vaccines for administration in birds less than 7 days of age. Eggs from CIAV-positive flocks may be used according to USDA guidelines. Vaccines for human use, such as measles and mumps, require the use of eggs free of CIAV in Australia, Europe, and the United States.

Public Health Significance
CIAV infection has only been recognized in chickens, turkeys (177) and perhaps Japanese quail (50) and some European

Corvids (18), but circoviruses or circo-like viruses have been found in other species of birds and mammals (202). Results of serologic tests suggest that CIAV has no public health significance (239).

History

CIAV (Gifu-1 strain) was first isolated in 1979 in Japan by Yuasa *et al.* (260). However, the virus was present in chickens at least as early as 1970, when Jakowski *et al.* (87) described a condition of hematopoietic destruction in chickens with Marek's disease. The ConnB isolate of CIAV was later isolated from an ampoule of tumor cells obtained from these chickens (188, 243). The recent demonstration of CIAV antibodies in archived sera indicates that CIAV was present in chickens in the United States as early as 1959 (215).

A major breakthrough was achieved in 1983 when Yuasa *et al.* (257) reported that virus could be propagated in certain chicken lymphoblastoid cell lines, e.g., Marek's disease chicken cell (MDCC)-MSB1 (MSB1), causing cytopathic effects (CPE). This enabled the development of *in vitro* serological assays such as indirect immunofluorescence assays (234, 254) and virus-neutralization (VN) tests (234, 258). In addition virus could be easily purified from supernatant fluids of CIAV-infected cell cultures and characterized (53, 65, 80, 123, 207).

Virus identification was followed by studies that unraveled much of the pathogenesis and epizootiology of the infection. In the early 1990s, remarkable progress was made in research on the molecular biology of CIAV (reviewed in 144, 202). This resulted in the development of refined diagnostic methods and the potential for development of new types of vaccines (85, 99, 141).

Aplastic anemia syndromes, including inclusion-body hepatitis, were described many years before CIAV was detected. Their possible etiologic association with CIAV infection has been reviewed and discussed in several papers dealing with CIA (117, 166, 232).

Etiology

Classification

CIAV is classified as the only member of the genus *Gyrovirus* of the *Circoviridae* (167). The nomenclature of the *Circoviridae* is discussed in more detail in the introduction of Chapter 8.

Morphology

CIAV virions consist of nonenveloped, icosahedral particles with an average diameter of 25 to 26.5 nm using preparations negatively stained with 1% uranyl acetate (53, 80, 123). In such preparations, two types of virus particles differing in their orientation on the grid are commonly detected. Type I particles exhibit three-fold rotational symmetry and show a pattern of one central hollow surrounded by six neighboring hollows with a center-to-center distance of 7.5 nm, forming a regular surface network (Fig. 8.1B). Type II particles exhibit five-fold rotational symmetry and are characterized by 10 evenly spaced surface protrusions giving the impression of a cog-wheel structure (Fig 8.1A). The

appearance of these particles suggested a regular T = 3 icosahedron with 32 morphologic subunits (53, 123). However, more recent modeling of unstained cryopreserved CIAV particles indicated a T = 1 lattice with 60 copies of VP1 in a capsid consisting of 12 pentagonal trumpet-shaped capsomeres. These protruding capsomeres distinguish CIAV from other *Circoviridae*, which have a smoother capsid surface (30).

Thin sections of CIAV-infected MSB1 cells, labeled with CIAV-specific monoclonal antibodies (MAb) and gold-labeled secondary antibodies, demonstrated the presence of intranuclear inclusions, often with a doughnut shape (123). All three viral proteins can be associated with apoptotic bodies, which show as electron-dense structures (42, 140, 210). In a minority of cells, virus particles were detected in the cytoplasm in association with microtubules (123).

Virions have a buoyant density in cesium chloride gradients variously reported as 1.33–1.34 g/mL (5, 207) or between 1.35 and 1.37 g/mL (53, 65). The sedimentation coefficient of CIAV has an estimated value of 91S in isokinetic sucrose gradients (5).

Chemical Composition
Viral DNA

The genome of CIAV consists of single-stranded, circular, covalently closed DNA (53, 207) of negative sense (138). The sequences of the complete genomes of many isolates have been determined (13, 24, 25, 51, 70, 84, 98, 127, 138, 170, 187, 224, 225, 244, 245). Nearly all CIAV viral genomes are 2298 nucleotides in length, and contain four 21-base direct repeats (DR), with a 12-base insert between the second and third DR. Todd *et al.* (204) reported that a fifth DR was obtained after about 30 passages of the Cux-1 strain in MSB1 cells, yielding a 2319-nucleotide genome. If the fifth repeat is present it is located upstream of the 12-bp insert. In infected cells, both single-stranded and double-stranded DNA are present, but virions contain only the circular minus-strand DNA (138, 161).

All sequenced strains have three partially overlapping ORFs coding for proteins of 52 (VP1, ORF1), 24 (VP2, ORF2) and 13 kDa (VP3, ORF3), one promoter region, and one polyadenylation signal. ORF3 is located within ORF2, and ORF2 partly overlaps ORF1. This genomic organization distinguishes CIAV from other members of the *Circoviridae*, which transcribe mRNA from both strands of their replicative intermediates, making their genomes ambisense (135).

The promoter-enhancer region, consisting of the four or five 21-base DR and the 12-base insert, is located upstream of ORF2 (143). The repeat units and the 12 bp insert contain recognition sites for different transcription factors (127, 131, 138). Optimal transcription requires both the DR and the 12 bp insert. The presence of the extra repeat enhanced transcriptional activity (143), whereas deletion of the first two DR reduced transcriptional activity by 40 to 50% (161). Disruption of the relative spacing of the DR region with other promoter elements and the start of transcription by insertion of a 7-bp linker decreases rate of virus replication in culture (142). The DRs contain sequences similar to the estrogen response element consensus half sites and compete with estrogen response elements for estrogen receptor bind-
8.1. Electron micrographs of chicken infectious anemia virus (CIAV). Different structural aspects of the CIAV capsids become apparent in negative-stained preparations. Two types of particle projections are obvious. A. Particle projection type II characterized by 10 peripheral protrusions. ×250,000. Bar = 100 nm. (Gelderblom) B. Projection type I showing CIAV capsids that exhibit 6 stain-filled morphologic units that surround one central hole.

ing in nuclear extracts (131). Expression from the CIAV promoter is higher in cells expressing estrogen receptor and is further increased by addition of estrogen (131). Noteborn (unpublished data cited in 142) found that CIAV DNA containing three DR but lacking the 12 bp insert was not able to produce viable virus particles. Although the 12-bp insert binds the transcription factor SP1 (143), substitution of a different 12-bp sequence did not further impair replication of virus already impaired by insertion of a 7-bp linker between the DR region and the rest of the CIAV promoter (142). Some changes in the length of the 12 bp insert region resulted in decreased cytopathogenicity and rate of spread in culture, but the virus neutralizing epitope was still produced (142). Sequences downstream of the transcription start site negatively regulate transcription (131).

Initially, only one unspliced, polycistronic mRNA of 2.1 kb, containing all three ORFs, was identified. Use of internal AUG start codons is required for the synthesis of VP1 and VP2 (139, 161). More recently, minor spliced mRNAs were identified in addition to the major unspliced mRNA by both Northern blotting and RT-PCR (97). One of the spliced mRNAs encodes a protein that shares amino- and carboxy-terminal sequences with VP1, but lacks 197 amino acids (positions 132–328) of VP1's 449 amino acids. Other spliced mRNAs encode novel proteins with frame-shifts. However, protein products of the spliced mRNAs have not yet been demonstrated.

Viral Proteins

A 50-kDa viral protein (VP1) is the only protein detected in highly purified virus particles (207). The N-terminal 40 amino acids show a limited similarity to histone proteins, suggesting a DNA binding role perhaps within the virus capsid (25, 127). The non-structural 30 kDa VP2 probably acts as a scaffold protein during virion assembly, so that VP1 folds in the proper way (99, 141). The third viral protein, VP3 (16 kDa) is associated with nu-

clei in infected cells (22, 42, 140), but not with highly purified virus particles (14).

Studies using neutralizing MAb on Western blots suggested that the neutralizing epitope(s) are conformational in nature and may consist of VP1 and VP2 components (14). This hypothesis was supported by studies showing that VP1 and VP2 were present in the same nuclear structures in infected cells (42). In addition, neutralizing antibodies were induced after inoculation of chickens with insect cells containing both VP1 and VP2, but not with cells containing only VP1 or VP2 (99). Virus-neutralizing MAb reacted with baculovirus-produced VP1 only if VP2 was co-produced. However, virus-neutralizing MAb bind to the native VP1 in virus capsids, which contain no VP2, but not to denatured VP1, lending further support to the role of VP2 as a scaffolding protein (141).

VP2 and VP3 are nonstructural proteins. VP2 is a multifunctional protein. In addition to its putative role as a scaffold protein enabling VP1 to attain its proper conformation, VP2 has serine/threonine and tyrosine protein phosphatase activities (159). VP3, also named apoptin, is a strong inducer of apoptosis in chicken thymocytes and chicken lymphoblastoid cell lines (140).

Virus Replication

Virions probably enter the cell by conventional adsorption and penetration. Low levels of the 2.1-kb polycistronic viral RNA transcript can be demonstrated at 8 hours post infection of MSB1 cells, with maximum levels attained at 48 hours (139, 161). Initially, only one unspliced mRNA of 2.1 kb and a minor transcript of approximately 4 kb were identified (161). More recently, minor spliced mRNAs in addition to the major unspliced mRNA were identified by both Northern blotting and RT-PCR (97).

Viral DNA replication occurs via a double-stranded replicative form (RF), probably by the rolling-circle mechanism (209). The

initiation site for the DNA replication has not been identified, although Bassami *et al*. (7) reported the presence of a nonanucleotide motif that may be involved in the initiation of DNA replication. Transfection experiments with the cloned tandemly-repeated CIAV RF suggest that homologous recombination can occur (209). This process can lead to double-stranded circular molecules that are identical to RF. The double-stranded RF may lead to the presence of latent episomal DNA and be responsible for the presence of viral DNA in gonadal tissues as reported by Cardona *et al*. (20). Todd (202) suggested that VP1 may have a role in DNA replication based on the presence of 3 amino acid motifs associated with rolling-circle replication of DNA.

VP3 can be detected at 6 hours, while VP2 is present at 12 hours post infection. The capsid protein VP1 is not detectable until 30 hours post infection (42).

The protein phosphatase activity of VP2 is very important, but not absolutely required, for CIAV replication. CIAV with a mutation of the catalytic cysteine of VP2 that abolishes both serine/threonine and tyrosine phosphatase activities (159) exhibits impaired replication and cytopathogenicity in MSB1 cells, reaching titers 10,000-fold lower than wild-type virus (160). Surprisingly, another VP2 catalytic site mutation that increases the tyrosine phosphatase activity and reduces serine/threonine phosphatase activity by only 30% impairs viral replication to a similar degree as the mutation abolishing both phosphatase activities (160). Other VP2 mutations, expected to have only subtle or no effects on protein phosphatase activity, resulted in varying degrees of impairment of CIAV replication (158). Unfortunately, the phosphatase activity of these other VP2 mutants was not reported. In addition to impaired replication, the VP2 mutants apparently exhibit reduced cytopathogenicity, which must be assessed subjectively, in culture. Interestingly, one VP2 mutation results in reduced cytopathogenicity without affecting viral replication efficiency, which suggests that viral replication functions and cyopathogenicity can be separated. In contrast to wild type CIAV, in cells infected with VP2 mutants, VP3 is cytoplasmic rather than nuclear in location, suggesting a role for VP2 in VP3 trafficking and function. This is significant, because the nuclear location of VP3 correlates with its ability to cause apoptosis in transformed, but not primary cells, where VP3 remains cytoplasmic (see below).

VP3 is essential for the virus replication cycle (Noteborn, unpublished data quoted in 140). Truncated apoptin lacking the last 11 amino acids is unable to induce apoptosis in transfected MSB1 cells (140). Interestingly, VP3 was found to induce apoptosis in several malignant human lymphoblastoid cell lines (264) and human osteosarcoma cells (265), but not in normal human cells (31). This finding has been confirmed in more than 70 cell types tested and extended to growth-transformed cells and cells from cancer-prone individuals exposed to UV irradiation (reviewed in 149 and unpublished observations cited in 172), but recently VP3 has been shown to induce apoptosis in a few normal human cell lines (68). Animal experiments using adenovirus vectors expressing VP3 suggest that VP3 may be used to treat humans with cancer (163, 221).

The potential of VP3 as an anti-tumor agent has stimulated in-vestigation into the mechanism whereby it induces apoptosis in transformed cells. In order to induce apoptosis, VP3 must be phosphorylated on a specific threonine residue near the carboxy terminus by a cellular kinase, resulting in a predominantly nuclear location of VP3 (172, 263). This specific phosphorylation of VP3 also occurs in CIAV-infected MSB1 cells (172). Nuclear location of VP3 is necessary but not sufficient for induction of apoptosis (34). VP3 functions as a stable, but non-covalent multimer or aggregate containing approximately 30–40 copies (103). Considerable evidence has accumulated suggesting that VP3 triggers apoptosis via the intrinsic mitochondrial death pathway. Thus, VP3 triggers loss of mitochondrial membrane potential and release of cytochrome c and apoptosis-inducing factor from mitochondria (15, 33, 107). The apoptosis-inducing factor released from the mitochondria in response to VP3 is relocated to the nucleus, where it colocalizes with VP3 (107). Furthermore Apaf-1, a component of the apoptosome assembled after release of cytochrome c from the mitochondria, is required for VP3-induced apoptosis (15), whereas FADD and caspase 8, important signaling components of the extrinsic death receptor signaling pathway, are not (33, 107). Release of mitochondrial components triggered by VP3 results in activation of the cellular caspases 3 and 7, downstream caspases of the apoptotic pathway that are essential for the execution of programmed cell death (15, 33). Caspase 3 contributes to VP3-induced apoptosis, but is not essential, likely because other downstream caspases can substitute for caspase 3 (15, 107). The only evidence inconsistent with VP3 inducing apoptosis via the mitochondrial pathway are reports that Bcl-2, which inhibits activation of the mitochondrial death pathway, enhanced rather than inhibited VP3-induced apoptosis (32, 264). However, others have shown an inhibition of VP3-induced apoptosis by Bcl family members Bcl-2 and Bcl-X_L, consistent with other evidence that VP3 triggers apoptosis via the mitochondrial pathway (15, 107). No explanation for the contradictory results was proposed.

Recent studies have provided insight into the mechanism whereby VP3 triggers the intrinsic mitochondrial death pathway. The process does not require p53 (265) or cellular RNA or protein synthesis (34). VP3 possesses functional nuclear localization and nuclear export signals (34, 71, 164, 165) and its capacity to shuttle between the nucleus and cytoplasm is essential for its ability to induce apoptosis (71). Phosphorylation of the specific threonine residue, which is necessary for predominantly nuclear location of VP3, inhibits one of the nuclear export signals (164). VP3 associates with predominantly cytoplasmic anaphase-promoting complex and recruits it to nuclear PML bodies, which are known to be involved in apoptosis (71). Association of VP3 with the APC1 subunit of anaphase-promoting complex, which functions in the mitotic checkpoint of the cell cycle, disrupts the complex and results in degradation of its components and G2/M cell cycle arrest (199). The transduction of the apoptotic signal from the nucleus to the mitochondria is thought to depend on Nur77, which is essential for induction of apoptosis by VP3 (107). VP3 associates with Nur77, resulting in movement of Nur77 from the nucleus to mitochondria. Movement of Nur77 from the nucleus to mitochondrial outer membranes, resulting in release of

cytochrome c, also occurs in response to various other apoptotic stimuli that trigger the intrinsic death pathway (104). As mentioned above, mutations in VP2 reduce the nuclear location of VP3 in CIAV-infected cells (158). However with the exception of demonstration of phosphorylated VP3 in CIAV-infected cells (172), studies on the mechanism of apoptosis induction by VP3 have all been conducted in the absence of VP2, so the influence of VP2 on VP3 induction of apoptosis has not been examined.

Whether VP3 has functions in the CIAV replication cycle in addition to induction of apoptosis is not known. However, VP3 multimers form non-sequence-specific complexes with double- and single-stranded DNA and with RNA, with preference for ends in double-stranded DNA (102). Association with VP3 induces bends in DNA. These observations suggest VP3 could affect gene expression or DNA replication.

The replication of CIAV in very young chickens occurs primarily in hemocytoblasts in the bone marrow and T cell precursors in the cortex of the thymus (reviewed in 1, 133). Replication of the virus in the cortex of the thymus results in cell death by apoptosis (91) caused by VP3. Virus replication has also been demonstrated in other organs, where it is often but not always associated with lymphocytes (185). In chickens infected at 3 or 6 weeks of age, CIAV replicates in the thymic cortex, but CIAV-positive cells are rare in the bone marrow (184).

Resistance to Chemical and Physical Agents

Chicken infectious anemia virus is extremely resistant to most treatments (117). Yuasa (249) and Yuasa *et al*. (260) examined the effectiveness of different treatments to inactivate CIAV. Treatment of virus in liver suspensions with 50% phenol for 5 minutes inactivated CIAV but treatment with 5% phenol for 2 hours at 37°C was ineffective. The virus was found to be resistant to treatment with 50% ethyl ether for 18 hours and chloroform for 15 minutes. Treatment of liver suspensions with 0.1 N NaOH for 2 hours at 37°C or 24 hours at 15°C inactivates CIAV incompletely. Treatment with 1% glutaraldehyde for 10 min at room temperature, 0.4% β-propiolactone 24 hours at 4°C, or 5% formaldehyde 24 hours at room temperature inactivates the virus completely. Commercial disinfectants based on invert soap, amphoteric soap, or orthodichlorobenzene are not effective against CIAV. Treatments with iodine or hypochlorite are effective, but require 2 hours at 37°C with final concentrations of 10% rather than the generally recommended concentrations of 2%. Formaldehyde or ethylene oxide fumigation for 24 hours does not inactivate CIAV completely. The virus is also resistant to acid treatment at pH 3 for 3 hours. Treatments with disinfectants with pH 2 are widely used by the SPF industry and are apparently effective in inactivating the virus (55, 246).

CIAV is also resistant to treatment with 90% acetone for 24 hours (198). As a consequence, acetone-fixed slides of CIAV-infected material may remain infectious and need to be sterilized prior to final disposal. CIAV is resistant to heating at 56°C or 70°C for 1 hour and at 80°C for 15 minutes (45, 64, 260). However, it is only partially resistant to heating at 80°C for 30 minutes, and is completely inactivated within 15 minutes at 100°C (64). Inactivation of CIAV in infected chicken byproducts requires a core temperature of 95°C for 35 minutes or 100°C for 10 minutes, whereas fermentation was ineffective (220).

Strain Classification

Antigenicity

No antigenic differences have been recognized among various Japanese, European, and American isolates of CIAV using polyclonal chicken antibodies (45, 231, 234, 251). As a consequence, it is generally accepted that all strains belong to one serotype (117, 144). However, based on differences in reaction patterns with MAb (124, 178, 186) and DNA sequence differences resulting in changes in the predicted protein folding patterns (170), it is expected that strains may differ in their antigenicity.

A second serotype of CIAV, represented by CIAV-7, has been proposed (190, 191). CIAV-7 has characteristics such as small size and resistance to heat, acid, and chloroform similar to CIAV (191), and produces similar clinical disease and gross and microscopic lesions (190). However, thymic and bone marrow lesions and anemia produced by CIAV-7 are much milder than those generated by CIAV. Furthermore, the lack of any antigenic cross reactivity using polyclonal chicken sera and lack of cross hybridization under low-stringency conditions suggest that CIAV-7 is a novel virus rather than a new serotype of CIAV. Some progeny from several breeder flocks in the eastern United States are protected from CIAV-7 challenge, suggesting that the novel virus is prevalent in this region.

Molecular Differences

Partial or complete genome sequences of numerous strains from different parts of the world have been determined and amino acid sequences predicted. In general, most strains are very similar. Todd *et al*. (213) assigned CIAV isolates to seven groups based on restriction-enzyme analysis of a polymerase chain reaction (PCR)-amplified 675-bp fragment coding for the N-terminal half of ORF3. It is not clear whether these groups differ biologically. Minor differences in predicted amino acid sequences have been noted, especially for the amino acids 139–151 of VP1 (hypervariable region), and also at the carboxy terminus of VP2 and VP3 (170). The predicted protein structure of VP1 is affected by the observed differences in the hypervariable region (170). Similar differences in this region of VP1 have been reported for isolates from Brazil (137, 182) and Australia (13). Only two different hypervariable regions were found among 14 CIAV sequences from commercial broilers in one state in the United States (224). Genomes encoding these two hypervariable regions could be distinguished by restriction-enzyme analysis of a PCR product (224). Changes in the hypervariable region as well as other locations in VP1 occur during passage in culture (24, 70, 178, 244). Chimeric constructs in which a fragment encoding the hypervariable region had been exchanged between the highly passaged Cux-1 and low-passage CIA-1 strains demonstrated that differences in the hypervariable region influence virus replication in MSB1 cells (170). However, low-passage field isolates with different hypervariable regions could not be differentiated based on their replication in cell culture (225). The importance of the hypervariable region for *in vivo* pathogenicity is not clear. Meehan

et al. (126) examined the pathogenicity of a number of chimeric viruses with multiple changes, including those in the hypervariable region, and concluded that changes in the hypervariable region did not contribute disproportionately to pathogenicity. However, studies with changes only in this region have not been reported, and the question of the importance of the hypervariable region for the pathogenicity remains unresolved.

Although more variability has been found as more CIAV sequences become available, variability remains minor. Several authors have divided CIAV into groups based on nucleotide or amino acid sequence relationships (84, 100, 182, 224). These analyses indicate that genetic relatedness of CIAV sequences does not correspond to geographic location. Phylogenetic patterns based on nucleotide sequence comparisons and predicted amino acid sequence comparisons differ from each other (224). Furthermore, apparent phylogenetic relationships may be influenced by adaptation to culture (24). For these reasons, the significance of groupings based on phylogenetic relationships of CIAV sequences is unclear.

Pathogenicity

Although it is generally accepted that strains isolated worldwide do not differ substantially in pathogenicity, very few studies have directly compared different strains under identical experimental conditions. Yuasa and Imai (251) compared 11 isolates, which were each passaged 12 times in MSB1 cells prior to inoculation. Minor differences in virulence were found when chicks were inoculated at 7 days but not at one day of age; inoculation at 14 days of age failed to induce anemia. Natesan *et al.* (134) compared the pathogenicity of four isolates in one-day-old chicks and detected no differences. Toro *et al.* (217) reported thymus and bone marrow lesions when 10-week-old broiler breeders were infected with strain 10343, but comparative studies with other isolates in these birds were not reported.

Attenuation

Attenuation of CIAV (Cux-1) has been reported after as few as 49 passages in MSB1 cells by von Bülow and Fuchs (233). Pathogenicity was further decreased but not completely lost during additional passages up to 100 passages. Goryo *et al.* and Yuasa (65, 247) found no decrease in pathogenicity of other CIAV isolates after 19–40 passages, and Tan and Tannock (194) did not detect attenuation even after 129 passages. However, Todd *et al.* (204) found that Cux-1 became substantially less pathogenic after 173 passages in MSB1 cells. Attenuation resulted in genetically diverse virus populations. Molecularly cloned isolates from attenuated virus were indeed less pathogenic than the original isolate, but attenuation may not be stable. One isolate reverted back to pathogenicity after 10 passages in young chicks. However, because all molecular clones of the revertant virus tested were attenuated, the molecular change(s) responsible for recovery of pathogenicity could not be identified (206).

Additional passages of Cux-1 to passage 320 (p320) in MSB1 cells led to further attenuation (205). Nine molecular clones of p310 of Cux-1 were further analyzed for antigenicity and pathogenicity. Most clones were attenuated substantially although not completely; the number of chickens developing anemia after infection with most clones varied from 0 to 31%, while one clone caused anemia in 67% of the birds, versus 50–83% with the low passage virus (178). The pathogenicity of a substantially attenuated p320 molecular clone (CI 34) and a highly attenuated molecular clone (CRI 18) derived from CIAV passaged 173 times in MSB1 cells, ten times in SPF chickens, then seven times in MSB1 cells was investigated further (113). Neither attenuated CIAV caused reduction in hematocrit values. Thymic atrophy was absent in chickens infected with CRI 18 and milder and of shorter duration in chickens infected with CI 34 compared to low passage Cux-1. Flow cytometry showed that although both attenuated clones caused depletion of both CD4$^+$ and CD8$^+$ T cells in the thymus, depletion was significantly less than caused by low passage Cux-1. With regard to T cell depletion of the thymus, CRI 18 is more highly attenuated than CI 34. It is not known whether attenuation of these clones is stable after passage in chickens.

Differences between clones were also noted in reactivity patterns with MAb. Attenuated p320 clones exhibited reduced reactivity with neutralizing MAb 2A9, which reacts with a conformational epitope (178). Selection of a pool of MAb 2A9-resistant CIAV from p320 resulted in substantially attenuated virus, which produced no anemia or thymic atrophy in some experiments, compared to up to 90% anemic chickens produced by low passage virus. Investigation of the molecular basis of attenuation using a chimeric virus approach mapped the change(s) responsible for attenuation to the portion of the genome encoding the amino terminus of VP1 and the carboxy portions of VP2 and VP3 (179). Further studies of the basis for attenuation of p320 clones using chimeric viruses and CIAV with a site-specific mutation at VP1 codon 89 showed that change of VP1 amino acid 89 from threonine to alanine was necessary, but not sufficient, for attenuation exhibited by p320 CIAV clones. Cux-1 containing the mutation in VP1 codon 89 in conjunction with other changes in VP1 found in CI 34 (codons 75, 125, 141, and 144) exhibited pronounced attenuation, causing neither anemia, pale bone marrow nor thymic atrophy (214). Three of these changes (at codons 75, 125, and 144) substitute amino acids with similar properties and have also been observed in field isolates (84, 182, 224).

Yamaguchi *et al.* (244) selected molecular clones with reduced pathogenicity from a non-attenuated 10th passage virus pool of a different CIAV isolate, AH9410. Three of eight clones tested showed reduced ability to cause mortality and reductions in hematocrit and weight gain. A single amino acid difference (histidine at VP1 position 394) distinguished molecular clones with reduced pathogenicity from highly pathogenic molecular clones (glutamine at VP1 position 394). Introduction of this single amino acid change into a highly pathogenic molecular clone of a different CIAV isolate that had been passaged 39 times in MSB1 cells resulted in CIAV with greatly reduced pathogenicity; infection caused no mortality and resulted in hematocrits and weight gain indistinguishable from uninfected chickens. Viral loads in the liver of chickens infected with the attenuated viruses were approximately 10-fold lower than in chickens infected with the highly pathogenic clones. Effects of the attenu-

ated viruses on the thymus and T cells and stability of the attenuation were not examined.

Chowdhury *et al.* (24) found, based on ability to cause anemia and thymic atrophy, that two Malaysian CIAV isolates were attenuated by 60 passages in MSB1 cells. One of the isolates was further attenuated by passage up to passage 123. However, pathogenicity of the passaged viruses was not directly compared to low passage virus in the same experiment. Sequence analysis of the p60 viruses showed multiple changes in the predicted amino acid sequences of VP1. Surprisingly, the two isolates were more similar to each other after 60 passages than before passage, suggesting that specific changes had been selected during passage. Stability of attenuation and which changes were responsible for attenuation were not examined. Changes in VP1 amino acid 89 or 394, found by Todd *et al.* and Yamaguchi *et al.*, respectively, to be crucial for attenuation during passage in cell culture, were not found in Chowdhury's study, showing that different changes occurring during passage of CIAV in culture may each result in attenuation.

Laboratory Host Systems

CIAV can be propagated and assayed in cell cultures, 1-day-old chicks, or in chicken embryos.

Cell Cultures

The use of cell cultures is the preferred method for virus isolation and propagation since Yuasa (247) reported that some lymphoblastoid T cell lines (e.g., MDCC-MSB1 and MDCC-JP2) and the B cell line LSCC-1104B1 are suitable for propagation and assay of CIAV. However, many other T cell and B cell lymphoblastoid cell lines, whether producers or nonproducers of the respective transforming viruses, are resistant to CIAV (17, 235, 247).

Until recently MSB1 cell cultures were preferred for *in vitro* cultivation, although sublines of MSB1 differ in their susceptibility to infection. Some strains of CIAV, e.g., CIA-1 (105) may not replicate at all in one subline of MSB1 (MSB1-L) and poorly in another subline of MSB1 (MSB1-S), whereas both sublines are susceptible to infection with Cux-1 (170, 171). Furthermore, sensitivity of susceptible MSB1 cells to CIAV is reduced after subculturing the cells as little as 8 weeks (17, 234). Currently, the MDCC-CU147 (CU147) cell line seems to be the best cell line for propagation of CIAV, including the CIA-1 strain (17). In comparative assays, infection of CU147 with Cux-1 resulted in the detection of VP3 at 3 days post infection, while MSB1 cells did not become positive until 5 days post infection. Moreover, the percentage of positive cells was significantly lower in MSB1 cells than in CU147 cells at that time. Furthermore, the sensitivity of CU147 cells to CIAV is not reduced by subculturing up to 82 days. CU147 cells are also more sensitive than MSB1 cells for regeneration of CIAV from CIAV genomes molecularly cloned directly from field specimens without previous isolation of the virus (225).

Virus titrations require subculturing of inoculated cells every 2–4 days until cells inoculated with the endpoint dilution of CIAV are destroyed (234, 247). Alternatively, endpoints can be determined by PCR (223) or immunofluorescence (17) assay.

Chickens

Inoculation of one-day-old chicks free of maternal antibodies can be used to isolate and propagate CIAV in instances where the clinical syndrome suggests that CIAV may be present, but *in vitro* virus isolation and/or PCR assays are negative. Positive chicks develop anemia and gross lesions in lymphoid tissues and bone marrow after 12–16 days (260). Mortality may occur between 12 and 28 days post-inoculation but usually remains low, rarely exceeding 30%. Neonatally (253) or embryonally bursectomized (105) chicks can be used to enhance the sensitivity of isolation, especially if samples with low titers are analyzed. Chicks with maternal anti-CIAV antibody are resistant to CIAV infection and cannot be used for isolation or propagation of CIAV (256).

Chicken Embryos

Propagation of CIAV in chicken embryos following yolk sac inoculation has been reported by von Bülow and Witt (240). Moderate virus yields were obtained after 14 days from all parts of the embryo, but not from yolk or chorioallantoic membrane. Lesions were not observed after inoculation with the Gifu-1 and Cux-1 strains of CIAV. Some strains, however, may cause significant embryo mortality between 16 and 20 days of incubation. The CL-1 strain caused up to 50% mortality, with embryos being small, hemorrhagic, and edematous (101). The Australian vaccine strain 3711 also caused up to 50% embryo mortality (194).

Pathobiology and Epidemiology

Incidence and Distribution

Serological data had suggested that CIAV is ubiquitous in all major chicken-producing countries of the world (reviewed in 117, 232, 239). This was confirmed by virus isolation from chickens in all continents (176).

Natural and Experimental Hosts

The chicken is the only known host for CIAV. All ages are susceptible to infection, but susceptibility to anemia rapidly decreases in immunologically intact chicks during the first 1–3 weeks of life (64, 173, 251, 259, 260), although some strains have been reported to cause a reduction in hematocrit values after experimental infection of 10-week-old broiler breeders (217). Chickens 3 weeks of age and older continue to be susceptible to effects of CIAV on immune function (109, 110, 168, 184, 217).

Antibodies to CIAV have been detected in Japanese quail but not in ducks, pigeons and crows in Japan, but information on the specific species was not provided (50). Fancy chicken breeds in The Netherlands were frequently positive for CIAV antibodies (39). A survey in Ireland found CIAV antibodies in jackdaws, rooks and rare avian breeds, but not in pigeons, pheasants or ducks (18). McNulty *et al.* (120) failed to detect antibodies in turkey and duck sera. Turkey poults inoculated at 1 day of age with high doses of the virus were resistant to infection and did not develop antibodies to CIAV (unpublished data cited in 117). However, a circovirus similar to CIAV, but with low pathogenicity in chickens, has been isolated from turkeys (177).

Transmission

CIAV spreads both horizontally and vertically. Horizontal transmission is very likely based on the presence of high concentrations of virus in the feces of chickens for 5–7 weeks after infection (72, 258). Horizontal infection by direct or indirect contact most likely occurs via the oral route, but infection via the respiratory route, as shown in chicks after intratracheal inoculation (173), may also be possible in the field. Virus shedding occurs through the feces and perhaps through feather follicle epithelium as recently suggested by Davidson and Skoda (36). CIAV spreads easily among chickens in a group only if they are immunosuppressed (259). In field flocks naturally exposed to CIAV, it commonly takes 2–4 weeks until most birds have seroconverted (120, 189, 231). Isolation may prevent early seroconversion; 70% of grandparent flocks that were imported into Sweden and kept in quarantine remained seronegative until 16 weeks of age (46).

It is important to differentiate vertical transmission in commercial flocks from that in SPF flocks that may experience sporadic outbreaks. In the former, vertical transmission of virus through the hatching egg is considered to be the most important means of dissemination (23, 46). Vertical transmission of virus occurs when antibody-negative hens become infected by horizontal infection or by semen from infected cocks (73). Egg transmission only occurred from 8–14 days after experimental infection of hens (72, 261). After the development of immune responses egg transmission of virus could not be demonstrated, even when birds were stressed by injections with betamethasone or exchanging hens in cages. Field observations indicate that vertical transmission can occur during a period of 3–9 weeks after exposure with peak transmission at 1–3 weeks. The duration of egg transmission depends on the rate of spread of infection and development of immunity to CIAV (8, 23, 48, 228). In contrast to earlier studies showing the absence of vertical transmission after the development of antibodies, more recent studies have demonstrated CIAV DNA in progeny of hens with high titers of neutralizing antibody. Detection of CIAV relied on highly sensitive nested PCR, and no disease or lesions were found in the progeny (11).

Seroconversion patterns in SPF flocks suggest a more complex situation than described for commercial birds. Seroconversion in SPF chickens has been reported for commercial and noncommercial SPF flocks and often occurs during the first laying cycle (19, 49, 55, 119, 120, 132, 246, 254). When CIAV was accidentally introduced in 3 genetically different SPF flocks maintained at Cornell University, seroconversion coincided with the development of sexual maturity even while birds were housed in a CIAV-infected environment (19). Not all genetic strains seroconverted for 100% during a 60-week-period while birds were kept in colony cages in an environment contaminated with CIAV. However, CIAV DNA could be detected in seronegative and seropositive birds by nested PCR assays of gonadal tissues and spleens, even in chickens that had been antibody positive for more than 40 weeks (19, 20).

Horizontal spreading in SPF flocks kept in cages may be less efficient than described for field flocks. Miller *et al.* (132) followed seroconversion in a flock of 90 chicks hatched from eggs supplied by a SPF producer. All birds were bled monthly and one bird seroconverted at 6 weeks of age; this bird was euthanized. The remainder of the flock remained seronegative until 16 or 20 weeks of age when 2 additional birds became antibody positive. In a horizontal transmission experiment, a rooster shedding virus through semen was placed in a cage flanked by cages with seronegative chickens, which remained virus-negative over at least a 2-month-period (21). Significant differences in seroconversion rates were noted among genetic strains (19), but even between different generations of the same genetic strains, seroconversion ranged from 4% to 95% (132). Examination of tissues from embryos obtained from hens positive for viral DNA in the gonads showed that the embryos can carry the viral DNA without signs of virus replication, thus continuing the transmission cycle (130). These data strongly support the suggestion, first made by McNulty (117) that CIAV can establish a latent infection (133).

Incubation Period

In experimental infections, anemia and distinct histologic lesions can first be detected at 8 days after parenteral inoculation of virus. Clinical signs generally develop after 10–14 days, and mortality begins at 12–14 days after inoculation (66, 196, 260). Clinical signs are delayed and milder after oral inoculation compared to intramuscular inoculation (194, 222).

Under field conditions, congenitally infected chicks show clinical signs and increased mortality beginning at 10–12 days of age, with a peak at 17–24 days (23, 48, 63, 94, 228). In heavily infected flocks, there can be a second peak of mortality at 30–34 days (48, 94), probably due to horizontal transmission.

Clinical Signs

The only specific sign of CIAV infection is anemia, with a peak at 14–16 days post inoculation (PI). Anemia is characterized by hematocrit values ranging from 6 to 27%. Affected birds are depressed and can become pale. Weight gain is depressed between 10 and 20 days after experimental infection. Affected birds may die between 12 and 28 days PI. If mortality does occur, it generally does not exceed 30%. Surviving chicks completely recover from depression and anemia by 20–28 days PI (64, 173, 195, 237, 260), although retarded recovery and increased mortality may be associated with secondary bacterial or viral infections. Secondary infections, causing more severe clinical signs, are frequently seen in field cases, but they may also occur inadvertently in experimental chicks (47, 63, 228, 237).

Hematology

In general, hematocrit values greater than 27% are considered normal, but values may vary between inbred lines of chickens (86). Normal values are lower in white leghorn chicks than in broilers and decrease in both types of birds with increasing age (56, 57, 60). Blood of severely affected chicks is more or less watery, the clotting time is increased, and the blood plasma is paler than normal. Hematocrit values begin to drop below 27% at 8–10 days after infection, are mostly in the range of 10–20% at 14–20 days, and may even drop to 6% in moribund birds. In convalescent chicks, hematocrit values increase after 16–21 days and re-

turn to normal (29–35%) by 28–32 days post infection (66, 78, 174, 196, 260).

Low hematocrit values in CIAV-infected chickens are due to a pancytopenia as a consequence of infection of hemocytoblasts as early as 3–4 days PI (1, 185, 196), resulting in markedly decreased numbers of erythrocytes, white blood cells, and thrombocytes. Anisocytosis has been noticed as early as 8 days PI. Juvenile forms of erythrocytes, granulocytes, and thrombocytes begin to appear in the peripheral blood by 16 days PI, and the incidence of immature erythrocytes may exceed 30% several days later. The blood picture in convalescent chicks returns to normal by 40 days (196).

Decreased clotting is most likely the direct consequence of thrombocytopenia and may lead to the hemorrhages associated with CIA. Coinfection with infectious bursal disease virus (IBDV) may aggravate the thrombocytopenia (166).

Morbidity and Mortality

The outcome of CIAV infection is influenced by a number of viral, host, and environmental factors. Uncomplicated infectious anemia, especially if caused by horizontal infection, may result in nothing more than slightly increased mortality and transient poor performance of affected flocks, and, therefore, it could even go unobserved in commercial settings. However, subclinical infections with CIAV can aggravate other diseases (see "Immunosuppression").

Morbidity and mortality are considerably enhanced if chicks are dually infected with CIAV and Marek's disease virus (MDV), reticuloendotheliosis virus (REV), or IBDV, probably due to virus-induced immunosuppression (26, 152, 173, 236, 237, 238, 259). Because lymphocytic depletion of the bursa often precedes lymphocytic depletion of the thymus associated with CIAV infection in commercial chickens (189, 218), immunosuppression by other viral agents, such as IBDV, likely plays an important role in the outcome of CIAV infection in commercial flocks. Certain strains of reovirus also can be immunosuppressive in chickens (47, 180), which may explain the enhanced pathogenicity of CIAV in the presence of reovirus as reported by Engström *et al*. (47). Dual infections between *Cryptosporidium baileyi* and CIAV can enhance CIA as well as Cryptosporidiosis under experimental conditions (76). Occasional outbreaks of disease due to concurrent infections have been reported in commercial flocks (40).

Pathology

Lesions associated with CIA may vary dependent on the route of infection, age of exposure, viral dose, and immune status of the host. Moreover, CIAV infection may often be involved in and complicated by other pathogens. The pathology will be described for uncomplicated infections mostly based on experimental infections, as part of the hemorrhagic-aplastic anemia syndrome, and as a complicating factor in other diseases.

Gross Lesions

Thymic atrophy (Fig. 8.2A), sometimes resulting in an almost complete absence of thymic lobes, is the most consistent lesion especially when chicks develop age resistance to anemia (64, 89,

184, 196). The thymic remnants may have a dark reddish color. Bone marrow atrophy is the most characteristic lesion seen and is best evaluated in the femur (66, 196). Affected bone marrows become fatty and yellowish or pink (Fig. 8.2B). In some instances, its color appears dark red, although distinct lesions can be detected by histologic examination. Bursal atrophy is less commonly associated with CIAV infection. In a small proportion of birds, the size of the bursa of Fabricius may be reduced. In many cases, the outer bursal wall appears translucent, so plicae become visible. Hemorrhages in the proventricular mucosa and subcutaneous and muscular hemorrhages are sometimes associated with severe anemia (64, 66, 105, 174, 195, 196, 237). More pronounced hemorrhages or bursal atrophy, and lesions in other tissues—e.g., swollen and mottled livers (66, 174)—have also been reported but may be caused by secondary infections with other agents.

Hemorrhagic-aplastic Anemia Syndrome

Outbreaks of infectious anemia in field flocks are mostly associated with the so-called hemorrhagic syndrome, with or without concurrent (gangrenous) dermatitis (Fig. 8.2C) (e.g., 8, 23, 41, 48, 228, 255). CIAV is also involved in the etiology of aplastic anemia associated with inclusion body hepatitis (IBH) (238) and with the IBH/hydropericardium syndrome (216) or infectious bursal disease (166). Hemorrhages seen in chickens with infectious bursal disease may, in most instances, be a consequence of CIAV rather than IBDV infection.

Characteristic lesions of so-called hemorrhagic syndrome are intracutaneous, subcutaneous, and intramuscular hemorrhages (Figs. 8.2D, E). Punctuate hemorrhages may be present even more frequently in the mucosa of the distal part of the proventriculus (Fig. 8.2F). Intracutaneous or subcutaneous hemorrhages of the wings are often complicated by severe edema and subsequent dermatitis, which may become gangrenous due to bacterial infection (48).

Subcutaneous hemorrhage of shanks and feet may result in formation of ulcers. Affected chicks also sometimes appear to be predisposed to develop pododermatitis.

Hemorrhages are not consistently seen in anemic chicks, although their occurrence is mostly correlated with the severity of anemia. Increased clotting time associated with thrombocytopenia, therefore, does not completely explain hemorrhages. Endothelial lesions and impaired liver functions, partly caused by viral infection and enhanced by secondary bacterial infection, are likely to be more important in the pathogenesis of hemorrhagic diathesis.

Microscopic Pathology

Histopathologic changes in anemic chicks have been characterized as panmyelophthisis and generalized lymphoid atrophy (66, 90, 105, 166, 185, 195, 196, 235, 237). In the bone marrow, atrophy and aplasia involve all compartments and hematopoietic lineages (Fig. 8.3). Necrosis of residual small cell foci may occasionally be seen. Hematopoietic cells are replaced by adipose tissue or proliferating stroma cells. Regenerative areas consisting of proerythroblasts appear 16–18 days after experimental infec-

tion, and there is a hyperplasia of bone marrow between 24 and 32 days PI in birds that recover.

Severe lymphoid depletion is seen in the thymus, starting with the cortical lymphocytes, but the nonlymphoid leukocytes and stroma cells are not affected. The thymus cortex and medulla become equally atrophic, with hydropic degeneration of residual cells and occasional necrotic foci (Fig. 8.4). In chicks that recover, repopulation of the thymus with lymphocytes becomes distinct at 20–24 days, and the morphology returns to normal by 32–36 days PI.

Lesions in the bursa of Fabricius may be present. These lesions consist of mild to severe atrophy of the lymphoid follicles with occasional small necrotic foci, infolded epithelium, hydropic epithelial degeneration, and proliferation of reticular cells (Fig. 8.5). Repopulation of lymphocytes until complete recovery is similar to that in the thymus.

In the spleen, depletion of T cells with hyperplasia of reticular cells is seen in the lymphoid follicles as well as in the Schweigger-Seidl sheaths. Necrotic foci in follicles or sheaths have been observed rarely.

In the liver, kidneys, lungs, proventriculus, duodenum, and cecal tonsils, lymphoid foci are depleted of cells, making them smaller and less dense than those in unaffected birds. Liver cells are sometimes swollen, and hepatic sinusoids may be dilated.

Small eosinophilic nuclear inclusions have been detected in altered, enlarged cells of affected tissues, predominantly in the thy-

mus and bone marrow, where they are most frequent at 5–7 days after experimental infection (66, 185).

Ultrastructural Lesions

Few ultrastructural studies have been described for CIAV-infected chicks (62, 67, 91). Changes in hematopoietic cells and thymocytes were first observed at 6 days PI and were most advanced at 8 days PI. The affected cells had electron-dense regions in the cytoplasm and inclusion bodies consisting of homogeneous or fine granular materials. In addition, irregular plasma membranes, vacuolization, and pseudopod formation were seen. Between days 12 and 16 PI, many degenerative cells were seen, as well as actively phagocytizing cells. Apoptotic bodies were present in infected thymocytes. After 20 days, regeneration started to occur.

Pathogenesis

The basic events during the pathogenesis of CIAV infection have been elucidated by sequential histopathologic (66, 184, 185, 196), ultrastructural (62, 67, 91) and immunocytochemical studies (75, 184, 185). Hemocytoblasts in the bone marrow and lymphoblasts in the thymus cortex are primarily involved in early cytolytic infection at 6–8 days PI leading to a rapid depletion by apoptosis of these cells. Besides enlarged proerythroblasts and degenerating hematopoietic cells, macrophages with ingested degenerated hematopoietic cells have been observed in the bone

marrow. In contrast to the thymus, depletion of lymphoid cells and occasional necrosis in the bursa of Fabricius, spleen, and lymphoid foci of other tissues have not been detected before 10–12 days PI (66, 185, 196, 237). Repopulation of the thymus with lymphocytes, repopulation of the bone marrow with proerythroblasts and promyelocytes, and recovery of hematopoietic activity beginning 16 days PI all appear to coincide with the beginning of antibody formation (see "Immunity"). These events result in complete recovery by 32–36 days.

Treatment of formalin-fixed thymus tissues with proteases III or XIV, needed to unmask viral antigens (116), facilitated immunocytochemical studies (2, 75, 79, 185). Large numbers of cortical thymic lymphoblasts become virus-positive within 4 to 6 days PI. In addition, intrasinoidal and extrasinoidal hemocytoblasts, reticular cells in the bone marrow, and mature T cells in the spleen can be vira antigen-positive. Infected cells in the thymus and bone marrow are most abundant at 6–7 days PI and can be detected until 10–12 days or even later. Viral antigen has also been demonstrated in lymphoid tissues in many other organs (185). Infection of proventriculus, ascending part of the duodenum, kidney, and lung, could provide an explanation for virus

shedding. Infected cells in these tissues usually cannot be detected for more than 22 days after infection at 1 day of age (185), although virus may persist in tissues until 28 days and in rectal contents until 49 days or later (258).

Although CIAV has a tropism for lymphoid tissue, particularly for the thymus cortex (90), susceptibility of thymocytes or spleen cells to infection is not dependent on the expression of particular cell markers such as CD4 or CD8 (2, 90). On the other hand, transient severe depletion of CD4$^+$ and CD8$^+$ lymphocytes, or a selective decrease in CTL, may play an important role in the mechanism of CIAV-induced immunosuppression (2, 26, 79, 90).

Age Resistance
Under experimental conditions, age resistance to anemia develops rapidly during the first week of life and becomes complete by 3 weeks or even earlier in immunologically competent chickens. The degree of resistance may vary based on the virulence of the virus, dose, and route of infection (64, 173, 174, 217, 251, 259). Development of age resistance is closely associated with the ability of the chicken to produce antibodies against the virus (251, 259). Chickens infected at 6 weeks of age with high doses of

CIAV rapidly develop neutralizing antibodies and do not shed virus, whereas chickens infected with a lower dose require more time to develop detectable antibody and do shed virus (43). Antibody development is considerably delayed by immunosup-pression, e.g., by simultaneous infection with infectious bursal disease virus (IBDV) (81, 173, 259) or by bursectomy (78, 253). Dual infection with IBDV increases the persistence of CIAV in blood cells of chickens infected at 6 weeks of age and prolongs viral shedding (81).

Although most CIAV experiments have been conducted in leghorn chickens, Joiner *et al.* (92) showed that commercial broilers also exhibit age resistance to clinical disease and have low viral loads under experimental conditions. However, under commercial conditions, anemia in association with CIAV infec-tion and accompanied by bacterial and parasitic diseases indica-tive of immunosuppression is observed in chickens up to 130 days of age (35, 219, 242). This suggests that the concept of age resistance may not always be valid in commercial operations, possibly due to environmental factors or other pathogens that af-fect the immune function of the flocks.

Jeurissen *et al.* (89) suggested that age resistance was depend-ent on susceptibility of thymic precursor cells during prehatching and posthatching development. However, embryonally bursec-tomized chickens remained fully susceptible and developed thy-mus atrophy and anemia when challenged at 5 weeks of age (78).

Moreover, mononuclear cell cultures established from thymus, spleen, and bone marrow tissues from 28-day-old chicks were fully susceptible to infection (115). Furthermore, CIAV repli-cated in the thymic cortex of chickens infected at 3 or 6 weeks of age, resulting in extensive depletion of the cortex, while CIAV positive cells were rare in the bone marrow and other tissues (184). Several studies have demonstrated lack of age resistance to the subclinical disease characterized by reduced cellular im-mune responses (109, 110, 168, 184, 217).

Route of Infection and Virus Dose
Virus dosage affects the severity of anemia or the proportion of affected chicks, but infection can be established by intramuscular injection of doses as low as $10^{0.75}$ 50% tissue-culture-infective-doses ($TCID_{50}$) (121, 173, 260). The route of infection also plays a role in experimental infection, because infection by contact usually does not cause anemia in immunologically intact chicks, in contrast to immunologically compromised birds (173, 259). Oral, nasal, or ocular infection routes are much less effective than parenteral inoculation in inducing disease (173, 194, 222, 248).

Genetic Resistance
There is little information on genetic resistance to infection and disease. Hu (77) suggested that S13 (MHC: $B^{13}B^{13}$) chicks seemed to be more susceptible to disease than N2a (MHC:

$B^{21}B^{21}$) and P2a (MHC: $B^{19}B^{19}$) chicks. This observation is compatible with the finding that S13 chickens have a poor seroconversion rate after natural exposure and after vaccination with a commercial vaccine using an adjuvant. S13 chickens had only a 73% seroconversion 7 weeks post vaccination, while the N2a and P2a strains were 100% and 85% seropositive, respectively (19). In an experiment designed to detect MHC influences on CIAV susceptibility in four-week-old broiler chickens, Joiner *et al*. (92) found no statistically significant differences among MHC types in seroconversion rates and viral loads 2 weeks PI.

Immunity

Active Immunity
Antibody responses are the major arm of protective immunity to CIAV, but neutralizing antibodies cannot be detected until 3 weeks PI of susceptible one-day-old chicks. Titers are low (1:80) and show little increase (1:320) until 4 weeks. Chickens inoculated intramuscularly at 2–6 weeks of age have a faster response with neutralizing antibody detectable as early as 4–7 days and with maximum titers (1:1280–1:5120) at 12–14 days PI (43, 254, 258). Humoral antibody formation is delayed if chickens are infected orally rather than intramuscularly (194, 222). Yuasa *et al*. (258) reported that increasing antibody production coincides with decreasing virus concentrations in chicken tissues. However, comparing the levels of antibody detectable by ELISA at 14 days PI among individual chickens inoculated at 4 weeks of age, Joiner *et al*. (92) found that higher virus levels corresponded to higher antibody levels, suggesting that higher antibody levels were a result of greater stimulation by virus.

Seroconversion in horizontally infected breeder flocks may be detected as early as 8–9 weeks of age, and most flocks have antibodies to CIAV at 18–24 weeks (82, 120). High titers of neutralizing antibody persist in all birds of a flock for at least 52 weeks. The prevalence of antibodies detected by indirect immunofluorescence assays, however, may decrease with increasing age (82) and is frequently less than 100% in a flock (58, 120). Antibodies detected by a commercial ELISA kit will remain present until 60 to 80 weeks of age in CIAV-infected SPF flocks (19). There is no information on the importance of cell-mediated and non-specific immunity, although Hu *et al*. (78) noted that some embryonally bursectomized birds recovered from anemia in the absence of antibodies.

Passive Immunity
Maternal antibodies provide complete protection of young chicks against CIAV-induced anemia (256). This protection can be abrogated if chicks are immunosuppressed by other factors, including viral infections, especially infections, such as IBDV, that affect humoral immune responses (173, 237). Maternally derived immunity, including protection against experimental challenge, persists for about 3 weeks (120, 154). Furthermore, vertical transmission of the virus is unlikely to occur from antibody-positive hens, but viral DNA can still be transmitted (11, 19, 20, 130). Outbreaks of infectious anemia in the field are in fact correlated with the absence of anti-CIAV antibody in the parent flocks (23, 46, 228, 255).

Immunosuppression
Impairment of the immune response by CIAV infection may result directly from damage to hematopoietic and lymphopoietic tissues and subsequent generalized lymphoid depletion or perhaps from cytokine imbalances. Splenocytes from experimentally infected 1 to 7-day-old chicks had depressed responses to mitogen stimulation between 7–15 days but not at 18–21 days PI (3, 9, 150, 155). Depressed mitogen responses were also noted between 14 and 21 days after oral infection of 3-week-old chickens (110). Decreases in macrophage functions such as Fc receptor expression, Interleukin (IL)-1 production, phagocytosis, and bactericidal activity were noted after infection of one-day-old and three-week-old chicks (110, 111). Although transient, effects on macrophage function persisted longer than effects on T-cell mitogen responses, up to 6 weeks PI (110, 111). Interferon (IFN) production by mitogen-stimulated splenic lymphocytes *in vitro* was increased at 8 days and decreased between 15 and 29 days PI (3, 4, 110). IFN-γ mRNA levels were also increased in the spleens of CIAV-infected chickens 7 days PI (109). Although IFN-γ mRNA levels in the spleen subsequently decreased, at 14 days PI they were not reduced compared to uninfected control chickens (109). T cell growth factor production (presumed to be IL-2) after *in vitro* stimulation was also decreased between 14 and 21 days PI (110), but a decrease in levels of IL-2 mRNA in spleens of infected chickens was not detected (109). CIAV infection interfered with the increase in both IFN-α and IFN-γ mRNA levels in blood cells induced within four hours in response to vaccination with trivalent inactivated IBDV/NDV/IBV vaccine (168). This marked effect on early innate responses was found 1, 2 and 3 weeks post CIAV infection of 4-week-old chickens. Markowski-Grimsrud and Schat (109) found that CIAV infection significantly reduced the development of antigen-specific CTL for MDV and REV in chickens infected with CIAV after 3 weeks of age, suggesting that CIAV can impact vaccinal immunity and recovery from infections when cell-mediated immune responses are important. There is apparently no "age resistance" to the immunosuppressive effects of CIAV.

CIAV as a Co-factor in Other Diseases
Based on the impact of clinical or subclinical CIAV infection on specific and non-specific immune responses, it is not surprising that infection has been linked to increased susceptibility to other pathogens. Immunosuppression in anemic CIAV-infected birds has been linked to increased bacterial and fungal infections (63, 169, 195, 235, 241) and to enhanced pathogenicity of adenovirus (216, 238), reovirus (47) and infectious bronchitis virus (IBV) (218, 226). van Santen *et al.* (226) found infection with CIAV delayed development of infectious bronchitis virus IBV-specific IgA in tears, prolonged respiratory signs, and delayed IBV clearance in IBV-infected chickens. Experimental infection with CIAV and *Salmonella enterica* Serovar Enteritidis resulted in a decrease in the number of gut-associated T cells and IgA$^+$ cells and the level of intestinal *Salmonella*-specific IgA compared to chickens infected with *Salmonella* alone. However, there was no significant increase of *Salmonella* positive cells in dually infected birds (181). Hagood *et al.* (69) found a significant associ-

ation between both presence of CAV DNA and thymic atrophy and coccidiosis, gangrenous dermatitis, or respiratory disease in commercial broiler flocks. De Boer *et al.* (37) used live attenuated Newcastle disease (ND) LaSota-type vaccine in 1- and 10-day-old chicks, which were infected at one day of age with CIAV. Severe respiratory distress was noted in the dually infected chicks without affecting the HI titers against ND virus. Impaired humoral immune response to inactivated ND vaccine may also occur (10, 27) but is not a usual phenomenon in commercial flocks (59).

Dual infections with CIAV and MDV have led to increased early mortality and increased incidence of MD (52, 151, 236, 262). A high proportion of MDV isolates from 14–24 week-old layers exhibiting acute MDV infection also contain CIAV, and inoculation of CIAV into commercial chickens reactivates latent MDV infections (52). Two factors may influence the degree of interactions. Infection with a low dose of MDV enhanced lymphoproliferative MD lesions, while high doses decreased the lesions (88). The virulence of the MDV strain may also influence the outcome of dual infections. Miles *et al.* (129) found that coinfection with CIAV and very virulent (vv)MDV strains exacerbated the mortality and thymus atrophy, but that this was less evident with vv+MDV strains. MDV vaccinal immunity is depressed by CIAV infection even if infection occurs at 14 days of age (150, 155, 252) and, based on the ablation of MDV-specific CTL responses, (109) probably at later times as well.

Diagnosis

Isolation and Identification of CIAV

Detailed procedures for the isolation and identification of CIAV have been published (118). Virus can be isolated from most tissues, buffy coat cells, and rectal contents from diseased chickens with maximum virus titers detected at 7 days after infection (118, 258). Virus titers will decrease after antibodies develop, but whole blood, buffy coat cells, and thymic homogenates were found to be infectious for at least 14 days PI, even in birds with neutralizing antibody (222, 236, 250).

Liver or lymphocytes from the spleen or buffy coat are preferred sources for virus isolation. Clarified homogenates can be heated for 5 minutes at 70°C (64) or treated with chloroform to eliminate or inactivate possible contaminants before inoculating cell cultures.

MDCC-CU147 or MSB1 cell cultures are preferred for virus isolation and titrations (17, 247). Some CIAV strains do not readily replicate in MSB1 and differences in susceptibility of MSB1 sublines have been reported (170). Freshly prepared cultures containing 2×10^5 cells/mL and seeded at 10^5 cells/cm^2 should be used. Cells are inoculated with 0.1 mL/1 mL of culture with 1:20 or greater dilutions (or serial 10-fold dilutions) of appropriately prepared tissue homogenates. Cultures are split every 2–4 days for 10 passages or until cell death is observed. Microscopic examination of cultures between 36 and 48 hours after passage is recommended to distinguish between virus-induced cytopathic effects (Fig. 8.6) and nonspecific cell degeneration. Isolation of CIAV should be verified by PCR analysis.

Bioassay by intramuscular or intraperitoneal inoculation of susceptible 1-day-old chicks is the most specific method available for primary isolation of CIAV. This approach can be used if CIAV is suspected, but virus cannot be isolated in cell culture. The bioassay is as much as 100-fold more sensitive than cell culture and the sensitivity can be further increased by bursectomy (78, 253). Between 14 and 21 days after inoculation hematocrit values are examined; values below 27% are considered indicative of the presence of CIAV (105, 174). Postmortem examination for bone marrow atrophy can be used in the case of nonanemic birds. Confirmation that CIAV is present in the lesions by PCR or immunohistochemistry is important.

DNA-based Detection of CIAV

Polymerase Chain Reaction-based Techniques

PCR assays have become the assay of choice for the detection of CIAV DNA in infected cell cultures, chicken tissues, archived formalin-fixed paraffin-embedded tissues, or vaccines (145, 188, 200, 201, 213). The test proved to be specific and definitely more sensitive than cell-culture isolation of the virus and facilitates sequence and restriction enzyme analysis. Very high sensitivity is achieved with a nested PCR, which, however, is also most sensitive to cross-contamination (20, 188). A hot-start PCR for CIAV is also highly sensitive; furthermore, the use of a spike DNA as an internal control enables the validation of CIAV-negative samples and an estimation of the number of CIAV genomes present in the tested samples (44). Competitive PCR assays using a template with a deletion of 33 nucleotides allow quantitation of viral DNA (245). Real-time PCR assays for the quantitation of viral DNA and RNA have also been developed (108, 223). Different primers and conditions have been used successfully by different laboratories. For routine assays primers are best selected from the conserved ORF regions. DNA can be extracted from the same tissues as used for virus isolation. Miller *et al.* (130) used nested PCR to screen embryonal tissues and egg membranes obtained after hatching to analyze the presence of viral DNA in offspring of SPF hens. *In situ* PCR assays have been used to detect CIAV infected cells in the absence of detectable levels of VP3 (20).

DNA Probes

Detection of CIAV in formalin-fixed, paraffin-embedded thymus sections by *in situ* hybridization using a biotinylated DNA probe prepared by PCR (6, 136) or a digoxygenin-labeled cloned CIAV genome probe (43) has been described. Microwave treatment combined with protease treatment significantly enhanced the sensitivity of the assay (114). Biotinylated DNA probes have been used successfully to rapidly diagnose the presence of CIAV in blood smears (146, 175). Dot-blot hybridization assays using cloned ^{32}P-labeled DNA probes can detect viral DNA extracted from chicken tissues from 5 through 42 days after infection (208) or from MSB1 cells infected with field isolates of CIAV (145). A competitive hybridization assay conducted in 96-well plates utilizing a biotinylated CIAV DNA probe detects CIAV in DNA prepared from buffy coat cells of infected chickens from 3–28 days PI and can be used as a quantitative assay (147). While less sensitive than virus isolation from buffy coat cells, the com-
8.6.   Cytopathic effect in cultured MSB1 cells 2 days after infection with chicken infectious anemia virus. A. Uninfected cells. B. Cells infected with a high dose of virus. Unstained. ×230. (von Bülow)

petitive hybridization assay has 100% specificity and has sensitivity similar to *in situ* hybridization of blood smears and dot-blot hybridization of buffy coat samples using biotinylated probes (147).

Detection of CIAV by Antibodies

Viral infection can be demonstrated in chicken tissues by immunofluorescence or immunoperoxidase staining. Thymus tissues, collected at 7–12 days after infection, are usually preferred for diagnostic tests. Tissue impression smears and cryostat sections, fixed with acetone, are used for either indirect or direct immunofluorescence staining employing polyclonal chicken or rabbit hyperimmune serum or MAb to CIAV (75, 78, 116, 124). Immunoperoxidase assays are performed with formalin-fixed, paraffin-embedded or frozen sections (78, 116, 185). Pretreatment of tissues with proteases III or XIV greatly enhances the detection of viral antigens (116). The most satisfactory results are obtained with MAb, because polyclonal antibodies may produce a high level of nonspecific background staining.

Electron Microscopy

Electron microscopy for routine diagnostic examination for CIAV is not recommended due to its lack of sensitivity.

Serology

Three serological assays are routinely used: ELISA-based assays, indirect immunofluorescence assays, and virus neutralization (VN) tests. Selection of a given test depends on the purpose of the serological examination and costs associated with each assay.

Indirect Fluorescent Antibody Tests

The indirect fluorescent antibody (IFA) test (120, 234, 254) for the detection of antibodies is a standard IFA test. CIAV-infected MSB1 or CU147 cells are used as the source of antigen. Cells are collected just before the beginning of cell lysis, usually 36–42 hours after inoculation, smeared on glass slides and acetone fixed. Fluorescent staining of rather small, irregularly shaped granules in the nucleus of enlarged cells (Fig. 8.7) is considered evidence for antibody in the test serum. The concurrent appearance of fluorescent, somewhat irregular circular structures is also specific, but less frequent. This pattern of immunofluorescence is considered typical of tests with neutralizing CIAV antibody (14, 124, 211). Positive and negative reference sera should always be included in FA tests. Noninfected cells can be used as a control. Sera may have antibodies against MDV, and CU147 and MSB1 cells can express MDV antigens in the nucleus and cytoplasm, which may cause some confusion. Nonspecific staining and background staining
8.7. Chicken infectious anemia virus antigens detected by immunofluorescent staining in cytospin preparations of MSB1 cells harvested at 40 hours postinoculation. Antigens are seen in enlarged cells with characteristic intranuclear granular fluorescence. ×400. (von Bülow)

masking specific reactions can be largely reduced by using sufficiently diluted test sera, i.e., 1:40 to 1:100 or even more (120). Nonspecific staining due to direct binding of anti-IgG conjugates (106) may be controlled by selection of pretested conjugates.

Enzyme Immunoassays

Various commercially available enzyme-linked immunosorbant assay (ELISA) techniques for the detection and measurement of CIAV antibodies in chicken sera have been developed. These tests are routinely used to screen breeder flocks in countries were vaccines are available (46), but false-positive responses have been reported (128). Antigens are generally prepared from partially purified virus preparations grown in MSB1 cells, which may include MDV antigens. Recombinant technology has been used to produce VP3 as a fusion protein in bacterial systems (157) or VP1, VP2, and VP3 in baculovirus systems (85). VP3 and VP2, but not VP1, proteins could be used as ELISA antigens. Unfortunately, these antigens will not detect VN antibodies. However, Todd *et al.* (212) developed a blocking ELISA using a MAb, 2A9, that reacts with field isolates from different parts of the world and recognizes a VN epitope (124, 211). A similar assay, using the same neutralizing MAb, but an Australian CIAV

isolate as antigen, has also been developed (197). The blocking assays have advantages in terms of costs (212) compared to the indirect assay described earlier (211) and yield fewer false positive results than commercial indirect ELISA kits that do not use a blocking format (197)**.**

Virus-neutralization Tests

In the VN test (234, 258) serial two-fold dilutions of serum or egg yolk are mixed with equal parts of a CIAV suspension containing 200–500 $TCID_{50}/0.1$ mL, and the mixtures are incubated at 37°C for 60 minutes or at 4°C overnight before assay in MSB1 cell culture. Microtest plates are recommended if large numbers of sera have to be examined (83, 93). It may take up to 5 weeks, requiring eight to nine subcultures, before the assay is completed; however, results can be obtained much earlier, and subcultures can be omitted, if the virus concentration in the mixture is increased to $10^{5.0}$ to $10^{5.5}$ $TCID_{50}/0.1$ mL (153, 231, 234). In this instance, inoculated cultures should be examined microscopically for CIAV-specific CPE after both 2 and 3 days. One subculture may be required if complete destruction of virus-control cultures is desired to establish the endpoint. Subcultures can also be omitted if virus replication is assessed by PCR 3–4 days postinfection (223).

Qualitative VN tests for flock screening can be made with a constant serum dilution of 1:80–1:100 and a high dose of test virus as described above. Lower serum dilutions are not recommended because they can occasionally be cytotoxic or cause nonspecific inhibition of the virus. This type of test can be rendered semiquantitative by making a series of subcultures; the relative antibody level is indicated by the number of subcultures in which the inoculated cells stay alive (231, 234).

Direct comparisons among an ELISA test, IFA assay, and VN test were made by Otaki *et al.* (153). The VN test was more sensitive than the other two assays and the IFA assay frequently gave false-positive results, especially when sera were tested at dilutions of < 1:50. Unfortunately, no reports compare commercial ELISA kits with VN assays.

Differential Diagnosis

Infection criteria have only limited value in diagnosis of CIAV-induced disease, because CIAV is virtually ubiquitous among chickens. Demonstration of the virus, viral antigens, or viral DNA may be considered etiologically significant if detected at sufficiently high levels in a high proportion of affected birds. In chickens under 6 weeks of age, a typical combination of signs, hematologic changes, gross and microscopic lesions, and flock history are suggestive of CIA. However, no particular lesions can be considered pathognomonic.

Aplastic anemia, but not a pancytopenia, with a concurrent atrophy of thymus and bursa of Fabricius, and depressed immune response also can be caused by osteopetrosis virus. Anemia induced by erythroblastosis virus can be distinguished from CIAV-induced anemia by microscopic examination of blood smears. MDV can cause severe atrophy of the thymus and bursa of Fabricius, especially after infection with very virulent viruses (16, 129). IBDV induces atrophy of lymphoid tissues with typi-

cal histologic lesions but normally does not affect the thymus. MDV and IBDV normally do not cause anemia, although anemia has been described with some strains of MDV (54). Aplastic anemia that may be associated with acute IBDV occurs and disappears much earlier than CIAV-induced anemia (148). Adenovirus is a major cause of an inclusion body hepatitis-aplastic anemia syndrome that occurs most frequently between 5 and 10 weeks of age (29). It does not, however, induce aplastic anemia after a single infection of experimental chickens.

Intoxication with high doses of sulfonamides, or mycotoxins such as aflatoxin, can result in aplastic anemia and "hemorrhagic syndrome." Aflatoxin also may impair the immune system. In the field, however, chickens are rarely exposed to doses of aflatoxin or sulfonamides that are sufficient to cause acute disease. On the other hand, subclinical intoxication of chickens might add to the pathogenicity of CIAV or *vice versa*.

Intervention Strategies

Management Procedures

Attention should be paid to management and hygiene procedures to prevent immunosuppression by environmental factors or other infectious diseases and to prevent early exposure to CIAV. Improved hygiene has reduced seroconversion rates, but this may cause problems when flocks get exposed later in life (46, 95, 112). Eradication of CIAV is virtually impossible under field conditions and may be difficult on infected SPF premises. In the latter case, this is not only because of the high resistance of CIAV to disinfection, but also because viral DNA can be transmitted vertically, which may be reactivated during the laying cycle (20, 130). Monitoring of breeder flocks for the presence of CIAV antibody should be done to avoid vertically transmitted disease outbreaks or to test the efficacy of vaccinations.

Vaccination

Current vaccine strategies are based on the prevention of vertical transmission and horizontal transmission of virus to very young chicks by immunization of breeder flocks and have been successful in reducing the incidence of anemia in young chicks (46). Artificial exposure of young breeder flocks was originally achieved by transfer of litter from CIAV-infected flocks or by providing drinking water containing CIAV-positive tissue homogenate. This method is still used in countries where vaccines are not available or where vaccines are not applied for economical reasons. However, these procedures are very risky with regard to hygiene and level of exposure and should be discouraged (228). Commercial live vaccines are available in several countries (193, 227, 229, 230). Vaccination should be performed at about 9–15 weeks of age, but never later than 3–4 weeks before the first collection of hatching eggs to avoid the hazard of vaccine virus spread through the egg. Vaccines can be applied in the drinking water or by injection in the presence of adjuvants. Although these live vaccines are considered safe and efficacious, further studies are needed to examine potential deregulation of cytokines as a consequence of vaccination.

Several strategies utilizing various combinations of natural ex-posure, monitoring for seroconversion, and vaccination of breeders are actually used in the broiler industry. Smith (183) recently surveyed 68 complexes of eight large vertically integrated broiler production companies across the United States to determine which strategies are most commonly used for broiler breeders. He found that the majority of operations relied on natural exposure. Half of the operations did not routinely test for seroconversion, but some of those operations vaccinated breeders in new or cleaned houses where natural exposure might not occur. Approximately one-third of the operations relying on natural exposure did routinely test for seroconversion and subsequently applied commercial vaccines to flocks that did not exhibit adequate seroconversion. Smith noted the relatively high cost of commercial live CIAV vaccines as the reason for reliance on natural exposure. However, approximately one-third of the complexes surveyed did routinely vaccinate all breeder pullets between 10 and 12 weeks of age. Males are not usually vaccinated.

Based on the negative effect of CIAV on the generation of cytotoxic T cells when infection occurs after maternal antibodies have disappeared (109) vaccination for broilers may also be necessary. Recently a vaccine has been licensed in the United States for use in one-day-old broilers. Although these live vaccines are considered safe and efficacious, further studies are needed to examine potential deregulation of cytokines as a consequence of vaccination.

An inactivated vaccine has been tested in SPF breeder hens. Vaccinated hens showed seroconversion and their offspring were protected against challenge (156). Unfortunately, viral titers in MSB1 cells are generally low (117) and therefore inactivated vaccines may not be cost-effective. Although recombinant vaccines expressing VP1 and VP2 are certainly possible (99, 141) these have not been licensed to date.

Treatment

No specific treatment for chickens affected by CIAV infection is available. Treatment with broad-spectrum antibiotics to control bacterial infections usually associated with CIA might be indicated.

Circovirus Infection of Pigeons and Other Avian Species

Leslie W. Woods and Kenneth S. Latimer

Introduction

Definition and Synonyms

Viruses belonging to the family *Circoviridae* are the smallest pathogenic DNA viruses that have been identified and characterized in mammalian and avian species (106). There are currently two genuses in the family *Circoviridae*; *Gyrovirus* and *Circovirus* (50). Chicken anemia virus (CAV) was recently placed in the newly designated genus, *Gyrovirus*; porcine circovirus-1 (PCV-1), porcine circovirus-2 (PCV-2), and psittacine beak and feather disease virus (PBFDV or BFDV) remained as members of the *Circovirus* genus (50), and pigeon circovirus (PiCV) (48, 111, 112), canary circovirus (CaCV) (62, 108), and goose circovirus (GoCV)(93, 105) were recently added to the *Circovirus* genus (109). Circoviruses have been identified from additional avian species over the past decade. Because of lower costs and more efficient technology, phylogenetic analyses have been performed on most circoviruses that have been recovered, allowing for comparison with the current members of the *Circovirus* genus. Tentative species in the genus *Circovirus* include duck (DuCV) (30, 109), finch (FiCV) (88) and gull (GuCV) circoviruses (110).

Circovirus infections have been documented in more than 60 species of Old World, New World and South Pacific psittacine birds (106), and in nonpsittacine birds including racing pigeons (*Columba livia*) (27, 87, 89, 111, 112), Senegal doves (*Streptopelia senegalensis*) (60, 68), canaries (*Serinus canaria*) (25, 62), finches (*Poephila castanotis, Chloebia gouldiae*) (55, 88), geese (4, 9, 91, 93, 117), Pekin and mulard ducks (30, 95, Banda et. al. submitted 2006), ravens (*Corvus coronoides*)(98), pheasants (*Phasianus colchicus*) (102), a southern black-backed gull (*Larus dominicanus*) (110), ostriches (*Struthio camelus*) (18, 19), and starlings (*Sturnus vulgaris* and *Sturnus unicolor*) (36).

Previously proposed names for this family of circoviruses have included *Diminuviridae* and *Circodnaviridae*. These names were based on the small size of the virion and the circular configuration of the DNA genome, respectively. Ultimately, the International Committee on Taxonomy of Viruses designated the new viral family as *Circoviridae* on the basis of the circular configuration of the genome (46). Synonyms of circoviral-associated diseases in various avian genera have included psittacine beak and feather disease (psittacine birds), feather and beak disease (psittacine birds), French moult (budgerigars), black spot (canaries), young pigeon disease syndrome (pigeons), fading chick syndrome (ostriches) and runting syndrome (geese).

None of the viruses in the genus *Circovirus* have been propagated in a cell culture system which has limited the accumulation of knowledge concerning these viruses and their associated diseases and thwarted attempts at commercial vaccine production. Recognition of circoviral infections in production flock species such as geese, ducks, pheasants and pigeons has increased awareness of the disease and emphasized the need for more research on the avian circovirus diseases and investigation of the potential impact of circoviruses on the commercial poultry industries. Currently, disease management requires extrapolation of biological understanding of viral disease from the well-researched companion bird circovirus, beak and feather disease virus (BFDV), and the clinical disease it produces. Therefore, all avian circoviruses of the genus *Circovirus* will be discussed in this chapter.

Economic Significance

Psittacine beak and feather disease is one of the most frequently diagnosed viral diseases of psittacine birds and, therefore, has caused tremendous economic loss in the pet bird trade and aviculture industry. The economic significance of many of the nonpsittacine circovirus-associated diseases has yet to be ascertained. Ultimately, the economic importance of circovirus diseases will be based on the future elucidation of the clinicopathologic significance of these circovirus infections in various avian species and circovirus prevalence and global distribution. Circovirus infections in pigeons and geese have been demonstrated to be highly prevalent in some regions of the world and may have global distribution. Putative immunosuppression and developmental abnormalities have been associated with circovirus infections in pigeons (104, 111, 112), geese (93), pheasants (102) and ducks (30, 95). Therefore, circovirus infections would have a globally significant economic impact if there is a high prevalence of circoviral-induced clinical disease in countries with large production industries of these species (4, 9, 95, 117). In addition to the economic impact, BFDV could have devastating effects on avian populations as some endangered species such as the Cape parrot (*Poicephalus robustus*) and black-cheeked lovebird (*Agapornis nigrigenis*) are highly susceptible to disease (31, 38).

Public Health Significance

Thus far, experimental work with a small number of the circoviruses has not demonstrated infectivity across host orders. In addition, natural cases of atypical host infections with circovirus have not been reported to date. Therefore, the public health significance of avian circoviruses appears to be minimal. Phylogenetic analyses have shown no substantial homologies between members of the genus *Circovirus* and human TT virus (TTV) and TTV-like minivirus, previously proposed members of the family *Circoviridae* (54, 100). In fact, these viruses were recently placed in a new genus *Anellovirus,* which is currently not attached to an existing virus family (8).

History

Feather changes consistent with PBFD have been observed in wild Australian parrots since the turn of the century (66). However, the disease *per se* was not described in detail in Aus-

tralian cockatoos until the early 1970s (41, 66). The disease was named "psittacine beak and feather disease" by Perry in 1981 (61). Viral particles measuring 17–22 nm in diameter were associated with histopathologic lesions. A viral etiology for PBFD was first proposed by Pass in 1984 and later established by Ritchie in 1989 (60, 72). Since that time, circoviral infections have been reported in more than 60 species of psittacine birds (108). By the mid-1980s, pathologists recognized intracellular inclusions in the lymphoid tissues of pigeons that resembled those of PBFD (28, 85, 111, 112). Pigeon circovirus (PiCV) subsequently was identified by electron microscopy in 1993 in the United States (111) and South Africa (22) and was proposed as the newest member of the *Circoviridae* family in 1994 (112). Reports of PiCV followed from the United States (87, 112), Canada (58, 112), Australia (112), the United Kingdom (89), Germany (92), Belgium (101), France (1), and Italy (10). During the next decade, circoviruses were identified and characterized in numerous other companion/captive/production and free-ranging avian species (30, 36, 62, 93, 95, 98, 102, 110).

Etiology

Classification

Porcine circoviruses (PCV-1 and PCV-2), chicken anemia virus (CAV), beak and feather disease virus (BFDV), canary circovirus (CaCV), goose circovirus (GoCV), and pigeon circovirus (PiCV) are currently listed in the *Circoviridae* family in the Eighth Report of the International Committee for the Taxonomy of Viruses (109). Based on similar virion size and genomic data, PCV-1, PCV-2, BFDV, PiCV, CaCV and GoCV were placed in the genus *Circovirus.* Chicken anemia virus was placed in the new genus, *Gyrovirus*, based on CAV's larger virion and genome, and different genomic organization. Duck circovirus (DuCV), finch circovirus (FiCV) and gull circovirus (GuCV) are tentative species in the genus (109) and starling circovirus (StCV) and raven circovirus (RaCV) have been proposed members of the genus *Circovirus* of the family *Circoviridae*. Each member is distinct based upon pylogeny and genomic structure (5, 9, 30, 36, 48, 62, 98, 103, 105, 106, 117).

Morphology

Ultrastructure
Ultrastructurally, circoviruses appear as nonenveloped virions with spherical to icosahedral (T=1) structures containing 60 capsid protein molecules arranged in 12 pentamer clustered units (11) and no obvious surface structures (flat capsomeres). Negatively stained particles have a mean diameter of 14–20.5 nm (11, 53, 106).

Genomic Size and Density
The entire sequence of the BFDV genome was published in 1998 by Niagro *et al.* (56) and Bassami *et al.* (5). Both groups determined that PBFDV genome was composed of 1,993 nucleotide bases. Later, analyses of eight PBFDV isolates revealed BFDV genomic sequences ranging from 1992 to 2018 nucleotide bases

(6). Variations of nucleotide size and identity were attributed to point mutations, deletions and insertions in coding and noncoding regions of the genome. Analyses of genomic sequences of numerous other avian species followed. Genome sizes of 2,037, 1,996, 1,898, 1,952, 2063, and 1,820–1,821 nucleotide bases were determined for PiCV (48), DuCV (30), RaCV (98), CaCV (62), StCV (36) and GoCV (9) respectively. The buoyant density of PBFDV in cesium chloride (CsCl) gradient is 1.378 g/cc (72, 109).

Chemical Composition
The DNA viral genome of members of the family *Circoviridae* is circular and single-stranded with a characteristic stem loop structure (53, 103, 106). Early work by Ritchie *et al.,* comparing several isolates of PBFDV from different species of psittacine birds, identified three major viral proteins with molecular weights 26,000, 23,000, and 15,000 daltons (73). Minor proteins with molecular weights of 48,000 and 58,000 also were observed. Later work, however, demonstrated only two viral proteins, 26,000 and 23,000, which are believed to represent the capsid protein and putative replicase-associated protein encoded by open reading frames C1 and V1, respectively (47, 48, 104).

Virus Replication
Because none of the avian circoviruses have been propagated successfully in long-term cell cultures or chicken embryos, little is known about their replication. At present, only two members of the family *Circoviridae* have been propagated in cell culture (53, 106) and provide much of the available information on replication. Chicken anemia virus (CAV) has been grown in MDCC-MSB1 cells derived from Marek's disease lymphoma, and porcine circovirus (PCV) has been grown in PK-15 cells (porcine kidney cell line). Due to the limited size of the genome, circoviruses are highly dependent on cellular enzymes for replication. Circoviruses typically replicate in the nucleus, produce intranuclear inclusions and probably depend on cellular proteins produced during the S phase of the cell cycle (106). Mitosis is needed for DNA to be taken up into the nucleus and replication likely occurs in targeted rapidly dividing cells such as the basal feather follicular epithelium, lymphoid tissues and intestinal crypt epithelium. Results of immunohistochemical studies of birds with natural BFDV infection suggest viral persistence or replication may occur within the intestinal tract and its associated organs (40). Replication of the genome is believed to occur via a rolling circle that originates at the stem-loop structure. A replication-associated protein is encoded within the open reading frame V1 of the viral genome (47, 48, 103, 106). This highly conserved region exhibits marked similarity with the putative replication-associated protein of plant nanoviruses and geminiviruses (5, 23, 56, 106).

Susceptibility to Chemical and Physical Agents
Chemical and physical stabilities have primarily been determined for the circoviruses that can be propagated in cell culture systems (CAV and PCV). As a group, circoviruses are environmentally stable (53, 106, 109). These viruses are relatively resistant to in-

activation by many common disinfectants, acidic environments (pH 3), ether, chloroform, and high temperatures (60° for 30 minutes; 70° C for 15 minutes) (106, 109). Ten percent iodine and hypochlorite are required to inactivate CAV following treatment at 37°C for 2 hours (118). PCV tested at 20°C and 10°C under protein load (40% fetal calf serum in virus suspension) with various combinations and amounts of glutaraldehyde, formic acid, formaldehyde and glyoxilic acid required over 60 minutes for inactivation (115). BFDV still retains ability to agglutinate erythrocytes after incubation at 80° C for 30 minutes (67). Because innate resistance to deleterious agents makes viral inactivation difficult, a commercially produced, killed circovirus vaccine is not currently available (79, 80).

Strain Classification

Antigenicity

A comparative study of four different BFDV preparations from two different species of cockatoos, an Amazon parrot, and a peach-faced lovebird showed that all four isolates were antigenically related using rabbit anti-BFDV polyclonal antibody (73). However, the circoviruses that infect pigeons and Senegal doves are antigenically distinct from BFDV. Immunohistochemical staining using both polyclonal (rabbit origin) and monoclonal (murine hybridoma origin) anti-BFDV primary antibodies (78) did not demonstrate visible chromagen deposition in circovirus-infected pigeon tissues (111). Tissue suspensions from psittacine birds infected with BFDV agglutinated cockatoo erythrocytes, while tissue suspensions of feather, liver, kidney, and gastrointestinal tract from circovirus-infected doves failed to hemagglutinate erythrocytes from galahs (68). Anti-psittacine circoviral hemagglutination inhibition antibodies were not found in doves exposed to psittacine birds infected with BFDV or in doves inoculated with BFDV.

Immunogenicity or Protective Characteristics

Clinically normal birds exposed to BFDV were demonstrated to have higher titers than birds with active viral infections, suggesting that antibody is protective against both viral infection and the development of clinical disease (77). Preliminary work with BFDV also demonstrated that maternal antibody is protective (76). Chicks from vaccinated hens remained clinically normal when challenged with BFDV, whereas chicks from unvaccinated hens were susceptible to viral infection and development of disease. Very few inoculation studies have been performed thus far with circoviruses infecting other avian orders. Anti-psittacine circoviral hemagglutination inhibition antibodies were not found in doves exposed to psittacine birds infected with BFDV or in doves inoculated with BFDV (68), so cross protective immunity does not appear to develop in avian species exposed to non-host circoviruses. However, further detailed studies are needed to clarify this observation.

Genetic and Molecular Characteristics

Putative phylogenies, comparative sequence analysis, and geographic distribution suggest there is an evolutionary link between the animal circoviruses (PCV and BFDV) and the plant nanoviruses and geminiviruses (23, 56). It is speculated that the circoviruses evolved from plant nanovirus DNA after a host-switch to a vertebrate, coupled with recombination in which the sequence encoding part of the replicase-associated protein combined with DNA from a calici-like virus.

Circoviruses have circular, single-stranded DNA, utilize an ambisense genome, and contain two major open reading frames (ORFs) in opposite orientation. One ORF codes for a putative replication protein (ORF V1) and the other ORF codes for a putative coat protein (ORF C1). These ORFs initiate close to a small noncoding region containing the potential stem loop and nonanucleotide motif (TAGTATTAC) associated with initiation of rolling circle replication of the viral DNA (5, 106).

Early work with pigeon circovirus demonstrated that it was related to, but distinct from, BFDV using DNA in situ hybridization with a short (40-base), single-stranded, oligonucleotide probe and a long (1900 bp), double-stranded, PCR-generated DNA probe (111). Complete nucleotide sequencing of the columbid circovirus (CoCV)/pigeon circovirus (PiCV) by Mankertz et al. displayed 55% homology to the genome of BFDV and 34% and 36% homology to PCV types 1 and 2, respectively (48). Nucleotide sequence analyses have been performed on most of the newly described tentative members of the avian circoviruses. Based on the regions encoding the capsid and the replicase-associated proteins, canary circovirus (CaCV) was shown to be closely related to PiCV (58.3%) (62). The starling circovirus (StCV) is closely associated with CaCV (67%) (36). Goose circovirus (GoCV) is less closely related to BFDV than PiCV is to BFDV (105). Sequence analysis of DuCV demonstrated 60% sequence homology with GoCV, 44% with PiCV, and 39% with CaCV (30). RaCV has greatest homology to canary and pigeon circoviruses (98).

Early studies with BFDV isolates showed no evidence supporting a relationship between genetic variation and region, pathogenicity, antigenicity or other physicochemical characteristics (6). In contrast, later investigations have suggested a relationship does exist between viral strain and region, species-specificity and pathogenicity. Recent studies have demonstrated that phylogenetic variation exists between isolates that infect different species within avian orders, suggesting the existence of viral strains. The first evidence presented to suggest variation in clinical disease and species susceptibility was reported in 1993 (38). In this report, 100% mortality occurred in captive black-cheeked and Lillian's lovebirds (Agapornis nigrigensis and A. lilianae) whereas exposed Fischer (Agapornis fischeri) and peach-faced (A. roseicollis) lovebirds had transient feather abnormalities and recovered. Sequence diversity has been demonstrated with BFDV isolates. Strains that infect lories and strains that cause the acute form of disease in African greys (P. erithacus) are specific genotypes (69). Ritchie demonstrated three distinct BFDV lineages in New Zealand in cockatoos, budgerigars and lorikeets suggesting a genotypic association between virus and host (81). Therefore it is apparent that different psittacine circoviral strains can infect different psittacine species causing disease in some but not other individuals within a species, subfamily or order. Additionally, individual species are often infected by closely related strains, but

highly divergent strains also have been detected. Different strains were detected in one clinically ill bird, suggesting either infection with multiple strains of circovirus or genetic divergence of non-pathogenic strains that mutated into a pathogenic strain. The relationship between viral strains, the avian species they infect and the pathogenicity of the strains is complex, however, and definite conclusions cannot be drawn at this time as to the nucleotide sequence of the genome of the infecting virus and its ability to cause disease (14).

The association between strains and the regions in which they are found has been investigated. Phylogenetic variation has been demonstrated between isolates from different regions. For example, variation exists between isolates of GoCV from Germany, Taiwan and China (4, 9) and between BFDV isolates from New Zealand, Australia and South Africa (31). South African BFDV isolates were shown to have diverged from viruses in other parts of the world with 8.3–10.8% diversity between African isolates and Australian isolates. In contrast, similarities exist between Australian and New Zealand circoviral isolates suggesting evolution of genotypic association between viruses and hosts predates dissemination throughout the world (81). There is no evidence of adaptive selection within BFDV populations (variation may be attributed to genetic drift).

DNA sequence analysis of 10 PBFDV isolates demonstrated that the sequence encoding the replicase-associated protein is highly conserved (116). Variation of findings evaluating the association of genotypes and factors such as region, host specificity and pathogenicity may be related to the region or length of the genome compared. Some investigations have evaluated variable lengths of the highly conserved replication-associated protein (ORF V1). Other studies have examined the ORF C1 region of the genome encoding the capsid protein which may more accurately reflect virus-host interaction.

Pathogenicity

Different clinical responses of different avian species to exposure and infection with circoviruses may be associated to numerous factors such as age of the bird at the time of exposure, natural resistance of individuals and species, and the strain of virus. The relationship between viral strains, the avian species infected, the clinical response, and the pathogenicity of the strains is complex and definite conclusions cannot be drawn at this time. (14)

The pathological significance of avian circoviruses has yet to be elucidated. There is substantial histologic and clinical evidence that immunosuppression is associated with circoviral infection in avian species (41, 43, 70, 71, 79, 80, 93, 104, 106, 110, 111, 112). Detailed evaluation of humoral and cell-mediated immune function following experimental infection with BFDV or PiCV has not yet been performed.

Pathobiology and Epidemiology

Incidence and Distribution of Disease

Psittacine beak and feather disease has worldwide distribution (41). The disease has been described in captive and wild populations in Australia (6, 51, 60), New Zealand (81), Africa (2, 31, 38,

39), Europe (7, 32, 63), North America (13, 58, 112) and Asia (37, 57) and is likely present in most regions of the world. The seroprevalence of BFD in different flocks of free-ranging psittacine birds in New South Wales ranged from 41–94% (66). In a 1993 study in which 10,000 captive birds in the United States were evaluated using a DNA probe test, 5% of birds tested positive for BFD viral antigen in blood (13). The majority of these birds did not have clinical signs of BFD, suggesting many birds may be subclinically or transiently infected with BFDV. Old World psittaciformes showed the highest incidence of positive tests. Eclectus parrots had the highest incidence of viremia (10.2%) followed by cockatoos (8.7%) and African grey parrots (8%). New World psittaciformes exhibited a much lower incidence of positive test results. Positive test results in lovebirds exceeded 30%.

Pigeon circovirus is distributed over a wide geographic area encompassing the United States (111), South Africa (22), Canada (58, 112), Australia (68, 112), and Europe (89, 92, 94, 101). The general practice of intermixing young, susceptible pigeons coupled with fecal shedding (27) and extreme persistence of the virus in environment (53, 80) may suggest widespread PiCV-infection of racing pigeons in all continents. Goose circovirus is highly prevalent in goose flocks in Hungary, Taiwan and China (4, 9, 117). In Hungary, GoCV was detected in 48% of 214 diseased or dead birds tested, representing 65% of 76 flocks tested (4).

Natural and Experimental Hosts

Beak and feather disease has been reported in more than 60 species of Old World, South Pacific, and New World psittacine birds with the highest prevalence in Old world and lowest prevalence in New World psittacine birds (106). Infection has been documented in both free-ranging and captive birds. Viral infection may cause acute to chronic, debilitating disease resulting in death. A few spontaneous clinical recoveries have been observed in budgerigars (*Melopsittacus undulatus*), lorikeets, and lovebirds (*Agapornis* sp.) with previous lesions of PBFD (38, 41). Pigeon circovirus infects racing pigeons (*Columba livia*) and Senegal doves (*Streptopelia senegalensis)*. It is currently unknown whether the PiCVs from pigeons and doves are genetically identical. Reports of natural circoviral infection in other avian species include infection of canaries (*Serinus canaria*) (25, 62), finches (55, 88) (*Poephila castanotis, Chloebia gouldiae*), geese (4, 9, 93, 117), ostriches (*Struthio camelus*) (18, 19), pheasants (102), Australian ravens (*Corvus coronoides*)(98), ducks (30, 95, Banda *et al.* submitted 2006), a western scrub jay (Woods, unpublished) and a southern black-backed gull (*Larus dominicanus*) (110). Experimental inoculation studies with avian circoviruses have been frustrated by the inability to replicate the avian circoviruses *in vitro*. Experimental inoculation studies have successfully reproduced disease in psittacine birds infected with virus purified from feather pulp homogenates (77, 114). Experimental inoculation of doves with BFDV has not produced clinical disease or an antibody response to the virus (68).

Age of Host Commonly Affected

Circoviral infection is typically reported in young birds (<3 years of age in psittacine birds and < 1 year of age in pigeons), but has

been reported to occur in birds as old as 20 years of age without previous clinical signs of disease (41, 71). This latter observation indicates that adult naïve birds may become infected and develop clinical disease, although subclinical or latent infection at a younger age or an extended incubation period of disease cannot be discounted. It is generally agreed, however, that birds are susceptible to infection prior to involution of the bursa. In single case reports of clinical circoviral disease in geese (2–9 wk old) (93), ducks (6 wk old) (95), ostriches (<8 wk old) (18), finches (3–6 mo old) (55), canaries (10–20 day old) (25), pheasants (10–30 days old) (102), and in a gull (bursa present) (110) the age of the affected birds were noted as neonates or juveniles. Subclinical infections with circoviruses have been demonstrated to be highly prevalent in both young and adult birds; however, younger birds have a higher rate of infection. In one study, 101/1516 apparently healthy parrots tested positive for BFDV by PCR. Furthermore, the young birds had a higher positive test result rate (7). In another study of clinically healthy psittacine birds, 58/146 tested positive for BFDV (63). In two other studies, 13/20 healthy older pigeons (1–9 years) tested positive by PCR (17) and another study using a PCR-based test detected circovirus in 45/50 healthy adult pigeons (20).

Transmission, Carriers, and Vectors

Neonatal budgerigars and galahs experimentally infected through the combined oral, intracloacal, and intranasal routes developed clinical BFD (75, 79, 80). Additionally, circovirus was demonstrated in crop secretions, feces, and feather dust of BFDV-infected psittacine birds. Results of this study suggest that aerosolized viral particles or direct ingestion of contaminated materials may account for natural routes of viral exposure. Transmission of PBFDV most commonly occurs through shedding of virus in feather dander, followed by fecal shedding, and feeding of chicks with regurgitated crop contents. Hess demonstrated that virus could be detected most frequently in the feathers which did not correlate with clinical signs, suggesting this may be where the virus persists and is shed by adult birds (32). Direct inoculation of the bursa via the cloaca has been suggested as another mode of viral transmission to psittacine birds in nests contaminated with feces and feather dander (65). Circoviruses have been demonstrated by direct electron microscopic examination of negatively stained preparations of intestinal contents from circovirus-infected pigeons, suggesting that shedding and transmission of virus may occur through ingestion or inhalation of feces-contaminated materials (22, 111). In another study by Duchatel et al., PiCV could be demonstrated in 13/20 apparently health pigeons that ranged from 1–9 years of age (17). Viral DNA was detected most commonly in the respiratory organs (trachea, pharynx, lung) followed by spleen, kidney and liver. DNA also was detected in 8/22 embryos supporting vertical transmission. Crop washings, which have been suggested as source of infection in pigeons, were tested by Duchatel. Of 64 crop specimens that were tested, none were positive for circovirus (16). The PCR test results on blood and intestinal contents from healthy pigeons were increasingly positive with the age of the pigeon in one study (20). This observation indicates that the major direction of transmission is likely horizontal.

Similar results were obtained by Duchatel in which cloacal swabs from 15.8 % of the birds were positive at 37 days of age and 100% at 51 days of age, suggesting that pigeons probably became infected in the rearing loft through horizontal transmission of the virus (17). Vertical transmission has been suggested in psittacine birds, pigeons and ostriches with circovirus infection. Chicks derived from artificially incubated eggs of a BFDV-positive Little Corella (*Cacatua sanguinea*) hen consistently developed PBFD after hatching (41). Additionally, 1-day-old pigeons had microscopic lesions compatible with circoviral infection that suggested probable vertical transmission (58). Lastly, circovirus was demonstrated in livers from nonhatched ostrich chicks supporting the theory of vertical transmission in ostriches (18).

Incubation Period

The incubation period of PBFD has been determined experimentally and varies with species and age at the time of viral exposure. In two studies with BFDV, experimentally inoculated chicks developed clinical signs of disease 25–40 days post-inoculation (76, 114). Disease incubation for galah cockatoos (*Eolophus roseicapillus*) and sulphur-crested cockatoos (*Cacatua galerita*) was 3–4 weeks (65). There are a few reports of circoviral infection in older birds; 4–5 years old (83) and 10–20 years old (41), suggesting that either older naïve birds can become infected or these birds were infected as young birds with a prolonged incubation period and/or latency of infection (41, 71).

Clinical Signs

Morbidity and Mortality

Mortality and clinical signs in psittacine birds infected with BFDV are variable and dependent on the species of bird; age of the bird at the time of infection; possibly the viral strain, and presence or absence of concurrent viral, bacterial, fungal, or parasitic infections (41). In some species, infected birds generally survive less than 6 months, but supportive care can considerably lengthen survival time. Secondary infections account for 69% of deaths in birds infected with BFDV (41). Putative immunosuppression may be associated with hypogammaglobulinemia and virus associated infection and destruction of lymphoid tissue. Jacobson found that birds infected with BFDV had lower serum protein concentrations with lower prealbumin and gamma-globulin concentrations (33). Experimentally inoculated birds became acutely depressed and anorectic 4 weeks post-inoculation (76, 114). Progressive symmetric feather dystrophy and loss subsequently developed. Less frequently, beak and claw deformities also occurred. Raue and coworkers found that African grey parrots had two distinct, genetically diverse strains of circovirus (69). One strain was associated with the acute form of disease that had severe leucopenia and nonregenerative anemia without feather disorders as described by Donely and Schoemaker (15, 86). The other strain of circovirus was associated with feather disorders.

In most disease outbreaks, circoviral infection in pigeons is associated with high morbidity and low mortality. However, mortality in circovirus-infected pigeon lofts may range from 1–100%.

Overall mortality ultimately depends upon age of the birds and presence of concurrent infections, as is the case with PBFD (49, 70, 112, 113). A broad range of signs and severity of clinical disease is observed in infected pigeons. In one report, clinical signs were not observed in king pigeons ranging from less than 1 week to 6 weeks of age (58). Red blood cell values and concentrations of hemoglobin and total protein were unaffected by viral infection. White blood cell values were more variable but apparently did not correlate with the degree of bursal damage.

When circoviral infection spreads through a pigeon loft, the most commonly reported clinical signs are poor performance, diarrhea, and ill thrift. Spontaneous clinical recoveries have been observed in some pigeons with clinical circoviral disease (112, 113).

Loss of flight and tail feathers was the only clinical sign reported in *Streptopelia senegalensis* (laughing turtle doves) with circoviral infection (60). Association between a clinical syndrome in ostrich chicks called fading chick syndrome and circoviral infection was demonstrated in 23/52 ostrich chicks with depression, weight loss, anorexia, and diarrhea prior to death (18)

Circovirus was detected in a canary with canary black spot disease and may be associated with this syndrome (25). Clinical signs in canaries with black spot include abdominal distension and failure to thrive. Chicks typically die within 7 days. Feather anomalies are not usually seen.

Clinical signs of circovirus infection in mulard ducks include feather dystrophy along the dorsum (hemorrhagic shafts) and poor body condition with low weight gain (30). Growth retardation and rearing losses between 10–70% have been reported (95)

A single case report of circovirus infection in a 10-wk-old finch described nasal discharge, dyspnea, anorexia and depression (88). In a separate report, circovirus virions were detected by electron microscopy in spleen from four 3–6 month old finches with feather loss over the neck, trunk and dorsal region (55).

Pathology
Gross Lesions
Feather loss in birds infected with BFDV may vary from subtle to severe, depending upon the stage of feather development when viral infection occurs (41, 59, 60, 114). Older birds may develop a chronic form of the disease in which the feathers stop growing shortly after emerging from the follicles. The number of dystrophic feathers increases during each successive molt. In some species, the powder down feathers over the hips are typically the first to show signs of dystrophy. The disease then progresses to involve the contour feathers in most tracts, followed by dystrophic changes in the primary, secondary tail, and crest feathers. Feather dystrophy and loss are roughly symmetrical. Changes in the feathers include retention of sheaths, hemorrhage within the pulp cavity, fracture of the proximal rachis, and failure of developing feathers to exsheathe. Short clubbed feathers, deformed curled feathers, stress lines within vanes, and circumferential constrictions may be observed. When present, beak deformities may occur including abnormal elongation, palantine necrosis, and transverse to longitudinal fractures or delaminations. Infrequently, the claws may develop deformities and the nails may slough.

Feather dystrophy is rare in racing pigeons with circoviral infection. The only gross lesion that can be attributed to circovirus infection in pigeons is bursal atrophy, but this lesion may not be present in all infected pigeons. The majority of the gross lesions observed at necropsy in pigeons that die of circovirus infection is usually attributable to secondary infections with other agents, such as concurrent viruses, bacteria, or fungi (112). However, there is a single report that describes feather dystrophy associated with an outbreak of circoviral infection in commercial pigeons in southern California (96). The gross appearance of the feathers was similar to that in psittaciform birds infected with BFDV. Symmetrical feather dystrophy and loss have been reported in Senegal doves with circoviral infection (60, 68). Feathering disorders also have been observed in finches (55), ravens (98), ducks (95) and geese (93) that were infected with circovirus. Canaries with circovirus infection or "black spot" have been reported to develop abdominal enlargement and gall bladder congestion (25). Necropsy findings in ostriches with fading chick disease include gastric stasis, yolk sac infection and enteritis (18).

Microscopic Lesions
Variable degrees of necrosis and inflammation commonly are observed in dystrophic feathers of birds infected with circovirus (41, 59, 114). Similar lesions have been reported in Senegal doves (60, 68), commercial squabs (96), geese (93), ducks (95) and finches (55). Multifocal to diffuse necrosis is evident in the basal feather (pterlogenic) epithelium, and inflammatory cell infiltrates composed of variable combinations and quantities of heterophils and mononuclear inflammatory cells are seen with and without hemorrhage in the pulp cavity. Lesions also occur in the follicular epithelium but generally are less frequent and less severe. Basophilic to amphophilic nuclear inclusions are typically confined to feather and follicular epithelial cells, while multiglobular, "botryoid," or needle-like cytoplasmic inclusions are confined to macrophages in the feather epithelium, follicular epithelium, pulp cavity, and feather sheath. Associated degenerative changes occasionally are seen in the beak and claws. Cleft formation in the beak results from degeneration and necrosis of epithelial cells in the basal and intermediate cell layers of the rhamphotheca. These changes may be accompanied by hyperkeratosis and the presence of viral inclusions. In some psittacine birds such as African grey parrots, peracute infection with BFDV may be unaccompanied by feather and beak lesions; however, leucopenia, anemia (hypoperfusion of the lungs), bursal lesions and hepatic necrosis may be observed (86).

Changes in primary and secondary lymphoid tissues in birds infected with avian circoviruses may be a direct or indirect effect of circoviral infection. A broad range of microscopic changes may be observed in lymphoid tissues of circovirus-infected birds. These changes range from lymphofollicular hyperplasia with discrete lymphocellular necrosis to severe lymphoid depletion that is often accompanied by globular cytoplasmic viral inclusions within macrophages in the spleen, bronchial-associated lymphoid tissue, and gut-associated lymphoid tissue and within macrophages and bursal follicular epithelium. (Figures 8.8 and 8.9) (41, 112).
8.8. Photomicrograph of the spleen from a pigeon infected with circovirus. Note the lymphofollicular hyperplasia with discrete lymphocellular necrosis within the splenic follicles. H & E. Reprinted courtesy of *Journal of Veterinary Diagnostic Investigation*.
8.9. Photomicrograph of the bursa of Fabricius from a pigeon infected with circovirus. Note the severe cystic bursal atrophy. Basophilic "botryoid" cytoplasmic inclusions are present within cells in remnant bursal lymphoid tissue (*arrow*). Inset. Higher magnification of the cytoplasmic inclusions. H & E. Reprinted courtesy of *Journal of Veterinary Diagnostic Investigation*.

Microscopic lesions, other than those in cutaneous and lymphoid tissues, are generally dependent upon concurrent infections. One study that examined the extracutaneous distribution of viral inclusions in more than 35 naturally infected psittacine birds reported intracytoplasmic inclusions in macrophages of lymphoid tissues (bursa of Fabricius, thymus, bone marrow, spleen), beak, hard palate, esophagus, crop, tongue, parathyroid gland, liver, intestine, thyroid gland, adrenal gland, pancreas, and nail bed (40). Intranuclear inclusions were seen in epithelial cells in the intestine, beak, palate, esophagus, crop, nail bed, and testicular germinal epithelium. Inclusions were limited to the cytoplasm of macrophages in the thymus, tongue, parathyroid gland,

8.10. Transmission electron photomicrograph of the bursa of Fabricius from a pigeon infected with circovirus. The bursal epithelial cell has numerous cytoplasmic nonenveloped virions arranged in paracrystalline arrays. Arrows show desmosomes between epithelial cells. Bar = 500 nm. Inset. bone marrow, liver (Kupffer cells), spleen, thyroid gland, adrenal gland, and pancreas. Although multisystemic distribution of circoviral inclusions occurs in psittacine birds, this has not been reported in pigeons. However, demonstration of PiCV by *in situ* hybridization has demonstrated systemic distribution of circovirus which can be detected in liver, kidney, trachea, lung, brain, crop, intestine, spleen, bone marrow, and heart (90). *In situ* hybridization also has demonstrated viral distribution in the nucleus of cells in the sinuoids of the liver in ostriches with fading chick syndrome (18).

Ultrastructural Observations
Cytoplasmic inclusions within macrophages and bursal epithelium appear as relatively organized paracrystalline arrays, circles, or semicircles of viral particles (Figure 8.10) Infrequently, loosely arranged viral particles also may be observed in epithelial or endothelial cell nuclei. Virions typically measure 14–17 nm in diameter (83, 111, 112).

Pathogenesis

Feather dystrophy and beak and claw deformities can be attributed to circoviral-induced necrosis of the basal epithelium in psittacine birds with BFD. In one study, circovirus-infected birds had increased numbers of apoptotic cells in bursal lymphoid tissue as compared to uninfected birds undergoing physiologic apoptosis (1). The absence of demonstrated viral antigen within lymphocytes suggests that accelerated activation of apoptosis is not likely a direct effect of virus but an indirect cytokine-mediated event. Circoviral cytoplasmic inclusions are typically found in macrophages and bursal epithelium and correlate with phagocytic activity of infected cells rather than endogenously replicating virus.

The small circoviral genome with limited protein-encoding capacity depends on the host cell DNA replication machinery. Therefore, circovirus exhibits tropism for rapidly dividing cells in mitosis (106) such as basal follicular epithelium, lymphoid tissue and intestinal epithelium. Secondary infections account for approximately 70% of deaths in birds infected with BFDV, suggesting that viral infection results in acquired immunodeficiency (41). Putative immunosuppression and death from secondary infections also have been reported in pigeons (112), ducks (95), geese (93), a black-backed gull (110), and other avian species infected with circovirus (18, 104). Lymphocellular necrosis and lymphoid depletion in the bursa of Fabricius and spleen easily explain hypogammaglobulinemia, lack of humoral response to vaccination, and multiple concurrent infections that occur in circovirus-infected birds. Lymphocellular necrosis and depletion may directly impair both humoral and cell-mediated immunity. However, acquired immunodeficiency also may occur in circovirus-infected birds with microscopically normal-to-hyperplastic lymphoid tissues. In such cases, circoviral infection initially may target the monocyte-macrophage system, affecting antigen presentation and cell-mediated immunity. Studies designed to investigate immune function of experimentally inoculated birds will help to clarify the pathogenesis of circoviral infections.

Immunity
Active Immunity
Birds exposed to BFDV have been shown to seroconvert (64, 65, 67, 77). Clinically normal birds that have been exposed to BFDV

have higher titers than birds with active infections, suggesting that antibody is protective against development of clinical disease.

Passive Immunity

Experimental vaccination studies have demonstrated that chicks from vaccinated hens remain clinically normal following challenge with BFDV (76, 77). In contrast, chicks from unvaccinated hens succumbed to BFD when challenged with the same virus. These observations indicate that hens that have been inoculated with killed BFDV can transfer protective antibodies to their offspring (76, 77).

Diagnosis

Presumptive diagnosis of avian circoviral infection is based on clinical signs of disease and routine histology. The primary histologic finding is the presence of characteristic intranuclear and/or intracytoplasmic viral inclusions. Definitive diagnosis of circoviral disease requires the specific observation of characteristic virions by electron microscopy, demonstration of circoviral antigen by immunohistochemistry, or confirmation of circoviral nucleic acid using nucleic acid-based tests such as polymerase chain reaction (PCR), dot blot hybridization (DBH), nested PCR or *in situ* hybridization techniques (4, 7, 18, 20, 21, 29, 32, 44, 57, 69, 79, 82, 91, 107). The hemagglutination (HA) and hemagglutination inhibition (HI) test can be used to demonstrate BFDV antigen and antibody, respectively. Since circoviral infections can be highly prevalent and subclinical and latent infections can occur, demonstration of specific antibodies using hemagglutination inhibition indicates viral exposure but is not necessarily definitive for current viral infection. Additionally, erythrocyte suitability for HA/HI testing varies amongst species (84). Erythrocytes collected from many of the Australian and African birds will agglutinate in the presence of BFDV but there is no agglutinating activity using erythrocytes from South American species such as macaws and amazon parrots (which correlates with resistance of South American avian species to clinical beak and feather disease) (39). Additionally, HI is not effective for demonstrating antibodies in chronically infected birds.

In two separate studies, Smyth demonstrated that nucleic acid-based tests are more sensitive than histopathology at detecting infected birds. Of 107 pigeons examined by *in situ* hybridization, 89% were detected by PCR and 66% were detected by histopathology (90). Liver, kidney trachea, lung, brain, crop, intestine, spleen, bone marrow and heart were positive in circovirus-infected pigeons. Smyth suggested that when bursa of Fabricius is not available, liver is the next best tissue to examine for circovirus. Smyth also showed that routine histopathology was not adequate to detect GoCV infection in geese (91). Goose circovirus was demonstrated in bursa of Fabricius, thymus, bone marrow, liver, kidney, lung, heart and intestines by *in situ* hybridization.

Hess showed that feathers are the tissue of choice over cloacal swabs and blood to detect circovirus in infected birds, but that blood, rather than feathers, best correlates with clinical disease (32). Blood should be drawn from the vein and not the toenail due to possible environmental viral contamination. Toenail blood may be used to screen for circovirus infection, but if the test result is positive, blood should then be collected via venipuncture for confirmation testing (13). Hess suggests that the virus may persist in feathers of carriers (32). Newly erupted quills are the best samples of feathers to examine for viral infection (15). Duchatel tested pharyngeal swabs, cloacal swabs and blood immediately before sacrificing birds and found that these samples did not correlate with PCR results on tissues collected at necropsy (17). He concluded that these specimens are not good samples to take to eliminate birds with asymptomatic viral infection. Respiratory tract tissues most commonly tested positive followed by spleen, kidney and liver.

Nested PCR using DNA from dried blood collected by venipuncture was a very sensitive test and in fact was 10–100 times more sensitive than PCR (29, 37).

Todd (107) and Ball (4) demonstrated that dot blot hybridization (DBH) was less sensitive than PCR. Dot blot hybridization detects between 4 and 40 pg of viral DNA whereas PCR can detect 0.10 fg of viral DNA. Todd suggests that even though DBH is less sensitive than PCR, it is more useful for several reasons. Results of DBH are more likely to correlate with clinical disease if virus load is considered to be an indicator of disease. Higher circoviral titers likely correlate with clinical disease in avian species as is the case in pigs with PCV. DBH is semiquantitative, cross contamination is not probable, and DBH is not limited by minor sequence variation like PCR.

Isolation and Identification of Causative Agent

Long-term propagation of the avian circoviruses in cell culture systems and embryonated chicken eggs has been unsuccessful. Only CAV has been propagated in MDCC-MSB1 cells derived from Marek's disease lymphoma.

Serology

Hemagglutination and hemagglutination inhibition have been used historically to confirm certain viral infections (hemagglutination) or to detect viral exposure by demonstrating viral-specific antibodies (hemagglutination inhibition). Ritchie *et al.* (77) and Raidal *et al.* (64, 67) have reported on BFDV-induced hemagglutination and the development of a hemagglutination inhibition test for detection of BFDV antibodies. These techniques have been used experimentally to partially elucidate the pathogenesis of BFD and to document the exposure of companion and free-ranging birds to BFDV. Erythrocytes from different avian species have variable hemagglutinating activity in response to circovirus. Therefore, validation of each assay system is necessary for accurate and precise diagnostic use.

Differential Diagnosis

Feather folliculitis (due to bacterial, fungal, or other viral infections such as polyomavirus), metabolic imbalance, endocrinopathy, and nutritional disease may result in feather dystrophy that mimics the clinical appearance of PBFD. Because secondary infections are common in circovirus-infected birds, circovirus should always be considered in conjunction with other infectious agents.

Intervention Stategies

Management Procedures
Prevention of circoviral infection is difficult in pigeon lofts and free-ranging bird populations where individuals of various age, origin, and species may intermix freely. Routine biosecurity and isolation procedures will be more effective in preventing viral spread in closed aviaries. After circoviral infection is established, disinfection of lofts, houses and aviaries is difficult to impossible. From results of studies with CAV and PCV, the circoviruses as a group appear environmentally stable and relatively resistant to inactivation by many common disinfectants (3, 53, 115).

Vaccination
Currently, an effective, commercial vaccine does not exist to prevent BFD in psittacine birds or circoviral infections in pigeons. Recombinant technology will be essential in developing effective vaccines, because none of the avian circoviruses (other than CAV) have been grown successfully in cell culture. Preliminary work with BFDV has shown that maternal antibody is protective (67, 77). Additionally, vaccination has been shown to be effective against the development of clinical disease but not against viral infection (65). Therefore, subclinical carriers are not prevented by vaccination. BFDV is extremely difficult to inactivate completely and is highly infectious to susceptible birds. Therefore, inactivated vaccines containing whole virus that is obtained from infected bird tissues should be considered too dangerous for clinical use (80). In one study (65), three sibling sulphur-crested cockatoos were vaccinated with inactivated vaccine but all three died of BFD prior to challenge with live virus. It is speculated that these birds may have been infected prior to vaccination, but the possibility of vaccine-induced disease was also considered.

Treatment
At the present time, an effective treatment does not exist for circoviral infections in psittacine or nonpsittacine birds. Because most birds infected with circovirus die from secondary infections with viral, bacterial, protozoal, or fungal agents, attempts should be made to diagnose and treat any secondary infections. Avian gamma interferon has shown some promise as part of a treatment regimen in birds with active infection. In one study (97), 7/10 African grey parrots (*Psittacus erithacus*) with active BFDV infection (PCR positive and severe leucopenia) responded to treatment with avian gamma interferon (Lowenthal;1 million IU IM SID x 90 d) coupled with quaternary ammonium (1:125; 15 minute, BID) nebulization. Leukocyte counts in surviving birds returned to normal 180 days after treatment was initiated.

Infection of macrophages and destruction of lymphoid tissues during viral infection undoubtedly affect both humoral and cell-mediated immunity. Therefore, birds should not be vaccinated while viral infection is active. Pigeons vaccinated with poxvirus and paramyxovirus vaccine during active circoviral infection in birds in the loft failed to elicit an antibody response to either agent (112). Therefore, antibody titers of birds in an aviary or loft that were vaccinated near or during the time of circoviral infection should be evaluated to determine the efficacy of vaccination. If postvaccinal serum antibody titers are low, revaccination should be performed after clinical signs of disease have subsided in the loft. Vaccination programs in aviaries should always remain current because viral infections are common, secondary viral infection may be concurrent with circovirus infection, and secondary viral infections often are responsible for increased mortality during circoviral outbreaks.

Chapter 9
Adenovirus Infections

Introduction
Scott David Fitzgerald

Adenoviruses are common infectious agents in poultry and wild birds worldwide. Many of the viruses replicate in healthy birds with little or no apparent signs of infection, although they can quickly take on the role of opportunistic pathogens when additional factors, particularly concurrent infections, adversely affect the health of the avian host. Some adenoviruses however (e.g., turkey hemorrhagic enteritis virus, quail bronchitis virus, and egg drop syndrome virus) are primary pathogens in their own right, and others continually turn up in specific disease situations, indicating a degree of guilt by association, although the results of experimental infections to elucidate pathogenic intent have not always been successful.

The first avian adenovirus was isolated in 1949 when material from a case of lumpy skin disease in cattle was inoculated into embryonated chicken eggs (12). Other early unintentional isolates of fowl adenoviruses were the chicken embryo lethal orphan (CELO) isolates made in embryonated eggs (13) and the GAL viruses from chicken cell cultures (4). The first isolate of an avian adenovirus from diseased birds was from an outbreak of respiratory disease in bobwhite quail (*Colinus virginianus*) by Olson (11). Human adenoviruses were isolated in 1954 during investigations of respiratory disease (8) and initially were called adenoidal-pharyngeal-conjunctival agents, but the name adenoviruses subsequently was adopted (7).

Most of the viruses replicate readily in avian cell cultures derived from tissues, such as liver or kidney. Replication takes place in the nucleus and is accompanied by the development of intranuclear inclusions, which may aid histopathological diagnosis (9). The general properties required for classifying an isolate as an adenovirus have been defined by the International Committee on Taxonomy of Viruses (ICTV) (3). This report recognized two genera, *Mastadenovirus* and *Aviadenovirus,* within the adenovirus family, with human adenovirus type 2 and CELO virus as the respective type species (Table 9.1). The aviadenoviruses are serologically distinct from mastadenoviruses (10)

and differ also in their genome organization (3). The genus contains most of the characterized adenoviruses isolated from chickens, turkeys, and geese (see "Group I Adenovirus Infections"), and these viruses often are referred to as group 1 avian adenoviruses in the literature (9).

However, two of the most important adenoviruses causing significant disease in avian species (hemorrhagic enteritis , referred to as group II [see section on "Hemorrhagic Enteritis and Related Infections"] and egg drop syndrome virus, referred to as group III [see subchapter on "Egg Drop Syndrome"]), show substantial differences at the molecular level from the aviadenoviruses. Currently, hemorrhagic enteritis (HE) virus, along with the related viruses of marble spleen disease (MSD) virus of pheasants and splenomegaly virus of chickens, and a recently isolated virus from a frog form the genus *Siadenovirus,* named to reflect one of their unique genome characteristics, namely the presence of a gene coding for sialidase (5, 6). Egg drop syndrome (EDS) virus, along with certain related adenoviruses isolated from ruminants, marsupials and reptiles, are now classified as members of the genus *Atadenovirus*, reflecting their high adenine-thymidine (AT) content (1, 2, 3, 6) (Table 9.1). In addition, a recently characterized adenovirus from a fish appears unrelated to currently recognized genera and may represent a fifth unnamed adenovirus genus (1, 6).

In this review, the group I, II, and III designations, which are commonly used in the literature, will be followed (9).

Table 9.1. Classification of adenoviruses.

Family: *Adenoviridae*
Genus: *Mastadenovirus* Mammalian adenoviruses
    Human, simian, bovine, equine, murine, porcine, ovine,
       caprine, etc.
Genus: *Aviadenovirus* Group I Avian adenoviruses
    Conventional adenoviruses of chicken, turkey, duck, and goose.
    Five species A, B, C, D, and E; 12 serotypes
Genus: *Siadenovirus* Group II Avian adenoviruses Hemorrhagic
    enteritis virus (turkeys)
    Marble spleen disease (pheasants)
    AASV (chickens)
Genus: *Atadenovirus* Group III Avian adenoviruses
    Egg drop syndrome virus and related viruses

Group I Adenovirus Infections

Brian McConnell Adair and Scott David Fitzgerald

Introduction

Definition and Synonyms

The subgroup I avian adenoviruses comprise the genus *Aviadenovirus* within the adenovirus family. In contrast with the clear association of subgroup II (turkey hemorrhagic enteritis and related viruses, and subgroup III (egg drop syndrome) adenoviruses with disease, the role of most subgroup I avian adenoviruses as pathogens is not well defined. Notable exceptions include the FAdV-1 strains, which cause quail bronchitis (see the subchapter on Quail Bronchitis), and also the FAdV-4 strains, which play a major role in the etiology of hydropericardium syndrome. In addition, other strains rapidly can exploit opportunities presented when the health of the bird is compromised (e.g., by coinfection with other pathogens such as chicken infectious anemia virus [CIAV] or infectious bursal disease virus [IBDV]). Strains from several species, but particularly those belonging to species E (see discussion later in this chapter), have a particular predilection for growth in liver cells, and in certain circumstances that at present are not clearly defined can cause severe liver damage leading to the condition known as Inclusion Body Hepatitis (IBH) (see later discussion). Several aviadenovirus reviews are available (7, 71, 94, 96, 97, 99, 101).

Economic Significance

With such variability in their disease association, it is not possible at present to assess the overall economic importance of the subgroup 1 viruses.

Public Health Significance

There is no evidence of productive infection of human cells by subgroup 1 viruses, and therefore any public health implications are likely to be minimal. However there is growing interest in the use of FAdV-1 (CELO) as a gene transfer vehicle for use in humans and possibly other species (142). The virus has been shown to be able to transduce human cell lines without productive replication, and a CELO vector, encoding the herpes simplex virus type 1 thymidine kinase (TK) gene, has been shown to induce anti-cancer activity in human cells (142). Also, there are indications that the avian adenovirus SMAM-1 may play a role in human obesity, although this remains controversial at the present time (48).

Etiology

Classification

Within the adenovirus family, species designation depends on at least 2 of a number of key criteria that include calculated phylogenetic distance, restriction enzyme fragmentation, host range, pathogenicity, cross neutralization, and possibility of recombination (16). Five aviadenovirus species, designated with the letters A–E are recognized, based largely on molecular criteria in particular restriction enzyme fragmentation patterns and sequencing data (Table 9.2). Viruses within each species are further subdivided into serotypes based largely on the results of cross neutralization tests (23, 39, 42, 67, 80, 81, 83, 99, 102).

Table 9.2. Group 1 avian adenoviruses—classification.*
Genus *Aviadenovirus* (Group 1 avian adenoviruses)

Species in the Genus
Fowl adenovirus *A*
  Serotypes: Fowl adenovirus 1 (FAdV-1) (CELO, 112, QBV, Ote, H1)
Fowl adenovirus *B*
  Serotypes: Fowl adenovirus 5 (FAdV-5) (340,TR-22, Tipton, M2)
Fowl adenovirus *C*
  Serotypes: Fowl adenovirus 4 (FAdV-4) (506, J2, KR5, H2, K31, 61)
Fowl adenovirus 10 (FAdV-10) (C-2B, M11, CFA20, SA2)
Fowl adenovirus *D*
  Serotypes: Fowl adenovirus 2 (FAdV-2) (GAL-1, 685, SR-48, H3, P7)
Fowl adenovirus 3 (FAdV-3) (SR-49, 75, H5)
Fowl adenovirus 9 (FAdV-9) (A2, 90, CFA19)
Fowl adenovirus 11 (FAdV-11) (380, UF71)
Fowl adenovirus *E*
  Serotypes: Fowl adenovirus 6 (FAdV-6) (CR119, 168)
Fowl adenovirus 7 (FAdV-7) (YR36, X-11, 122)
Fowl adenovirus 8a (FAdV-8a) (58, TR-59, T-8, CFA40)
Fowl adenovirus 8b (FAdV-8b) (764, B3, VRI-33)
Tentative Species in the Genus Aviadenovirus
Duck adenovirus (DAdV) (Duck adenovirus 2)
Pigeon adenovirus (PiAdV)
Turkey adenovirus (TAdV) (Turkey adenovirus 1, 2)

*(Based on Benko *et al*. [14])

9.2. Growth of FAdV-8 (764) in chick kidney cell cultures. Intranuclear inclusions stained by direct immunofluorescence.

Morphology
Ultrastructure and Symmetry
Details have been reviewed previously (94, 97). The virion is composed of 252 capsomeres, surrounding a core 60–65 nm in diameter. Capsomeres are arranged in triangular faces with six capsomeres along each edge. There are 240 nonvertex capsomeres (hexons) of 8–9.5 nm diameter and 12 vertex capsomeres (penton bases). Vertex capsomeres carry projections known as fibers (134). Mammalian adenoviruses have one fiber on each penton base, and the aviadenoviruses appear to have 2 (27, 59). In most cases, both fibers are of similar length, and there appears to be a relationship between fiber length and antigenic properties, because serotypes, which are related in cross-neutralization tests, have fibers of similar length. FAdV-1 (CELO), however, possesses 2 fibers of different lengths (i.e., 42.5 and 8.5 nm) which appear as 2 distinct proteins by partial peptide mapping (87, 89). Sequencing studies with FAdV-1 (CELO) have confirmed these findings and indicated the presence of 2 fiber genes (27). Exactly how the vertex capsomere is assembled to accommodate 2 fibers is not fully understood (27).

Ultrastructural studies demonstrate accumulation of virus particles in the nucleus of infected cells, and these often form crystalline arrays (3) (Fig. 9.1). Four types of inclusions, which differ in morphology and density depending on the content of viral protein and DNA, have been recognized (2,3). Large intranuclear inclusions are also clearly visible in tissues from infected birds or in infected cell cultures by cytochemical or immunostaining methods (Figs. 9.2 and 9.3), and these may be useful in diagnosis of adenovirus infections.

Size and Density
The adenovirus virion is a nonenveloped, icosahedral structure 70–90 nm in diameter (97). Densities between 1.32 and 1.37 g/mL in cesium chloride (CsCl) have been estimated for aviadenoviruses. Similar differences in density, which have been attributed to differences in DNA content and base composition in different isolates, have also been found in human adenoviruses.
9.3. H & E staining of chick kidney cells infected with FAdV-8 (768) showing basophilic inclusions in the nucleus.

Chemical Composition

The nucleic acid is double-stranded DNA, which accounts for 11.3–13.5% of the virion, with the remainder being protein (162). Others, however, have reported 17.3% DNA in FAdV-1 and estimated the guanine-cytosine (G-C) content of DNA at 54%, intermediate between the G-C contents of highly oncogenic (47–49%), and nononcogenic serotypes (57–59%) of human adenoviruses. Between 11 and 14 structural polypeptides have been described for FAdV-1.

Virus Replication

Adenovirus replication is divided into 2 well-defined phases. The early phase involves the entry of virus into the host cell and the transfer of the virus DNA to the nucleus, which is followed by the transcription and translation of the so-called early (E) genes (134). Proteins coded by the early genes are responsible for a redirection of cellular functions, in order to facilitate replication of the virus DNA and the consequent transcription and translation of the late (L) genes, coding for the virus structural proteins. Assembly of the viral proteins into complete virions is completed in the nucleus, and this is followed by disruption of the nuclear membrane and release of virus by destruction of the cell.

Susceptibility to Chemical and Physical Agents

All avian adenoviruses tested so far have shown typical adenovirus properties (see reviews 7,21,94,97,100). They are resistant to lipid solvents such as ether and chloroform, sodium deoxycholate, trypsin, 2% phenol, and 50% alcohol. They are resistant to variations in pH between 3 and 9 but are inactivated by a 1:1000 concentration of formaldehyde. They are inhibited by the DNA inhibitors IuDR and BuDR.

Although it is accepted that adenoviruses in general are inactivated in aqueous solution after exposure to 56°C for 30 minutes and that heat stability is reduced by divalent ions, the avian adenoviruses show more variability and are apparently more heat resistant. Some strains survive 60°C and even 70°C for 30 minutes. The infectivity titer of one FAdV-1 virus fell rapidly after 180 minutes at 56°C, and another FAdV-1 strain apparently survived 18 hours at 56°C. Even strains tested in the same laboratory have shown differences in thermostability, suggesting the differences were not due to variation in technique. Although most workers found that divalent cations destabilize adenoviruses, some have found no effect. These divergent results may be due to technique, and it is important to standardize suspending media and pH carefully.

Hemagglutination

Hemagglutination has been reviewed by McFerran (97). FAdV-1 virus hemagglutinates rat erythrocytes. Optimal agglutination of erythrocytes occurs between pH 6 and 9 at temperatures between 20° and 45°C. The hemagglutinin is stable to treatment with trypsin, RNase, DNase, and neuraminidase. It is inactivated after 15 minutes at 56°C, and 0.2% formaldehyde reduces the HA titer by eightfold. Apart from rat erythrocytes, most FAdV-1 strains do not agglutinate erythrocytes from other species. However FAdV-1 (Indiana C) was found to agglutinate sheep erythrocytes, suggesting some variation within serotypes. No evidence exists for hemagglutination by any of the other fowl serotypes or by the turkey or duck aviadenoviruses (18).

Strain Classification

Antigenicity

The adenovirus hexon is the major capsid protein and contains type, group, and subgroup specific antigenic determinants (97, 98). Birds infected with aviadenoviruses, therefore, produce type-specific, group-specific, and subgroup-specific antibodies. The group-specific determinants are shared by all subgroup I viruses, but are not present in subgroup II or subgroup III adenoviruses (although EDS virus appears to show some partial cross reactivity with subgroup I viruses, which has been demonstrated by indirect means). The double immunodiffusion (DID) test, which has often been used to demonstrate group-specific reactivity, can be used, therefore, to differentiate subgroup I, II, and III viruses.

Type-specific determinants give rise to antibodies that neutralize viral infectivity, and, therefore, the neutralization test has been widely used to separate isolates into serotypes (23, 39, 42, 67, 80, 81, 83, 99, 102). The current classification of subgroup I adenoviruses is shown in Table 9.2.

Immunogenicity and Protective Characteristics

Neutralizing antibodies produced against the type-specific epitopes should provide protection, but field and experimental experience indicates that the protection is relatively short lived.

Molecular

Restriction enzyme (RE) analysis was used to differentiate 12 recognized serotypes into 5 genotypes designated A–E (161), which are now recognized as separate adenovirus species (Table 9.2) (16). PCR has been applied to detection of subgroup I aviadenoviruses, with primer sequences based on the hexon gene (71) and allocation of viruses to species A–E and to serotypes within species is now frequently carried out by PCR (16, 71, 161).

Laboratory Host Systems

Most chicken isolates have been made in chick kidney (CK) or chicken embryo liver (CEL) cells. Although it has been claimed that CEL cells are more sensitive, there appears to be little difference when examining clinical material. However, CEL cells are preferable for diagnostic purposes because of their greater sensitivity to other viruses. Fowl adenoviruses form plaques in CK cells. Chicken tracheal organ cultures and chicken embryo fibroblasts appear to be less sensitive than other cells (98).

Adenoviruses have been isolated from turkeys and from a variety of other birds, including ducks (18), guinea fowl (120), pigeons, budgerigars, and mallard ducks (104, 152), using chicken cell cultures. Some turkey adenoviruses, however, grow only in turkey cells and do not grow or grow only poorly in chicken cells (123). It may be that if other avian species are examined using homologous cell systems, an extended range of viruses will be recognized.

Although it is probable that all aviadenoviruses multiply in the embryonated egg, not all chicken or turkey isolates cause recognizable lesions. The chorioallantoic membrane route of inoculation was found to be more sensitive for virus isolation than the allantoic cavity (80). High virus titers of all prototype strains except FAdV-3 (SR49) killed chicken embryos, but when low infectivity titers were used, only FAdV-1 (Ote) killed embryos. When material from naturally occurring adenovirus infections was used (20), only three isolations were made in embryonated eggs compared with 45 in cell culture. Most adenovirus isolates made in eggs have been typed as FAdV-1 or 5, which are not the most prevalent viruses in chicken populations when either serologic surveys (67) or virus isolation studies (40,41,157) have been carried out in cell cultures. However, inoculation into the yolk sac, and to a lesser degree onto the chorioallantoic membrane, supported the growth of 11 recognized serotypes (37). Signs and lesions produced in the embryo were death, stunting, curling, hepatitis, splenomegaly, congestion and hemorrhage of body parts, with urate accumulations in the kidneys. Hepatocytes usually contained basophilic or eosinophilic, intranuclear inclusion bodies. The FAdV-4 viruses associated with hydropericardium syndrome grew on the chorio-allantoic membrane and in the yolk sac on egg inoculation (6, 92).

Pathogenicity

Because the role of subgroup I adenoviruses as primary pathogens is not clearly established, factors determining pathogenicity are not clear. Different serotypes, and even strains of the same serotype, can vary in their ability to produce illness and death (19, 34) or respiratory disease (47). Variation in the ability to grow and persist in embryo tendon explants has also been noted (60). With some isolates, a relationship has been found between genotype and virulence but not between serotype and virulence (52). Although FAdV-1 produces a variety of tumors when inoculated into hamsters and will transform human and hamster cells (97), attempts to demonstrate oncogenicity with other avian serotypes have been unsuccessful (54).

In many studies, the route of inoculation has been extremely important in producing disease. Many isolates have failed to cause disease when inoculated by natural routes or by direct spread but were highly pathogenic when given by parenteral inoculation. This may suggest that many adenoviruses are potential pathogens but require the presence of some other agent to allow them to cause disease. Thus, coinfection with IBDV enhanced the pathogenicity of some aviadenoviruses (55,132), and the ability of some viruses to cause hepatitis and death was also considerably enhanced by coinfection with CIAV (19). In contrast, presence of an adenovirus-associated parvovirus may reduce the growth of the adenovirus in cell cultures as well as pathogenicity and oncogenicity (97).

Pathobiology and Epidemiology
Incidence and Distribution
Subgroup I avian adenoviruses are distributed widely throughout the world, and domestic avian species of all ages are susceptible.

Other avian species appear to be susceptible to infection with fowl serotypes as well as serotypes of their own, but this has not been fully investigated.

Natural and Experimental Hosts
Chicken adenoviruses are ubiquitous in fowl populations, as demonstrated in antibody surveys (67, 157) and by the high levels of virus isolation from specimens taken from normal and sick birds (41, 80, 83, 101). In addition to infecting chickens, fowl adenovirus serotypes have been recovered from turkeys, pigeons, budgerigars, and a mallard duck (28, 104), and probable fowl isolates have come from guinea fowl (102) and pheasants (22).

Particles that are probably adenoviruses have been observed by electron microscopy in thin sections of tissue taken from kestrels (144), herring gulls (88), peach-faced lovebirds (153), a rose-ringed parakeet (45), budgerigars, rosella, red-rumped parakeets (109), eclectus parrots (124), common murre (90), a cockatiel (141), and a tawny frogmouth (127).

In addition to being infected with chicken serotypes, turkeys are also infected with adenoviruses that grow in cells of turkey origin but either do not grow or grow poorly in cells of fowl origin (140). Antibody to these viruses is widespread in turkeys.

Adenoviruses have been isolated from geese, and antibodies in geese are widespread. These viruses are unrelated in cross-neutralization tests to the recognized fowl serotypes but grow in cells of both goose and fowl origin (129, 160). A subgroup I adenovirus has been isolated from a Muscovy duck (18). This virus was unrelated to recognized fowl or turkey serotypes but did grow in chicken as well as duck cells. This virus is now classified as duck adenovirus type-2 (DAdV-2; Table 9.2), egg drop syndrome (EDS) virus being duck adenovirus type-1 (DadV-1).

Attempts to grow avian adenoviruses in mammals have met with very limited success. FAdV-1 has produced fibrosarcomas, hepatomas, ependymomas, and adenocarcinomas when injected into hamsters (97), and another isolate has produced hepatitis in hamsters (54).

Age of Host Commonly Affected
Some viruses cause mortality in day-old chicks, following inoculation, but not in 10-day-old birds (34). Virulence could be associated with the strain of virus, the age of bird, and the infectivity titer, with the minimum lethal dose ranging from 4 to >300,000 $TCID_{50}$ (15).

Transmission, Carriers, and Vectors
Vertical transmission is important in the spread of adenoviruses. Adenoviruses are transmitted through the embryonated egg and are often reactivated in cell cultures prepared from embryos and young chicks taken from infected flocks (98). This has been one of the strongest motivations for establishing SPF flocks. There is evidence that adenovirus infection can remain latent and undetected for at least one generation in an SPF flock (56).

Although adenoviruses can be isolated from day 1 following infection onward, viruses normally are excreted from week 3 onward. In broilers, peak excretion occurred between 4 and 6 weeks of age (97). In layer replacements, virus excretion was at a max-

imum level from 5–9 weeks following infection but was still at 70% after 14 weeks, and six adenovirus serotypes were isolated from samples taken from four farms (157). In a study beginning with 8-week-old birds (41), excretion continued at a high level until 14 weeks of age, and eight different serotypes were isolated from samples from seven farms. It is not uncommon to isolate two or even three serotypes from one bird, suggesting that there is little cross protection. Certainly birds can excrete one serotype in spite of high levels of neutralizing antibody to other serotypes. There appears to be a second period, around peak egg production, when adenoviruses are often detected. Presumably, the stress associated with egg production or the increased levels of sex hormones at this time caused reactivation of the virus. This would ensure maximum egg transmission to the next generation.

Horizontal spread of virus is also important. Virus is present in feces, the tracheal and nasal mucosa, and kidneys. Therefore, virus could be transmitted in all excretions, but highest titers are found in the feces. Virus may also be present in the semen, presenting a potential risk where artificial insemination is used. A juvenile as well as an adult pattern of virus excretion has been demonstrated. A 35-day-old bird showing the adult pattern had a lower peak titer of adenovirus present in the feces with an earlier decline in virus titer, and excretion persisted for a shorter time than in newly hatched chicks, which exhibited the juvenile excretion pattern (33). Horizontal spread within a flock seemed to take place mainly by direct fecal contact but was also achieved by aerial contact over short distances, with infection spreading at a very slow rate for several weeks (33). This pattern has also been seen in experimentally infected and in adventitiously infected SPF flocks and contrasts markedly with the normal pattern usually found in commercial flocks in which most birds in a flock are often excreting adenoviruses. In these circumstances, it is probable that many foci of infection exist, due to reactivation of latent viruses. Commercial flocks are often derived from a number of parent flocks, each of which harbor their own range of adenovirus serotypes. Consequently, cross infections resulting in the mixing of several serotypes take place when the birds are brought together. Aerial spread between farms does not appear to be important, except when cleaning of depopulated houses takes place, when the dust created can transmit infection between farms. Spread by fomites (e.g., egg trays and egg trolleys), personnel, and transport can also be important.

Incubation Period

Although adenoviruses have been associated with a number of clinical conditions, the evidence for a primary role in disease is conflicting. The incubation period is short (24–48 hours) following infection by natural routes.

Clinical Signs
Inclusion Body Hepatitis
Inclusion body hepatitis (IBH) is characterized by sudden onset of mortality peaking after 3–4 days and usually stopping on day 5 but occasionally continuing for 2–3 weeks. Morbidity is low; sick birds adopt a crouching position with ruffled feathers and die within 48 hours or recover (73,93,105). Mortality may reach

10% and occasionally as high as 30% (15). IBH normally is seen in meat-producing birds at 3–7 weeks of age, but it has been reported in birds as young as 7 days old (15) and as old as 20 weeks (76). There is evidence that in an integrated broiler operation, disease occurs in chickens from certain breeder flocks (93).

Many different serotypes have been associated with naturally occurring outbreaks of inclusion body hepatitis (IBH). Among those recorded are FAdV-1 (138); FAdV-2, FAdV-3, and FAdV-4 (65, 105); FAdV-5 (53, 104); FAdV-6, FAdV-7, and FAdV-8 (81); FAdV-7 and FAdV-10 (15); FAdV-8 (68 ,93, 105); FAdV-9 (69); and FAdV-12 (137).

Some workers have been successful in reproducing liver lesions with basophilic intranuclear inclusions (68, 95, 137) (see Fig. 9.4A), or both liver and pancreatic lesions (130) following parenteral inoculation of very young chicks with adenovirus. When 12-month-old birds were inoculated intravenously with an FAdV-1 virus (78), no clinical signs were seen, but there was degeneration, necrosis, and a cellular response in the liver, with a mild response in the trachea and lungs. Occasionally, liver lesions have developed following natural routes of infection in older birds (53), but more typically, no disease results even when unnatural routes of exposure are used (93,96).

Outbreaks of IBH in chickens less than 3 weeks of age with mortality up to 30% has occurred in Australia (15). IBH has been reproduced by inoculating day-old chicks by nasal and ocular routes with 24 isolates belonging to serotypes 6, 7, and 8. When these isolates were analyzed using restriction enzymes, it was found that all were FAdV-E viruses (52). In New Zealand, FAdV-8 was the most common isolate from IBH outbreaks, but FAdV-1 and 12 were also isolated. All belonged to the FAdV-E genotype (29) but differed from the Australian IBH FAdV-E isolates (137). These isolates produced focal hepatitis in 2-day-old birds infected orally. In contact, birds did not develop IBH but showed severe growth retardation (135).

Immunosuppression induced by IBDV infection appears to facilitate adenoviruses in producing IBH (55, 132). In both Northern Ireland and New Zealand, however, IBH occurred in chickens before IBD was present in the country (29), and IBH has occurred spontaneously in SPF birds in the absence of IBD (126). When birds were infected with both CIAV and adenovirus, there was increased incidence of hepatitis and death (19).

Inclusion Body Hepatitis in Other Birds
A number of outbreaks of IBH have been recorded in pigeons. In addition to hepatitis, pancreatitis has also been found (35, 61, 82, 105, 146). Inclusion body hepatitis has been diagnosed in a group of eclectus parrots (124), kestrels (144), and a merlin (138), and an adenovirus was also recovered from day-old turkeys with IBH (64).

Hydropericardium Syndrome
In 1987, a new condition—Hydropericardium Syndrome or Angara disease—was recognized in Pakistan, and within one year it had devastated the national broiler industry in Pakistan. The disease subsequently was recognized in India, Kuwait, Iraq, Japan, and the former U.S.S.R. A very severe form of IBH was
9.4. A. Large basophilic intranuclear inclusion bodies in liver of a chicken experimentally infected with FAdV-8. B. Eosinophilic intranuclear inclusion body in hepatocyte of a chicken with naturally occurring inclusion body hepatitis.

diagnosed in South and Central America and Mexico. This disease was similar to hydropericardium syndrome, and it appears that the only differences between hydropericardium syndrome and IBH is that the mortality rate and incidence of hydropericardium is higher in the former disease. It caused between 20 and 80% mortality, with very low morbidity. Typically, mortality starts at 3 weeks, peaks for 4–8 days in weeks 4 and 5, and then declines (13, 38). Hydropericardium syndrome also occurs in breeding and laying flocks, with lower mortality rates. Adenoviruses are considered to be the cause of this condition, but some workers have claimed that other agents may also be involved (6, 13, 26). Twelve isolates from clinical outbreaks of infectious hydropericardium in 7 Asian and American countries were studied. Nearly all were shown to be FAdV-4 viruses, although one report included a FAdV-12 isolate, and there was also a genomic relationship between the FAdV-1 isolates (72, 121). Experimental studies indicate that there may be variation in virulence between strains (9). Some FAdV-4 isolates can reproduce the condition by themselves, and other strains appear to require the assistance of an immunosuppressive agent such as CIAV or exposure to immunosuppressive aflatoxins in the feed (143, 148).

The agent spreads well laterally among birds, and personnel appear to be important vectors (10, 11). Liver suspension from affected birds is infectious when inoculated by the oral or in-

tranasal routes. Higher mortalities follow subcutaneous inoculation and the possibility that the initial massive spread throughout Pakistan was the result of a contaminated vaccine has been raised (10). In addition, this virus is also spread vertically (14, 150).

The disease has also been seen in pigeons (110). It was possible to reproduce the disease in broilers using liver suspensions from infected pigeons, and the disease in pigeons was controlled using the poultry vaccine.

Gizzard Erosions

There have been several reports over the last six years describing outbreaks of gizzard erosions in broilers from which a group I avian adenovirus has been associated (1, 118, 119). To date, these reports have originated in Japan, and have predominantly isolated a serotype 1 adenovirus, although one report has identified a serotype 8 adenovirus (113, 118, 119). No clinical signs except for mortality in young broilers have been reported in natural outbreaks. Gizzards are distended with hemorrhagic fluid, and contain multiple black patchy erosions within the koilin layer (1). A number of experimental inoculation studies using oral inoculation into young broilers or leghorns between 1 and 5 weeks of age reproduced the gizzard erosions in 3 to 18 days postinoculation (111, 113, 114, 116, 117). In some experiments, in addition to reproduction of gizzard erosions, investigators also found pancreatitis, hepatitis, cholecystitis, and cholangitis, indicating in-

fection spread through a number of digestive organs beyond the gizzard (113, 116).

Recently, a report from the United States described a similar condition of broilers to adenoviral-induced gizzard erosions, but this time the lesions were restricted to the proventriculus, and the authors termed this condition transmissible viral proventriculitis (TVP) (70). This adenovirus appears to be distinct from all known avian adenoviruses, failing to cross react with groups I, II, or III by IFA or PCR assays.

Aviadenovirus Infection in Chickens
Egg Production. Some workers have reported adenovirus infection resulting in a 10% fall in egg production (32) or an adverse effect on eggshell quality (40, 154). In a similar study, however, no effect on egg quality was demonstrated following experimental infection of birds with four strains of adenovirus, and only one virus strain had a minimal effect on the number of eggs produced (40). Adenoviruses can be isolated from commercial flocks, even when exceptionally high levels of production and fertility exist, and adenovirus infections of SPF flocks in lay are often associated with little or no effect on either egg production or shell quality.

Food Conversion and Growth. There have been reports of adenovirus infection resulting in decreased food consumption (40). Although birds inoculated with adenovirus may have depressed body weights and even high mortality (34, 66), there is little evidence to suggest that naturally occurring infection causes either reduced food utilization or growth. However, growth retardation did occur in naturally infected birds kept under experimental conditions (137). Chickens inoculated with adenovirus had reduced weight gain accompanied by excess fat deposition and depressed cholesterol and triglyceride levels (49). However, a study in Denmark was unable to detect any effect on broiler flock performance (77).

Respiratory Disease. Subgroup I aviadenoviruses frequently have been isolated from both the upper and lower respiratory tract of birds with respiratory disease (51, 79, 101, 115, 130). A survey of records of virus isolations, clinical, and necropsy findings over a 20-year period, involving hundreds of adenovirus isolations, indicated no primary role for adenoviruses in fowl respiratory disease. Before infectious bronchitis was controlled by vaccination and *Mycoplasma gallisepticum* and *Mycoplasma synoviae* were eradicated from poultry flocks, lesions in the respiratory tract were considerably more severe when adenoviruses were isolated from the respiratory tract specimens. Schmidt *et al.* (139) recorded similar findings and reported that mixed infectious bronchitis-mycoplasma-adenovirus infections presented with a similar clinical picture to infectious laryngotracheitis. Catarrhal tracheitis and multifocal pneumonic lesions, similar to lesions resulting from experimental adenovirus infections, were found in 13 outbreaks, leading to the conclusion that adenoviruses were a significant cause of respiratory disease (43).

Experimental infections have produced equivocal results. Using aerosol exposure, mild respiratory disease was produced

(8). Following intratracheal inoculation, respiratory disease usually occurred (32, 96), but occasionally no signs were noted (42).

Tenosynovitis. Adenoviruses have been isolated from chickens with tenosynovitis, but experimental work has not confirmed their involvement (76).

Aviadenovirus Infection in Turkeys
Adenoviruses have been isolated from clinical outbreaks of respiratory disease, diarrhea, and depressed egg production in turkeys, but attempts to reproduce disease generally have been unsuccessful (51, 145).

Aviadenovirus Infection in Geese and Ducks
Three serotypes isolated from geese did not reproduce disease in goslings (160). In outbreaks of high mortality associated with hepatitis, adenovirus-like particles were seen in the liver (128).

A diphtheroid, stenosing tracheitis with occasional bronchitis and pneumonia was seen in up to 10% of 7–21-day-old Muscovy ducks, and the tracheal epithelial cells contained numerous adenoviruses (17). A similar condition was recently described in geese in Canada (129), where an isolated parent flock became infected with adenovirus, and produced two hatches in which mortality reached 12% in 4–11-day-old goslings.

Aviadenovirus Infection in Pigeons
Adenoviruses have been associated with two clinical diseases in pigeons in Belgium, described as adenovirus type I (classical adenovirus), and type II (necrotising hepatitis) (44, 82). Classical adenovirus occurs in pigeons under 1 year of age and appears to be associated with the stress associated with the first pigeon races. The virus replicates in the nuclei of epithelial cells of the intestinal tract and also in the liver. The affected pigeons have watery diarrhea, vomiting, and weight loss. There is rapid spread within affected pigeon lofts, with up to 100% morbidity in birds under 1 year old within 2 days. Uncomplicated cases resolve in about 1 week, but secondary bacterial infections can lead to more severe and prolonged disease and death. Pigeons that recover suffer greatly impaired racing performance.

Necrotising hepatitis occurs throughout the year in pigeons of all ages. There are often only minimal signs of disease, however, vomiting and yellow liquid droppings have been reported in some cases, although sudden death within 24–48 hours of infection is often the only sign. The virus induces massive hepatic necrosis in affected birds. New cases in a pigeon loft may occur over a period of 6 weeks, with total mortality reaching 30%, although 100% mortality has been reported. The birds that do not die remain completely normal. On autopsy, the liver is yellow in color and swollen. There is extensive hepatic necrosis, with eosinophilic or amphophilic intranuclear inclusion bodies in hepatocytes (44). These conditions have been reviewed by Vereecken *et al.* (152).

Aviadenovirus Infection in Guinea Fowl
Two strains of adenovirus were isolated from naturally occurring outbreaks of pancreatitis in guinea fowl. One strain induced se-

vere disease and death with respiratory and pancreatic lesions after oral and nasal infection of 1-day-old guinea fowl (120). Foci of necrosis with large basophilic and smaller eosinophilic inclusion bodies were seen in guinea fowl suffering from necrotic pancreatitis (125). An FAdV-1 isolate from guinea fowl with necrotizing pancreatitis reproduced the condition experimentally (85). A hemorrhagic disease of guinea fowl in which adenoviral inclusions were present in the spleen has been described and reproduced experimentally (91).

Aviadenovirus Infection in Ostriches
Adenoviruses have been associated with illness, death, and poor hatchability on ostrich farms (122), and an isolate from an ostrich caused pancreatitis in guinea fowl (24, 63). In a study in which 3-day-old ostrich chicks were inoculated with an ostrich-derived adenovirus, all died (123).

Pathology
Inclusion Body Hepatitis
In the literature are several descriptions of a disease primarily affecting the liver and also one in which the primary lesions appeared to be present in the hemopoietic system. It is probable that the aplastic anemia described was due to infection with CIAV (159) (see Chapter 8). The main lesions of IBH are pale, friable, swollen livers. Petechial or ecchymotic hemorrhages may be present in the liver and skeletal muscles (73, 93, 105).

Inclusion bodies are seen in the hepatocytes. These can be eosinophilic, large, round, or irregularly shaped with a clear pale halo (67, 68, 74) or occasionally basophilic (67, 68, 74) (Fig. 9.4A, B). In IBH cases in Australia, basophilic inclusions appear to predominate (15, 81). Virus particles were detected only in cells with basophilic inclusions, and the eosinophilic inclusions were composed of a fibrillar, granular material (75). In New Zealand, lesions included atrophy of the bursa and thymus, aplastic bone marrow, and hepatitis. Inclusions were eosinophilic. The description of bursal and thymic atrophy in the absence of IBD is interesting (29).

Hydropericardium Syndrome
In cases of hydropericardium syndrome, there is an accumulation of clear straw-colored fluid in the pericardial sac, pulmonary edema, swollen and discolored liver, and enlarged kidneys with distended tubules showing degenerative changes. Multiple areas of focal necrosis exist with mononuclear infiltration in the heart and liver. Basophilic inclusions are present in the hepatocytes (13). One report describes multifocal pancreatic necrosis and gizzard erosions in associated with hydropericardium syndrome (112).

Respiratory Disease
In naturally occurring outbreaks, mild to moderate catarrhal tracheitis with excess mucus were the only gross lesions noted (46). Hyperemia of the lungs, cloudy air sacs, and petechial hemorrhages in the pharynx and larynx were described after experimental infection (7). Microscopically, the main lesions were loss of cilia, necrosis of some epithelial cells, intranuclear inclusion bodies, and infiltration of mononuclear cells into the lamina pro-

pria. Multifocal or occasionally diffuse interstitial pneumonia was found (7, 46, 47). Following aerosol exposure, epithelial hyperplasia, edema, and infiltration by mononuclear cells were seen in the air sacs (7).

Necrotizing Pancreatitis and Gizzard Erosions
Focal pancreatitis and gizzard erosions have been described in broiler chickens in both natural outbreaks and experimental studies in Japan (113, 116). Intranuclear inclusion bodies containing adenovirus antigen in glandular epithelial cells were associated with necrosis of the koilin layer, and infiltration of the lamina propria, submucosa and muscle layers by macrophages and lymphocytes (1, 111, 112, 116, 117, 118, 119). Intranuclear inclusions have also been demonstrated in necrotic pancreatic acinar cells (112, 116, 147). Pancreatitis associated with adenoviral infection has been recorded in guinea fowl (120, 125).

Immunity
Subgroup I avian adenoviruses have a common group-specific antigen that is distinct from that of human adenoviruses (24, 80, 103). There are differences in the degree to which this antigen is shared between serotypes. For example, FAdV-1 gave a strong reaction with its own antiserum, but FAdV-1 antigen failed to detect antibody to FAdV-2 or FAdV-4 (80). A microtiter fluorescent antibody test (4) confirmed these differences in titer.

Subgroup I adenoviruses isolated from turkeys (TAdV-1 and 2; Table 9.1) have a common antigen detected in double immunodiffusion (DID) tests, and this distinguishes them from the subgroup II (turkey hemorrhagic enteritis) adenoviruses (50, 103). The adenovirus isolate from a Muscovy duck (DAdV-2) was also reported to share an antigen with FAdV-1 (18).

Following infection, birds rapidly developed neutralizing (type-specific) antibodies that were detectable after 1 week and reached peak titers after 3 weeks (158). Group-specific antibodies were also detected by DID following infection but were often transient. Their detection probably depends on the sensitivity of the test used (32, 103, 158). Antibodies have also been detected using indirect immunofluorescence (4).

The development of neutralizing antibodies coincides with cessation of virus excretion. Young chicks excrete virus longer because of slower development of neutralizing antibody (31).

It has been found that birds were resistant to reinfection with the same serotype 45 days after primary infection (30). In another study (158), however, birds were reinfected with the same strain after 8 weeks, eliciting a secondary response of both neutralizing and precipitating antibodies. Virus excretion also occurred, despite the presence of humoral antibodies. Peaks of virus excretion were found when birds were 2.5, 4.5, and 7.5 months of age (84), consistent with the theory that local immunity lasts about 8 weeks but then regresses allowing virus to replicate again at mucosal surfaces.

Neutralizing antibodies induced by an inactivated vaccine had no effect on virus excretion in the feces but did reduce pharyngeal excretion, possibly by preventing hematogenous spread of virus from the intestine to the pharynx. It is, therefore, possible that the resistance to challenge found after infection is due to

short-lived local immunity while circulating antibodies protect mainly against invasion of the internal organs. The apparent correlation between appearance of circulating antibodies and cessation of virus excretion is more likely due to concurrent development of both local immunity, which is more transient, and humoral immunity, which is more persistent. Support for this hypothesis is provided by the finding that maternal antibody does not protect against natural routes of infection (30) but does protect against intra-abdominal infection (53,66). There is evidence that infection with some strains of aviadenovirus results in severe depletion of lymphocytes in the bursa, thymus, and spleen, causing immunosuppression (136).

Diagnosis

Isolation and Identification of Adenoviruses

Specimens of choice for virus isolation are feces, pharynx, kidney, and affected organs (e.g., liver, in cases of IBH). A 10% suspension of tissue in medium is prepared and, in the case of chickens, inoculated onto either chick embryo liver cells or chick kidney cells. Chick embryo fibroblasts and tracheal organ cultures are less sensitive. Although three passages have been used (20, 41), generally two blind passages of 7 days' duration each are sufficient. If attempting to isolate adenoviruses from other avian species, it is preferable to use cells from the species being investigated, although chicken cells can be used. However, some turkey adenoviruses either grow poorly or not at all in chick cell cultures (140). Embryonated eggs are insensitive for primary isolation of most aviadenoviruses, although Cowen (37) has shown that the yolk sac is a sensitive route for isolating laboratory strains representative of 11 serotypes. It remains to be seen whether this route of embryo inoculation is equally sensitive for isolation of adenoviruses from field material, but it clearly should be tried in laboratories lacking cell culture technology.

Confirmation of a virus isolate as an adenovirus can be carried out in a number of ways. Direct examination of the lysate from an infected cell culture by electron microscopy gives a quick and positive answer and has the added advantage that parvoviruses can also be detected if present. Immunocytochemistry can be used to detect adenoviruses in infected cells by staining with an avian adenovirus antiserum labeled with a fluorescent dye, such as fluorescein isothiocyanate (direct immunofluorescence) (Fig. 9.2). To identify the serotype of virus that has been isolated, virus neutralization tests with the isolate against standard reference antiserums to all known serotypes (23, 24, 39, 99, 102) has been widely applied. Confirmation using molecular methods is also available and is now widely used. Detection of adenovirus DNA in tissue samples by *in situ* hybridization (ISH) has been reported (71), and ISH probes based on reported sequences of FAdV-10 and FAdV-1 have been used (62, 86). PCR has been widely applied to detect subgroup 1 adenoviruses and can be used to allocate isolates to species and to serotype. The rationale for the design of primers is based on a number of considerations, in particular the purpose for which the test is required. Thus, while a general diagnostic PCR that detects adenoviruses from subgroups I, II and III is possible (71), primers that detect individual

species or serotypes are generally more useful. Studies with FAdV-4 strains isolated from cases of infectious hydropericardium syndrome in different countries and locations have shown the usefulness of this approach (58, 72, 151). If these techniques are not available, then H&E staining of infected cell monolayers, or tissue sections, and demonstration of intranuclear basophilic inclusions, provides a nonspecific indication of the presence of DNA containing virus (Fig. 9.3).

Serology

Antibody to the group-specific antigen can be detected using the double immunodiffusion (DID) test, but its apparent sensitivity in naturally occurring outbreaks is often due to multiple infection with adenovirus serotypes, making it unreliable for detecting infection in SPF flocks (32, 56, 103). However, use of a trivalent antigen incorporating three adenovirus serotypes increases sensitivity of the DID test (36). The indirect immunofluorescent test is much more sensitive and rapid and is inexpensive (4), but its interpretation requires some previous training and experience. The enzyme-linked immunosorbent assay (ELISA) has been used to detect group-specific antibodies, and it is inexpensive and sensitive (24, 43, 107). Type-specific antibodies normally have been detected using the serum-neutralization test, but ELISA can also be used for this purpose (107).

The main problem with any serologic test for adenoviruses is the interpretation of the results. Adenovirus-specific antibodies are common in both healthy and diseased birds, and birds are frequently infected with a number of serotypes. Virus genotype may be of more interest than serotype for predicting disease-producing capability. Furthermore, the presence of humoral antibody gives no indication of the state of local immunity at mucosal surfaces.

Intervention Strategies

Management Procedures

As both IBDV and CIAV can potentiate the pathogenicity of adenoviruses, the first step must be to control or eliminate these two viruses. Adenoviruses are resistant to inactivation, and although it is possible to eliminate them from most environmentally controlled houses with impervious floors and walls that can be made airtight, the value of attempted eradication of adenovirus from commercial flocks is questionable. This is because the virus is effectively transmitted vertically through the embryonated egg, so that adenoviruses would almost certainly be introduced to subsequent flocks. Therefore, effective control would have to start at primary breeder level. Furthermore, experience with SPF flocks has indicated that horizontal spread is also a major problem, and it would be exceedingly difficult to keep a commercial flock free from adenovirus infection.

Vaccination

As evidence mounts that certain genotypes may be primary pathogens, the possibility of vaccination is more appealing. Maternal antibody titers of 1/64 or greater were successful in preventing the development of IBH, but the birds experienced some growth retardation (156). A vaccine prepared by inactivating

homogenates of liver from infected birds has been used extensively with apparent success in Pakistan to control hydropericardium syndrome (5, 12, 133). One study has shown enhanced protection against hydropericardium syndrome by vaccinating broiler breeders against both CIAV and FAdV-4 followed by experimental challenge of their progeny, compared to lesser protection achieved by vaccinating against either disease alone (149). This reemphasizes the importance of management to control immunosuppressive viral infections in order to decrease the effects of aviadenoviruses. The genome of FAdV-1 (CELO) has been shown to have substantial capacity for insertion of foreign DNA sequences, and consequently there is substantial interest in the development of CELO as a vaccine vector for use in avian species (106). Experiments in which infectious bursal disease virus (IBDV) sequences were incorporated demonstrated efficient expression and processing of IBDV proteins indicating that the CELO virus offers potential as a vaccine delivery vehicle or as a vector for production of recombinant proteins (57).

Egg Drop Syndrome

Brian McConnell Adair and Joan A. Smyth

Introduction

Definition and Synonyms

The egg drop syndrome (EDS) virus has recently been reclassified (12). It was originally designated as the sole member of the subgroup III avian adenoviruses, but it has now been moved to a new genus, the genus *Atadenovirus* (Table 9.1). Ovine adenovirus D is the type species of this genus, and EDS virus is currently the only recognized atadenovirus from avian species. It is serologically unrelated to the aviadenoviruses (formerly called subgroup I), and the siadenoviruses (formerly called subgroup II). Only one serotype is recognized, although variations have been demonstrated in restriction endonuclease analysis of isolates (53,58).

Since its initial description (64), EDS virus has become a major cause of lost egg production throughout the world. It is caused by an adenovirus, probably introduced into chickens through a contaminated vaccine. The disease is characterized by the production of thin-shelled or shell-less eggs by otherwise healthy birds. Once established in a breeding organization, the condition more often is seen as a failure to achieve production targets, and eggshell changes are less apparent. Since its initial recognition, it has become apparent that sporadic outbreaks of EDS occur as a result of fowl becoming infected through direct or indirect contact with infected wild or domestic waterfowl.

History

A condition of laying hens was described by Dutch workers in 1976 (64), and hemagglutinating adenoviruses were isolated (42). Through serologic studies with one of these isolates and examination of flock records, it was possible to establish the disease pattern (42, 44). The virus appeared to be transmitted vertically through the egg, and horizontal transmission between flocks was not a feature of the disease. The virus often remained latent until birds were approaching peak egg production. Because of the absence of antibody to the virus in chickens prior to 1974 and the failure of the virus to grow in mammalian cells, as well as its poor growth in turkey cells and optimal growth in duck cells, it was suggested that this was probably a duck adenovirus. This suggestion was quickly confirmed by isolation of EDS virus from normal ducks and demonstration of antibody in many duck flocks (9, 16).

Public Health Significance

The virus affects only avian species and, therefore, has no public health significance.

Etiology

Classification

EDS virus is classified as an adenovirus on the basis of its morphology, replication, and chemical composition. The virus is not related to 11 fowl and 2 turkey prototype aviadenoviruses using serum neutralization (SN) or hemagglutination inhibition (HI) tests (3). Although the aviadenovirus group specific antigen is not detected by immunodiffusion or immunofluorescence tests in EDS virus preparations, presence of common antigenic determinants were indicated in experiments in which aviadenovirus group-specific antibodies, which had developed in chickens after inoculation with an aviadenovirus, were restimulated following a subsequent inoculation with EDS virus (43).

Sequencing of the genome of EDS virus indicated some significant differences from the subgroup I aviadenoviruses (28). These differences include smaller genome size (33.2kb compared to 43.8kb for FAdV-1) and high AT content (28). Also although some aviadenovirus early genes appear to be missing in EDS virus, other genes were identified that have no obvious homology with known aviadenovirus proteins (28). EDS virus was shown to have similarities in its genetic characteristics to an ovine adenovirus (strain 287), certain bovine adenoviruses, and a possum adenovirus. This group is sufficiently different from the mammalian adenoviruses (mastadenoviruses), and from the aviadenoviruses (subgroup I) and siadenoviruses (subgroup II) to warrant classification as a separate adenovirus genus, for which the name *Atadenovirus* has been proposed, to reflect the high AT content of the viral DNA (11,12,13). Although initial isolates of EDS virus were from chickens (44), the virus is now recognized

as having originated from ducks, and its species designation is as duck adenovirus type A, and its strain name as duck adenovirus type 1 (DAdV-1), or egg drop syndrome virus (12). A study of recent Japanese isolates from chickens showed no evidence of change of the virus after two decades of the virus circulating in chickens (63).

Morphology

Ultrastructure

Purified virus preparations from cesium chloride (CsCl) gradients showed typical adenovirus morphology with triangular faces having six capsomeres on the edge and a single 25-nm fiber projecting from each vertex (35). In nonpurified preparations, the detail of the surface structure is not obvious (44, 69). Although EDS virus particles are clearly adenoviruses with well-defined capsomeres with hollow centers, it is possible to distinguish them from conventional adenoviruses in some electron microscope preparations (Fig. 9.5). In thin sections of infected chick embryo liver cells, virus particles of 70–75 nm are seen in the nucleus (3). Particles of 68–80 nm in diameter have also been described in the nuclei of epithelial cells of oviduct mucosa (60). The EDS virus has a single fiber per penton base, unlike the aviadenoviruses, which have two fibers (35).

Size and Density

The size of EDS virus observed in negatively stained preparations has been reported to range from 76 nm (44) to 80 (65) nm (35). These sizes are within those acceptable for adenoviruses (68).

Differences in the reported density of EDS virus in CsCl have been reported. Todd and McNulty (61) found that infectious virus particles banded at densities of 1.32 and 1.30 g/mL. The heavier particles, however, did not agglutinate chicken erythrocytes and appeared by electron microscopy to be slightly damaged. Particles with a density of 1.30 g/mL hemagglutinated and appeared undamaged. A band of empty, disrupted, noninfectious hemagglutinating particles was present at a density of 1.28 g/mL. In contrast, Kraft *et al.* (35) reported presence of two bands of infectious, hemagglutinating particles at 1.32 g/mL, with noninfectious disrupted particles banding at 1.30 g/mL. Yamaguchi *et al.* (69) reported hemagglutinating particles banding at 1.30 g/mL and infectious particles with a density of 1.33 g/mL, and Takai *et al.* (59) found infectivity and hemagglutinin associated with a band at 1.33 g/mL and hemagglutinin in a band at 1.29. This discrepancy was explained, at least in part, by Zsak and Kisary (74), who reported that density and hemagglutinating ability of EDS virus particles depended on the method used for virus purification and whether the virus was grown in cell cultures or embryonated eggs.

Chemical Composition

Labelling with H^3-thymidine and inhibition with iododeoxyuridine showed that EDS virus contained DNA (3, 35, 61, 69). The molecular weight of the DNA was estimated at 22.6×10^6 d compared with 28.9×10^6 d for FAdV-1 (Phelps), and restriction endonuclease patterns indicated no relationship between these
9.5.   Four particles of egg drop syndrome (EDS) virus. Although individual capsomeres are well resolved, typical adenovirus morphology is not apparent. Inset: Fowl adenovirus type 8 (FAdV-8) particle showing well-defined, triangular faces. Bar = nm.

two viruses (74). The EDS virus has 13 structural polypeptides, at least 7 of which correspond with polypeptides of FAdV-1 (61,71).

Hemagglutination

EDS virus agglutinated erythrocytes of chickens, ducks, turkeys, geese, pigeons, and peacocks but did not agglutinate rat, rabbit, horse, sheep, cattle, goat, or pig erythrocytes (3, 38).

The hemagglutinin (HA) is resistant to heating at 56°C. An initial fourfold fall in HA titer was reported after 16 hours at 56°C, and thereafter the titer remained stable for 4 days; however, no HA activity was detected after 8 days at 56°C. The HA also survived heating at 60°C but was destroyed by heating to 70°C for 30 minutes. The HA activity was also stable for long periods at 4°C (3,45) and was resistant to treatment with trypsin, 2-mercaptoethanol, ethylenediaminetetraacetic acid (EDTA), papain, ficin, and 0.5% formaldehyde at 37°C for 1 hour, but the titer was greatly reduced by treatment with potassium periodate and 0.5% glutaraldehyde (59). However, the purified soluble HA was destroyed by trypsin treatment (61). Alpha-chymotrypsin destroyed the virus receptor on chicken erythrocytes; whereas trypsin and neuraminidase had no effect (59).

Virus Replication

EDS virus replicates in the nucleus of infected cells in a similar fashion to aviadenoviruses (1, 2, 3). Intranuclear inclusions were observed in hematoxylin- and eosin-stained preparations of virus-infected cell cultures (3), in epithelial cells of the infundibulum, tubular shell gland, pouch shell gland, isthmus, and in nasal mucosa and spleen of experimentally infected chickens (57,60). In ultrathin sections of EDS virus-infected cells examined by electron microscopy, adenovirus particles and type I–IV inclusions similar to other avian adenoviruses were obvious in the nucleus (2, 3).

Susceptibility to Chemical and Physical Agents

The EDS virus was stable to treatment with chloroform and variations in pH between 3 and 10. The virus was inactivated by heating for 30 minutes at 60°C, survived for 3 hours at 56°C, and was stable in the presence of monovalent but not divalent cations (3, 69). Infectivity was not demonstrated after treating with 0.5% formaldehyde or 0.5% glutaraldehyde (59).

Strain Classification

Only one serotype of EDS virus has been recognized (21,69). With the use of restriction endonuclease analysis, however, it has been possible to divide a number of isolates into three genotypes (62). One group included isolates made over an 11-year period from infected European chickens, and a second group included viruses isolated from ducks in the United Kingdom. One virus isolated from chickens in Australia formed the third group.

Laboratory Host Systems

EDS virus replicated to high titers in duck kidney, duck embryo liver, and duck embryo fibroblast cell cultures and grew well in chick embryo liver cells, less well in chick kidney cells, and rather poorly in chicken embryo fibroblast cells. Growth in turkey cells was poor, and no replication was detected in a range of mammalian cell cultures (3). The virus grew to high titers in goose cell cultures (74). In chick liver cell cultures, peak virus and intracellular HA titers were reached after 48 hours, with peak extracellular HA titers being achieved after 72 hours (69). The virus also grew very well when inoculated into the allantoic sac of embryonated duck or goose eggs producing HA titers of 1/16,000–1/32,000. No growth was detected in embryonated chicken eggs (3, 71).

Pathogenicity

Although all chicken isolates of EDS virus appeared to be of similar virulence, isolates from ducks in the United States produced no effect on egg production in chickens (65) or affected only the egg size (15). Isolates from ducks and chickens in Europe behaved in an identical manner in chickens (7).

Pathobiology and Epidemiology

Incidence and Distribution

EDS virus has been isolated from chickens in Australia (24), Belgium (45), China (73), France (48), Great Britain (9), Hungary (74), India (36), Israel (40), Italy (72), Japan (69), Northern Ireland (44), Singapore (54), South Africa (14), and Taiwan (38). Serologic evidence of infection has been found in chickens in Brazil (31), Denmark (5), Mexico (51), New Zealand (30), and Nigeria (46).

Natural and Experimental Hosts

Although disease outbreaks have been recorded mostly in laying hens, it is probable that the natural hosts for EDS virus are ducks and geese. EDS virus HI antibody is widespread in domesticated ducks (5, 8, 9, 16, 24, 39, 40) and domestic geese (8, 75). In a study of ducks in the Atlantic flyway in the United States, antibody was found in ruddy, ring-necked, wood, bufflehead, lesser scaup, mallard, northern shoveler, and gadwall ducks and in mergansers, coots, and grebes (27,51). Antibody was also detected in Muscovy ducks and in cattle egrets (40), Canada geese (51), herring gulls (8), owls, a stork, and a swan (33).

The virus has been isolated from healthy domestic ducks (9, 65) and from diseased ducks (25), but the disease could not be reproduced using this isolate. A virus was isolated from ducks with a fall in egg production and severe diarrhea (6), and it has been suggested that EDS virus may cause rough, thin shells and decreased egg production in ducks (23,37). EDS virus was isolated from the latter ducks, but experimental reproduction was not attempted. It remains possible that the viruses recovered from these ducks were incidental, as the virus can be found commonly in healthy ducks.

Infection was also shown to be common in geese (33,39,75), but goslings and geese experimentally infected with the virus showed neither illness nor change in egg production (75). However, there has been a recent report of a severe respiratory disease outbreak in young goslings, in which adenoviral inclusion bodies were found in the trachea and bronchial epithelium of affected birds. EDS virus was recovered from affected geese and the disease was reproduced experimentally in 1-day-old goslings (32).

Quail (*Coturnix coturnix japonica*) have also been shown to be susceptible to infection and to develop classic signs of EDS (22). There is no evidence of naturally occurring infection of turkeys or pheasants, although they can be infected experimentally (8,47,72). Guinea fowl may be infected naturally or experimentally, and soft-shelled eggs may be produced. However, in other studies, guinea fowl became infected but remained clinically normal following exposure to a fowl isolate of EDS virus (66).

Because EDS virus initially was transmitted vertically in chickens, there was often an apparent association with certain chicken breeds. A wide range of breeds, however, have been shown to be equally susceptible to experimental infection, although analysis of naturally occurring outbreaks suggests that broiler breeders and heavy breeds producing brown eggs are more severely affected than white-egg producers. When two brown and one white-egg layer strains were infected (29), egg production was depressed in the white layer strain. There was little depression in egg production of the brown layers, but more eggs were produced with shell defects. One brown egg-laying strain produced almost three times as many affected eggs as the white egg-laying strain.

Chickens of all ages are susceptible to EDS virus infection. Introduction of EDS virus into a laying site affected egg production in all ages of laying hens. However, the appearance of disease at around peak egg production (44) may be due to reactivation of latent virus.
9.6.   Eggs from hens infected with egg drop syndrome (EDS) virus. Changes range from normal brown egg (N), to loss of shell pigment (1 and 2), thinning at the pole (1), thin-shelled (2), soft-shelled (3), and shell-less eggs (4). Eggs may be eaten or broken, but many membranes (5) may be found.

Transmission, Carriers, and Vectors

It is now possible to divide EDS outbreaks into three types. In the initially observed classic form of the disease, primary breeders were infected, and the main method of spread was vertically through the embryonated egg (44). Although the number of infected embryos was probably low with this type (10), lateral spread of virus was very efficient. In many cases, chicks infected *in ovo* did not excrete virus or develop HI antibody until the flock had achieved greater than 50% egg production. At this stage, the virus was reactivated and excreted, resulting in rapid spread due to multiple foci of infection.

Probably arising from the classic form of EDS, the virus has become established in commercial egg-laying flocks in some areas. In India, 32.6% of poultry flocks were found to be infected (36). This endemic form was often associated with a common egg-packing station. Both normal- and abnormal-shelled eggs produced during the period of virus growth in the pouch shell gland contained virus on their exterior and interior (56). This led to contamination of egg trays. Droppings also contained virus, but this excretion was intermittent, and the virus was often present only at low titer (18). In the adult bird, presence of virus in the feces probably arises from contamination by oviduct exudate (57). Apart from direct spread between birds, there is evidence

that spread can occur when birds are transported in inadequately cleaned trucks or when unused food has been moved between sites. There is also evidence that needles or blades used for vaccination or bleeding of viremic birds, if not properly sterilized, can transmit infection. Lateral spread of virus is slow and intermittent, taking up to 11 weeks to spread through a cage house, and in one case, spread to an adjoining pen was prevented by a wire fence. Spread of virus between birds on litter is usually faster (18,64).

Spread of EDS virus from domestic or wild ducks, geese, and possibly other wild birds to hens through drinking water contaminated by droppings appears to give rise to a third type of disease outbreak. This type of disease is very important in some areas, and cases tend to be sporadic, but there is always the danger of an infected flock becoming the focus for endemic infection.

Clinical Signs

Following experimental infection, most workers detected the first signs of EDS after 7–9 days (19,41), but in some experiments, disease signs did not appear until 17 days PI (45).

The first sign was loss of color in pigmented eggs. This was quickly followed by production of thin-shelled, soft-shelled, or shell-less eggs (Fig. 9.6). Thin-shelled eggs were often rough,

with a sandpaper-like texture or had a granular roughening of the shell at one end of the egg. If the abnormal eggs were discarded, there was no effect on fertility or hatchability and no long-term effect on egg quality. If birds were infected in the late stages of egg production, forced molting of the flock appeared to restore egg production to normal. The fall in egg production was very rapid or extended over several weeks. EDS outbreaks usually lasted 4–10 weeks, and egg production was reduced by up to 40%; however, there was often compensation later in lay, so that the total number of eggs lost was typically 10–16/bird. If the disease resulted from reactivation of latent virus, the fall usually occurred when production was between 50% and peak level. Small eggs have been described in naturally occurring outbreaks (44), but no effect on egg size was found in experimental infections (41). Watery albumen has been described (45,64), although no effect on albumen was reported by other workers (21,41,70). Age at time of infection may be important, however; birds infected at 1 day of age produced apparently normal eggs except for impaired albumen quality and smaller size (19).

If some birds have acquired antibody before latent virus is reactivated, an apparently different clinical syndrome is seen. There may be failure to achieve predicted egg production, and onset of lay may be delayed. If a careful examination is made, it can often be established that there have been a series of small clinical episodes of classic EDS. Presumably, presence of EDS-specific antibodies slows down the spread of the virus in the bird. A similar picture has often been observed in birds housed in caged units, where spread of the virus can be slow and EDS not suspected.

Affected birds remain otherwise healthy. Although inappetence and dullness have been described in some affected flocks, these are not consistent findings. Transient diarrhea described by some authors is probably due to the exudate from the oviduct (57). EDS virus does not cause clinical disease in growing chickens in the field. Oral infection of susceptible day-old chicks resulted in increased mortality in the first week of life (19), but there was no increase in mortality in many flocks of chickens produced by virus-infected parent flocks.

Pathology

Gross Lesions

In naturally occurring outbreaks of EDS, inactive ovaries and atrophied oviducts were often the only recognizable lesions, and these were not consistently present. In one outbreak, uterine edema was observed (38). The absence of lesions reflects the difficulty in selecting birds that are actually in the acute phase of disease.

Following experimental infection with EDS virus, edema of the uterine folds, and presence of exudate in the pouch shell gland commonly occurred within 9–14 days PI (55,60). Mild splenomegaly, flaccid ovules, and eggs in various stages of formation in the abdominal cavity were also observed (60).

Microscopic Lesions

The major pathologic changes occurred in the pouch shell gland (Fig. 9.7). Virus replication occurs in the nuclei of surface epithelial cells, and intranuclear inclusion bodies were detectable from 7 days PI onward (Fig. 9.8) (55,60). Many affected cells
9.7. Pouch shell gland from a hen experimentally infected with egg drop syndrome (EDS) virus. Note the viral nucleic acid in the surface epithelial layer, demonstrated by a biotinylated purified virus genome probe. (Allan)

were sloughed into the lumen, and there was a rapid and severe inflammatory response with heterophilic infiltration of the epithelium and lamina propria and mucosal edema, together with macrophages, plasma cells, and lymphocytes, in the lamina propria (Fig. 9.7, 9.8). Inclusion bodies were not seen after the third day of abnormal egg production, but viral antigen persisted for up to 1 week (55). As the lesions progressed, heterophils were less common and the mononuclear cells dominated. The sloughed surface epithelium was replaced initially by squamous to cuboidal epithelium, with rapid return to the normal pseudostratified, ciliated columnar epithelium. In some recovering and recovered birds which were producing normal eggs, a few areas
9.8. A. Normal uterine mucosa. Surface epithelium consists of a single layer of columnar cells, many of which are ciliated; underlying these are tubular glands. B. Pronounced edema of uterine submucosa, atrophy of tublar glands, and infiltration of entire mucosa by mononuclear cells are present at 8 days postinoculation (PI). Inset: Intranuclear inclusion body in superficial epithelial cell. Note margination of nuclear chromatin and three eosinophilic inclusions in the nucleus.

of cuboidal surface epithelium, and a few lymphoid aggregates or minimal loose infiltrates of lymphocytes and plasma cells persisted.

Most descriptions of the pathology of birds from naturally occurring disease outbreaks do not include the finding of inclusion bodies or the acute inflammatory and necrotizing phase of the disease. This is due to the transient nature of these lesions and the difficulty in finding affected birds among the thousands of birds which may be present in an affected flock, where not all birds will be infected simultaneously.

Pathogenesis of the Infectious Process

Experimental oral infection of adult hens with EDS virus resulted in a viremia with limited virus replication in the nasal mucosa (57). At 3–4 days postinfection (PI), virus replication occurred in lymphoid tissue throughout the body; particularly in spleen and thymus. In addition, the infundibulum of the oviduct was consistently affected. At 7–20 days PI, substantial levels of virus replication were detected in the pouch shell gland (Fig. 9.8) with lower levels of replication in other parts of the oviduct. This replication was associated with a pronounced inflammatory response in the pouch shell gland, and production of eggs with abnormal shells (57, 60, 70).

Unlike the aviadenoviruses and siadenoviruses of birds, EDS virus does not appear to replicate in the intestinal mucosa, and presence of virus in the feces is probably due to contamination with oviduct exudate (57).

Immunity

Following experimental infection with EDS virus, antibody was detected by indirect fluorescent antibody test (IFA), enzyme-linked immunosorbent assay (ELISA), and SN and HI tests 5
9.8. (*continued*) C. Uterine surface epithelium is markedly hyperplastic 11 days PI; there is complete loss of cilia. (Smyth) D. Exudate in uterine lumen consists of degenerating epithelial cells and heterophils mixed with mucus. Epithelium is devoid of cilia; tubular glands are almost absent; and uterine wall is infiltrated with lymphocytes and heterophils. (Smyth)

days after infection and by double immunodiffusion (DID) test after 7 days (4). Antibodies reached a peak after 4–5 weeks, and the immunoprecipitating antibodies were more transient.

Birds still excreted EDS virus in the presence of high levels of HI antibody, but some birds that excreted the virus failed to develop antibody (19).

Antibody was transferred to the embryos through the yolk sac, and young chicks had high EDS HI titers (geometric mean titers, 6–9 $\log_2$). This antibody had a half-life of 3 days (21). Active antibody production was not stimulated until the chicks reached 4–5 weeks of age, when maternal antibodies were almost undetectable (21). When the disease was being eradicated, it was found that some flocks, which were apparently free from detectable antibody, as indicated by HI testing on two or three occasions, nevertheless suddenly developed EDS. This suggested that some chicks had become infected *in ovo* and had developed a latent infection but had failed to develop antibody. With the onset of egg production, the virus then was reactivated and virus excretion took place. It is not known if all chicks developed anti-

body at this point, but it is possible they did not, because less than 100% of birds in infected flocks had antibody.

If a flock as a whole develops antibody to EDS virus before coming into lay, egg production will not be affected (10).

Diagnosis

Isolation and Identification of EDS Virus

The most sensitive medium for virus isolation is either embryonated duck or goose eggs derived from a flock free of EDS virus infection or duck or goose cell cultures. If these are unavailable, chicken cells should be used. Chicken embryo liver cells were more sensitive than chicken kidney cells, and chicken embryo fibroblasts were insensitive (3). Embryonated chicken eggs are not suitable. Not only are duck or goose cells or embryonated duck or goose eggs more sensitive, they also have the advantage that they do not support the growth of many chicken viruses.

It is not sufficient to rely on embryo death or cytopathic effect to indicate isolation of EDS virus. Allantoic fluid from inocu-

lated goose or duck eggs or supernatant from infected cultures should be checked after each passage for presence of EDS virus HA, using avian erythrocytes. (0.8% chick erythrocyte suspension is suitable). Alternatively, immunofluorescence, using a labeled EDS virus antiserum, can be used to detect the presence of the virus in the cells. Antiserum conjugated to aviadenoviruses will not detect EDS virus. If duck cells are used for isolation, a minimum of 2 passes are required, and with chick cells, 2–5 passes are necessary before declaring a specimen negative. The need for extensive passage is partly due to poor growth of the virus on primary isolation in chick cells, and partly because virus titers in the tissues can vary particularly if the bird submitted to the laboratory is not at the stage of the disease process where virus titers are maximal. The successful use of antigen capture ELISA and PCR-based tests have recently been described (20,49,52,53,67).

Selection of Specimens

Because of the absence of obvious clinical signs and the often slow spread of infection, it can be very difficult to select infected birds for either virus isolation or serology. The finding that abnormal eggs contained virus and that these eggs were produced after the bird had developed EDS antibodies has allowed a rational approach to diagnosis (56). To isolate the virus, abnormal eggs may be fed to antibody-negative adult laying hens. At the first appearance of abnormal eggs, the hens may be euthanised and virus isolation attempted from the pouch shell gland. For serological diagnosis, all the birds in cages where abnormal eggs are being produced should be blood sampled. If the birds are housed on litter, care must be taken to select samples throughout the house, as it is usually not possible to determine which birds are producing abnormal eggs in these circumstances.

Serology

The HI, ELISA, SN, DID and IFA tests are of similar sensitivity (4). When birds have been infected with a number of adenovirus serotypes however, with consequent stimulation of high levels of cross-reactive antibodies, there were positive reactions in the ELISA, IFA, or DID tests but not in the HI or SN tests (4). HI is the test of choice for serological diagnosis. Antigen for HI test can be prepared in either embryonated duck eggs or in cell culture. Higher HA titers are obtained if duck eggs are used, but high HA titers can also be obtained using chick embryo liver cell cultures. A suitable HI test uses 4 HA units of antigen, an initial 1:4 serum dilution, and 0.8% chicken erythrocytes. The EDS virus agglutinates erythrocytes from chickens, geese, turkeys, and ducks but not mammalian erythrocytes. There is no hemolysin. If nonspecific hemagglutinins are present in the serum, they can be removed by pre-adsorption of the serum with a 10% erythrocyte suspension. The SN test, using 100 $TCID_{50}$ of EDS virus, 1 hour reaction time at 37°C, and duck or chick cell cultures as the indicator system, is sensitive and specific. When using chick cell cultures, it often helps if the end-points are read by presence of hemagglutinins in the supernatant fluid rather than by cytopathology. The SN test is really required only in diagnostic situations to confirm an unusual HI test result as in an

eradication program or to confirm a positive HI result in species in which EDS has not previously been recognized.

Many flocks containing birds that had been infected with EDS virus in ovo did not develop antibodies during the growing period; it only became apparent immediately following the development of clinical signs of the disease. Therefore, even a negative serological test of all birds in a flock, at around 20 weeks of age, gives no guarantee of freedom from infection.

Differential Diagnosis

Egg drop syndrome should be suspected whenever there is failure to achieve predicted egg production levels or if there are falls in egg production, especially if birds are healthy and eggshell changes precede or are concurrent with the decline. Shell-less eggs are usually a feature of EDS but are often missed because they may be consumed by the birds, be trampled into the litter, or fall through the wire mesh of cage floors. Therefore, an inspection should take place early in the morning before the eggs can be eaten. If the birds are housed on litter, a careful search will reveal egg membranes. Although shell-less, soft-shelled, and thin-shelled eggs are characteristic, misshapen and ridged eggs are not a feature. In an infected flock in which vertical transmission of EDS virus has occurred, most if not all cases occur around peak egg production, but any age of flock can be infected by lateral spread.

Although signs of EDS are quite characteristic, diagnosis must not be made on the clinical picture alone but should be confirmed by EDS HI test before vaccination is considered.

Intervention Strategies
Management Procedures

Because classical EDS is spread primarily by vertical transmission through the egg, replacement birds should be derived from uninfected flocks. Endemic EDS has often been associated with a common egg-packing station in which contaminated egg trays have been a major factor in the spread of the disease. Virus is also present in droppings, and lateral spread is possible because the virus is resistant to inactivation. Circumstantial evidence exists for spread by personnel and transport, and, therefore, sensible hygienic precautions are required.

The infected birds develop a viremia, and thus it is important that bleeding needles, needles for inoculating vaccines, and other equipment should be sterilized between birds.

If infected and uninfected breeding flocks exist within the same organization, separate hatcheries, staff, and transport should be used. If this is not possible, separate setters and hatchers should be used, and hatches should be scheduled to take place on different days of the week. The minimum possible precautions (which are not recommended) would be to use separate hatchers and to sex, vaccinate, and dispatch the clean stock before handling potentially infected chicks. It is particularly important to keep basic or grandparent breeding stock from an infected breed separate from noninfected birds of another breed, and these eggs should never be incubated in the same hatchery.

In certain areas of the world, particularly where the drinking

water for the birds is derived from dams, lakes, or rivers, EDS virus infection has been common. These outbreaks have been controlled either by using water from wells or by chlorination of the water. In units where ducks or geese are kept, they should be carefully segregated from the chickens. If possible, all housing should be made wild bird-proof. It is now well documented that wild ducks and wild geese are often infected with EDS virus, but it is not known how widespread infection is in other avian species.

Eradication

Egg drop syndrome was eradicated successfully from a breeding organization in Northern Ireland. The method was based on a number of presumptions: (i) chickens produced from EDS virus-infected eggs may be latently infected and fail to develop antibody; (ii) the virus will become reactivated and will be excreted at around the time of peak egg production, and EDS antibody will develop, which will prevent or reduce further excretion; (iii) lateral spread is poor.

The eradication program was based on the elite and grandparent flocks aged 40 weeks or more. At this stage, these flocks had produced abnormal eggs and had EDS HI antibody. Chicks hatched from these eggs were divided into small groups of about 100 (separated by netting wire). Ten to twenty-five percent of the chicks were HI tested for EDS antibodies by HI test at about 6-week intervals. If one or two reactors were found, they were removed; 100% of the birds in the pen and 100% of adjoining pens were then tested twice at weekly intervals. If HI test positive reactors were found or if positive reactors kept appearing within a single pen, the whole pen was then removed and the in-contact pens of birds were tested. At 40 weeks, 100% of the birds were tested by HI test, and eggs were collected for the next generation. This program was successful, and subsequently, the grandparent and parent flocks were found to be free of infection.

Vaccination

Types of Vaccine

An oil-adjuvant inactivated vaccine is widely used and gives good protection against clinical EDS. The birds are vaccinated between 14 and 16 weeks of age. If uninfected birds are vaccinated, EDS HI titers of 8–9 $\log_2$ can be expected. If the flock has been exposed previously to EDS virus, HI titers of 12–14 $\log_2$ may be found. An HI antibody response can be detected by the seventh day after vaccination, with peak titers achieved between the second and fifth weeks. Vaccinal immunity lasts at least 1 year (10,19,34,58). Although properly vaccinated birds are protected against disease and do not appear to excrete EDS virus, improperly vaccinated birds with low EDS HI titers excreted the virus following challenge (17).

Field Vaccination

When vertical or lateral transmission of EDS virus is a possibility, flocks in danger can be protected by vaccination in the growing period. If one or more houses on a multiage laying site become infected due to lateral spread of the virus, careful evaluation must be undertaken before vaccinating the healthy

birds during lay. Undoubtedly, the healthy birds can be protected by vaccination, but the cost of vaccination, combined with costs and effects of the handling of the birds in order to administer the inactivated vaccine, must be carefully weighed against the economic returns achieved from the protection. It is possible to limit the spread of virus on a site by good hygiene. It is particularly important to remember that the infected egg is potentially the most dangerous source of virus.

Treatment

Various treatments have been tried (for example, vitamins and increasing calcium or protein in the ration), but in controlled trials, no effect could be demonstrated. Therefore, no successful treatment is available.

Hemorrhagic Enteritis and Related Infections

F. W. Pierson and S. D. Fitzgerald [1]

Introduction

Definitions and Synonyms

Hemorrhagic enteritis (HE) is an acute viral disease of turkeys 4 weeks of age and older characterized by depression, bloody droppings, and death. Clinical disease usually persists in affected flocks for 7–10 days. Due however to the immunosuppressive nature of the agent, secondary bacterial infections may extend the course of illness and mortality for an additional 2–3 weeks.

Marble spleen disease (MSD) is a condition affecting confinement-reared pheasants 3–8 months of age. The causative virus is serologically indistinguishable from that of HEV and varies only slightly at the genomic level. However the clinical disease is predominantly respiratory in nature with death occurring due to lung edema, congestion, and asphyxia.

Evidence of similar infections in other gallinaceous fowl exists. In particular, a condition referred to as avian adenovirus splenomegaly (AAS) has been described in broiler breeder chickens characterized by splenomegaly, pulmonary edema, and congestion.

Economic Significance

Financial losses due to HE within the United States are purported to have exceeded $3 million per year prior to development of a vaccine (20). In 1984, losses due to HE associated *Escherichia coli* infections were estimated to be $40 million per year (108). Today, due to the extensive use of vaccines, highly pathogenic outbreaks of HE are rare in the U.S. However lapses in protection may result in primary HE or more commonly a secondary bacterial infection like colibacillosis, which is considered to be a disease of economic importance in the commercial turkey industry.

The economic impacts of MSD in pheasants or AAS in chickens have not been assessed.

Public Health Significance

The etiologic agents responsible for HE, MSD, and AAS are not known to cause illness in humans nor has evidence of seroconversion been documented.

History

HE was first observed in Minnesota by Pomeroy and Fenstermacher (99) and later in Ohio by Gale and Wyne (44). The disease commonly known as "bankruptcy gut," reached epidemic proportions in Texas in the early 1960s and Virginia in the mid-1960s (48). It occurred in both confinement and range turkey operations and exhibited a strong tendency to infect successive flocks on the same premises. In 1966, the first reported outbreak of MSD in ring-necked pheasants was described by Mandelli *et al*. (69). AAS was identified in broiler breeder chickens by Domermuth *et al*. in 1979 (27).

Experimental transmission of HE using filtered and unfiltered intestinal contents from turkeys dying of the disease was first described in 1967 (48) and by the mid-1970s, the causative agent definitively identified as an adenovirus (8, 19, 25, 43, 47, 59, 117). Parallel studies with MSD have yielded similar results (55, 56, 58, 59).

Etiology

Classification

Morphologic, histologic, immunologic, and chloroform-resistance studies indicate that HE virus (HEV), MSD virus (MSDV), and AAS virus (AASV) are members of the family *Adenoviridae* (8, 19, 25, 43, 47, 56, 60, 118).

HEV, MSDV, and AAS were originally assigned to the genus *Aviadenovirus* and designated as avian adenovirus group (type) II (28) to distinguish them from the other members of the genus (fowl adenoviruses, group I; EDS 76, group III). This classification was based on the observation that convalescent HE antiserum from turkeys protected pheasants against MSD (25) and that MSDV and AASV were indistinguishable from HEV in agar-gel immunodiffusion tests (19, 25, 27, 28, 29, 58). As a group, they were shown to be serologically distinct from CELO virus and other turkey adenovirus isolates (28, 62). Recent DNA sequence homology data have shown HEV and MSDV to be different enough from other members of the genus to warrant reclassification (4, 14, 63, 98,). They therefore have been placed in a new genus, *Siadenovirus,* and been given one species name, turkey adenovirus A (5, 13, 14). The other member of the genus is frog adenovirus 1. The genus name is derived from an open reading frame in the early transcription region (E1) that has a high sequence homology with bacterial genes coding for sialidase. There are also several other putative genus-specific genes that share no sequence similarity with other adenoviruses (13). The functional importance of the sialidase homolog and other genus-specific genes has yet to be determined. It has been speculated that the siadenoviruses originated in amphibians and then adapted to avian species (15).

Morphology

Ultrastructure

Thin-section tissue preparations examined by electron microscopy reveal that HE and MSD viral particles are non-enveloped icosohedrons, with a total capsomere count of 252. They occur in empty and dense forms and are arranged intranuclearly in loosely packed aggregates or crystalline arrays (8, 43, 56, 60, 118, 127). Only one penton fiber appears to be present at each vertex (124) which distinguishes them from members of the genus *Aviadenovirus* that possess two fibers (73).

Size, Density

In early studies, HEV was found to readily pass through filters with porosities of 220 and 100 nm but not 10 nm (17, 48). Electron microscopy of intranuclear inclusion bodies and cesium chloride-purified preparations reveal virions to be 60–90 nm in diameter (9, 56, 59, 60, 118), but differences in size are probably within the limits of experimental error. HEV and MSDV are reported to have buoyant densities between 1.32–1.34 g/mL (8, 55, 57, 124, 127)

Chemical Composition

HEV, MSDV, and AASV are linear, double stranded DNA viruses (14, 55). Complete sequences (Genbank Accession Numbers AF074946, AY849321) and maps of the HEV genome have been published for both virulent and avirulent strains (4, 13, 98,). The genome length is approximately 26.6 kb, which ranks it as one of the shorter adenovirus genomes (15). Guanine and cytosine comprise 34.9% of the bases, which is low by comparison with other adenoviruses (98, 4). However, sixteen genes appear to be conserved based on comparative analysis with a variety of DNA sequences from other members of the family *Adenoviridae* (15).

An extensive list of putative HEV proteins has been published (14). Polyacrylamide gel electrophoresis and Western blotting techniques suggest that HEV and MSDV have at least 11 distinct structural polypeptides with molecular weights ranging between 14 and 97 kD (82) and 9.5 and 96 kD (124). Six of these proteins have been further characterized. They include a 96 kD polypeptide believed to be a monomer of the major outer capsid or hexon protein, 51/52 kD and 29 kD polypeptides believed to be the vertex penton base and fiber proteins, a 57 kD homologue of human adenovirus group 2 IIIa protein, and two core nucleoproteins of 12.5 kD and 9.5 kD each (124).

Virus Replication

Early electron micrographic studies suggested that HEV and MSDV replication took place in nuclei of reticuloendothelial cells (9, 43, 60, 118, 127). Adherent mononuclear macrophages and nonadherent mononuclear cells bearing IgM have since been reported to support viral replication (111, 112, 123). Thus, macrophages and B lymphocytes are considered to be the primary target cells (111, 112).

Enzyme-linked immunosorbent assay (ELISA), immunofluo-

rescent and immunoperoxidase staining and polymerase chain reaction (PCR) have revealed the presence of infected cells in a variety of tissues including intestine, bursa of Fabricius, cecal tonsils, thymus, liver, kidney, peripheral blood leukocytes, lung, and spleen (4, 35, 40, 52, 94, 108, 112, 119). However, on the basis of immunodiffusion and immunoperoxidase studies, the spleen appears to be the major site of viral replication (20, 107).

The replication strategy at the cellular level is presumed to be similar to that of other adenoviruses. Infection begins by viral attachment facilitated by the fiber and penton base proteins. Receptor-mediated endocytosis then occurs. DNA transcription takes place in the nucleus and utilizes host cellular RNA polymerase II. Genome replication also occurs in the nucleus and involves virus-encoded DNA-dependent DNA polymerase and the formation of a pan-handle intermediate with base pairing occurring at inverted terminal repeats. Virions are assembled in the nucleus and released upon cell disintegration (14).

Susceptibility to Chemical and Physical Agents

Infectivity of HEV can be destroyed by heating at 70°C for 1 hour; drying at 37° or 25°C for 1 week (17); or by treatment with 0.0086% sodium hypochlorite (18). Sodium lauryl sulfate, phenolic and iodine based disinfectants are also known to be effective (17). Treatment with 50% chloroform or 50% ethyl ether does not alter infectivity (20) nor does heating at 65°C for 1 hour, wet storage for 4 weeks at 37°C, 6 months at 4°C, or frozen storage for 4 years at -20°C. The virus is also stable at low pH (20).

Strain Classification

Traditionally, HEV, MSDV, and AASV strains have been classified according to their host source i.e., turkeys, pheasants, or chickens. Antigenic differences have been reported based on monoclonal antibody affinity (122, 129) but strains are considered to be serologically indistinct and provide cross protection (22, 25, 26, 27, 30, 58). A comparison of the genomes for virulent and avirulent strains of HEV indicates that they are 99.9% identical (4). However, the occurrence of mutations in the penton fiber, open reading frame 1 (ORF1), and/or E3 genes may account for variations in virulence (4). Strain differences based on restriction endonuclease fingerprinting have been reported (128) but the method appears to be unreliable which is not surprising given the high level of sequence homology. Finally, it is not uncommon for HEV isolates to be referred to as virulent or avirulent based on the severity of lesions they produce in turkeys i.e., splenomegaly, gastrointestinal hemorrhage, and death in the case of the former and splenomegaly alone in the case of the latter.

Laboratory Host Systems

For laboratory purposes, HEV is commonly propagated in 6-week-old turkey poults via intravenous (IV) or oral inoculation with splenic tissue derived from infected birds diluted 1:1 v/v with phosphate buffered saline (PBS). Spleens from these birds can then be harvested 3 or 5 days postinoculation (DPI) respectively and frozen. Inoculation of specific-pathogen-free turkey eggs with MSDV on day 24 of embryonation also results in in-

fection and replication with peak viral loads occurring in the spleen, intestine, and liver 6 DPI (1). Although theoretically possible, attempts at *in vitro* propagation of HEV in isolated spleen cells have been unsuccessful. Perrin *et al.* (89) inoculated turkey splenocytes with HEV and were able to recover virus but unable to confirm viral replication. Likewise, Fasina and Fabricant (35) demonstrated *in vitro* infection of chicken, turkey, and pheasant splenocytes by immunofluorescence but could not demonstrate viral release. It was not until 1982 that successful *in vitro* propagation was achieved by Nazerian and Fadly (79) who demonstrated serial passage of HEV and MSDV in a turkey lymphoblastoid B cell line derived from a Marek's disease virus associated tumor. The cell line, known as MDTC-RP19, has since become the standard system for *in vitro* HE vaccine production. An *in vitro* method using purified peripheral blood leukocytes from turkeys has also been described (123).

Pathogenicity

Mortality in field outbreaks of HE is reported to vary from more than 60% (48) to less than 0.1%. Experimentally where spleen size and the presence of precipitating antigen indicated 100% infection, mortality was found to range between 80% for the most pathogenic strain and 0% for the least. Present information suggests that the ability of a given strain to produce mortality is a fairly stable characteristic. Only one instance of possible reversion to virulence of an avirulent strain has been reported (96).

Mortality rates in pheasants naturally infected with MSDV have been reported to be 5–20% over a period of 10 days to several weeks (72). As with HEV, variations in pathogenicity among MSDV isolates would be expected. However pheasants experimentally infected with cell-culture propagated MSDV or virulent and avirulent HEV showed typical gross and microscopic splenic lesions but no lung lesions or mortality (30). It has been suggested that other environmental factors may be involved in occurrence of lung lesions and mortality in field outbreaks of MSD (30).

Pathobiology and Epidemiology

Incidence and Distribution

Hemorrhagic enteritis has been a serious problem in at least 10 states in the U.S. and observed throughout the world wherever turkeys are raised (20). Serologic surveillance data suggest that infection with HEV is widespread among adult turkeys (92). MSDV has been documented in confinement pheasant operations throughout the U.S., Canada, Europe, Australia, and Korea (6, 68, 69, 72, 101, 110, 113, 114, 115). Similarly, a high incidence of antibody in mature chickens suggests a wide distribution of AASV (29).

Natural and Experimental Hosts

Until recently, turkeys, pheasants, and chickens were the only known natural hosts for HEV and related viruses. It is now thought that guinea fowl (11, 71) and psittacines (45) may also be naturally infected. With regard to wild birds, a serologic survey of 42 different species revealed no evidence of infection outside the order Galliformes (16). Even wild populations of turkeys ap-

pear to be at little risk (51) due to their elusive nature. When infection does occur, host genetics appear to influence the severity of clinical disease and lesion formation in both turkeys (67) and pheasants (64). Laboratory experiments indicate that HEV isolates from turkeys will infect ring-necked pheasants and MSDV isolates from ring-necked pheasants will infect turkeys (26). Chicken isolates will also infect turkeys (27, 28, 29). Lesions have been produced in a variety of other gallinaceous species including golden pheasants, peafowl, chickens, and chukars by experimental infection with HEV (20). However death has not been reported in species other than the natural hosts.

Age of Host Most Commonly Affected
Primarily due to the protection afforded by maternal antibody (32), HE is not typically seen in turkeys until about 6 weeks of age, with most field cases occurring between 6–11 weeks of age (44, 100). A single case in 2.5-week-old poults has been reported and was thought to have been associated with a lack of maternal antibody (49). Newly hatched, seronegative poults have been shown to be susceptible to infection but refractory to intestinal lesion formation (79, 31) which suggests that some sort of target cell maturation may be necessary for the development of fulminant disease (32).

Marble spleen disease in pheasants occurs naturally in birds 3–8 months of age (6, 72). Those younger than 4 weeks of age appear to be less susceptible to infection either due to the presence of undetectable, yet effective levels of maternal antibody or an insufficiency of target cells (39).

In chickens, field infection with AASV has been observed in broiler breeders 20–45 weeks of age (27, 29).

Transmission, Carriers, and Vectors
HEV can be transmitted by oral or cloacal inoculation of susceptible poults with infectious feces (48, 61). Virus can remain viable for several weeks in carcasses protected from drying or in wet fecal material. HEV has also been recovered from contaminated litter and the disease is known to reoccur in houses where it has appeared before (20). Recent data suggest the development of persistent infection in recovered birds (4). However there is no epidemiologic evidence of egg transmission or true biological vectors (20). Therefore it is likely that HEV, MSDV, and AASV are transmitted mechanically from actively or persistently infected birds to susceptible ones.

Incubation Period
In turkeys clinical signs and mortality begin about 5–6 days after oral or cloacal and 3–4 days after IV inoculation with splenic extracts containing HEV (24). The incubation periods following oral inoculation with MSDV in pheasants (25) and AASV in chickens (27, 126) appear to be 6 and 5–7 days respectively.

Clinical Signs
HE is characterized by a rapid progression of clinical signs over a 24 hr period (20, 99). These include depression, bloody droppings, and death. Feces containing frank blood are frequently present on the skin and feathers surrounding the vents of moribund and dead birds. Bloody feces may also be forced from the vent if moderate pressure is applied to the abdomen. In naturally infected flocks, signs of disease tend to subside within 6–10 days of the appearance of bloody droppings. In pheasants infected with MSDV, death is often acute. Signs if present consist of depression, weakness, and progressive dyspnea. Occasionally, a pre-mortem nasal discharge is noted (37). The presentation for AASV in chickens is similar to that of pheasants but generally less severe (27, 29).

Morbidity and Mortality
In field outbreaks of HE, all or nearly all birds appear to be infected, as indicated by seroconversion (24) and resistance to subsequent experimental challenge. Depressed, clinically affected poults usually die within 24 hours or recover completely. Field mortality ranges from less than 1 to slightly more than 60% with the average being 10–15%. Mortality of 80% is often seen in laboratory experiments where 100% infection is achieved. Morbidity associated with MSD and AAS is likely to be similar to that of HE. Mortality in MSDV-infected pen-reared ring-necked pheasants has been reported to be 2–3%, but may reach as high as 5–20% over a course of 10 days to several weeks (9, 20, 62, 72). In mature chickens with AAS, mortality as high as 8.9% has been reported (29).

Pathology
Gross
Dead poults routinely appear pale due to blood loss but are often in good flesh and have feed in their crops. The small intestine is commonly distended, grossly discolored, and filled with bloody contents (Fig. 9.11F). The intestinal mucosa is congested and in some individuals, covered with a yellow fibrinonecrotic membrane. Lesions are usually more pronounced in the proximal small intestine (duodenal loop) but can extend distally in severe cases. Spleens of infected birds are characteristically enlarged, friable, and mottled in appearance (Fig. 9.11G); however, those of dead poults tend to be smaller presumably due to blood loss and subsequent contraction. Lungs may be congested, but other organs are generally pale. Enlarged livers and petechial hemorrhages in various tissues of dead poults have also been reported post mortem, but these findings are too inconsistent to be of diagnostic value (8, 43, 44, 46, 60, 100). Lesion formation with virulent strains appears to be dose dependent (80, 88).

Gross lesions in pheasants infected with MSDV consist of enlarged, mottled (marbled) spleens and edematous congested lungs (6, 72). Intestinal lesions have not been noted. In broiler breeder chickens infected with AASV, gross splenic and lung lesions resemble those of MSDV in pheasants (27, 29).

Microscopic
Pathologic changes that characterize HE are most evident in the immune and gastrointestinal systems. Splenic lesions present at death (Fig. 9.9) include hyperplasia of white pulp and lymphoid necrosis. Intranuclear inclusions can be found within mononuclear cells i.e., macrophages and lymphocytes (75, 107, 112). Proliferation of white pulp surrounding splenic ellipsoids is evident as early as 3 DPI. This leads to large, irregular, confluent is-

9.10. Section of small intestine of turkey affected with hemorrhagic enteritis. Lesions include severe congestion of the mucosa, degeneration of epithelial cells covering tips of villi, sloughing of epithelial cells and tip of villus, and hemorrhage into the lumen. H & E, × 550.

lands of white pulp which are grossly visible as mottling 4–5 DPI (107). Hematoxylin and eosin (H&E) and immunoperoxidase staining reveal numerous intranuclear inclusions in these zones between 3 and 5 DPI. By 4–5 days PI white pulp begins to undergo necrosis and by 6–7 DPI it has completely involuted with only occasional plasma cells appearing in the red pulp (107). In addition to splenic changes, lymphoid depletion is also noted in both the cortical and medullary areas of the thymus (56) and bursa of Fabricius (56, 107) between 3 and 9 DPI.

Typical lesions in the gastrointestinal tract include severe congestion of intestinal mucosa, degeneration and sloughing of villus epithelium, and hemorrhage in the villus tips (Fig. 9.10). Hemorrhage is believed to result from endothelial disruption rather than destruction because blood vessels in the lamina propria appear intact and red cells are observed moving out of these vessels by diapedesis (107). Increased numbers of mononuclear cells positive for intranuclear antigen are observed in the lamina propria (52) in addition to mast cells (86), plasma cells, and heterophils (107). These histopathologic changes are most pronounced in the duodenum just posterior to the pancreatic ducts, but similar less severe lesions may also occur in the proventriculus, gizzard, distal small intestine, ceca, cecal tonsils, and bursa of Fabricius (20). Additionally cells containing intranuclear inclusions can be seen in the liver, bone marrow, peripheral blood

leukocytes, lung, pancreas, brain, and renal tubular epithelium (8, 43, 46, 52, 60, 75, 119).

MSDV and AASV produce intranuclear inclusions and splenic lesions similar to those of HEV but without significant gastrointestinal involvement. In naturally occurring cases of MSDV and AASV flooding of the atria and tertiary bronchi with fibrin and red cells as well as vascular congestion are observed in the lung (6, 29, 40). However, these lesions are not commonly seen with experimental infections. Typical intranuclear inclusions can be found in the liver, lung, kidney, bursa, and bone marrow. However, no inclusions are noted in the gastrointestinal tract (37, 40). Immunohistochemical staining for MSDV antigen on sections of lung from naturally infected pheasants reveals moderate numbers of positively stained nuclei in mononuclear cells within atria (40). Whether these are infected peripheral blood leukocytes similar to those seen with HEV or a finding of significance in the pathogenesis of the pulmonary edema with MSD is unknown.

Pathogenesis of the Infectious Process

HEV and related viruses are considered to be lymphotropic and lymphocytopathic (38, 52, 107, 123) with IgM bearing B lymphocytes being the primary target (105, 112). Macrophages can also

appear to support viral replication (111, 123). Given this it is not surprising that bursectomy impairs viral replication and lesion formation (31, 38, 111) or that marked depletion of IgM bearing cells in the spleen and peripheral blood occurs during the acute phase of HEV infection (105, 111). HEV and MSDV are also known to produce transient inhibition of antibody responses to sheep erythrocytes (36, 76) and Newcastle disease virus (77) as well as suppression of B and T cell mitogenic responses *in vitro* (36, 76, 77, 78).

Multiple hypotheses regarding the immunopathogenesis of HE and related viruses have been proposed (31, 52, 74, 86, 87, 92, 103, 106, 107, 111, 112). Based on the work of numerous authors, Rautenschlein and Sharma (104) have suggested the following composite model. After oral exposure, HEV either undergoes an initial round of replication in B lymphocytes located in the intestine and bursa of Fabricius, or it travels directly to the spleen via the peripheral blood. There it infects more B cells and macrophages and replicates to high numbers. This results in an influx of CD4+ T cells and macrophages into the white pulp, presumably in an attempt to clear virus, and accounts for the hyperplasia observed during the acute phase of infection. Once activated, macrophages produce a variety of cytokines including interleukin (IL)-6 and tumor necrosis factor (TNF). These induce T cells to produce interferons (IFN) and TNF. Type II IFN activates the macrophage population, stimulating production of nitric oxide, which has antiviral, immunosuppressive properties. It also appears that type I IFN may be produced in an attempt to limit viral replication (106). As the infection process continues, HEV replication induces apoptosis and necrosis of target cells, thus depleting the IgM bearing B cell population. Cytokines released by activated T cells and macrophages also potentially induce apoptosis of by-stander cells. The result is a massive apoptotic event accompanied by a transient period of immunosuppression. It also has been proposed that the release of large amounts of cytokines initiates systemic shock and fosters the development of characteristic vascular lesions in the gastrointestinal tract, the proposed primary shock-responsive organ in the turkey.

As it applies to intestinal lesion formation, this mechanism of HEV pathogenesis is corroborated by additional evidence that suggests that histamine and prostaglandin play a role in lesion formation (85, 86). The presence of few infected cells in the intestine (112) and the ability of cyclosporin A, a T cell inhibitor, to abrogate intestinal hemorrhage also suggest that gastrointestinal lesion formation is immune mediated (111). If this model holds true, it is likely that the pulmonary lesions seen with MSDV and AASV in pheasants and chickens may be related to species differences in primary shock-responsive organs.

Presumably, as a result of the described mechanism of immunosuppression, HEV alone (66,109) or in combination with other agents like *Bordetella avium,* Newcastle disease virus (NDV), and *Mycoplasma meleagridis* appears to predispose turkeys to secondary infection with *E. coli* in the field (91). Similar findings have been reported under laboratory conditions with avirulent strains of HEV (65, 66, 83, 95). Paramyxovirus-2 and *Chlamydiophila psittaci* infections have also been observed following HEV exposure (2).

Surprisingly, improved weight gains and reduced oocyst shed-

ding have been found in turkeys concomitantly infected with HEV or MSDV and *Eimeria meleagrimitis* (84). Likewise, dual vaccination with NDV and HEV appears to have a peculiar effect i.e., NDV antibody production is enhanced while HEV antibody production is suppressed. The spleens in this case also exhibit a more pronounced hyperplasia of the white pulp and an increased rate of apoptosis (103).

Finally, immunosuppression appears to occur with virulent as well as avirulent strains of HEV (66, 74, 90). Therefore although virulent strains may certainly be considered pathogenic, avirulent strains should not be considered completely apathogenic.

Immunity
Active
Poults recovering from natural or experimental infections with HEV are refractory to challenge. Protection does not appear to be strain specific. Strains that cause less than 1% mortality induce sufficient immunity to prevent infection with those producing much greater mortality (22). Antibodies against HEV may be detected as early as 3 DPI by ELISA (121). Such immunity appears to be long lasting if not life-long. One flock monitored over a 4–year period demonstrated a seroconversion rate of 100% at 4 week PI and was still found to be 83% positive 40 months later (21). The occurrence of life-long immunity is believed to be the result of persistent infection since viral DNA can be detected in numerous tissues up to 70 DPI despite high levels of circulating antibody (4).

Cell-mediated immunity undoubtedly plays a role in active protection against HEV and MSDV infections and lesion formation, but its role is not fully understood. Inoculation of turkeys with HEV causes an increase in splenic CD4 bearing T cells 4–6 DPI (104, 111) and elevations of CD8 bearing cytotoxic/suppressor T cells are also reported to occur at 8–10 and 16 DPI (90, 111). Selective *in vivo* T cell depletion with cyclosporin A seems to enhance splenic lesion formation and viral replication in MSDV infected pheasants (42) but the same effect has not been observed in HEV infected turkeys (111).

Passive
Maternal antibody can provide protection from clinical HE for up to 6 weeks post-hatch and has been reported to interfere with vaccination for up to 5 weeks (32). However in a commercial setting, maternal antibody typically declines enough by 3.5–4 weeks to permit vaccination with splenic HEV vaccine. Passive immunity can also be conferred by injection of birds with convalescent antiserum obtained from recovered flocks. In laboratory experiments 0.5–1.0 mL of antiserum prevented all gross lesions and as little as 0.1–0.25 mL prevented intestinal lesions (19). Administered in this fashion, hyperimmune serum has been shown to afford protection from lesion formation for up to 5 weeks (32).

Diagnosis
Isolation and Identification of Causative Agent
Large concentrations of HEV can be found in bloody intestinal contents or splenic tissue obtained from dead or moribund poults (48). Splenic material from MSDV-infected pheasants and

AASV-infected chickens is also a suitable source of virus. For all three agents, HEV seronegative turkeys preferably 6 weeks of age, can be inoculated *per os* (PO) with intestinal contents or, PO or IV with a splenic homogenate (1:1 v/v spleen:PBS). Death often occurs about 3 days after IV and 5–6 days after PO inoculation with virulent isolates. Poults that do not die as a result of infection usually have enlarged mottled spleens with typical intranuclear inclusions. Ample virus can be obtained from the spleen to perform precipitin reactions or molecular diagnostics. Sera obtained at these times also contain virus (24). Alternatively, MDTC-RP19 cells (American Type Culture Collection, Manassas, VA) grown in 65% McCoy's 5A and Leibowitz L-15 with L-glutamine media (combined 1:1 v/v), 5% tryptose phosphate broth, 20% chicken serum (HEV negative), and 10% fetal bovine serum, with 100,000 IU of penicillin/streptomycin per L can be inoculated with filtrates (.22 μm) of splenic material to isolate and propagate the viruses(79, 80).

Positive identification of HEV, MSD, and AASV is commonly accomplished through the use of an Agar Gel Immunodiffusion (AGID) method in which splenic tissue (fresh or frozen) is diluted 1:1 v/v with PBS and precipitated against polyclonal anti-HEV serum (23, 24, 93). Viral antigen can also be identified in thin sectioned (4–6 μm) frozen or formalin fixed tissues using immunofluorescent (35) or immunoperoxidase staining methods (40, 41, 53, 107). The availability of genomic sequencing data has permitted the development of standard (4, 50, 94, 98), nested, and real time (4) PCR assays for detection of viral DNA in fresh or frozen tissues. Drying of crude splenic material or DNA extracts on filter paper has also been shown to be an adequate method of storage (98). For standard PCR, DNA extraction can be performed using commercially available kits. DNA polymerase, $MgCL_2$, deoxynucleotide triphosphates (dNTPs), oligonucleotide primers, sterile de-ionized water, and sample DNA are combined in a total reaction volume of 25–50 μL. Primers which amplify a 270 base pair region of the hexon gene have been found to be reliable (nHEVL, 5′-gtg gtt cag cag aaa gtt ctt-3′; nHEVR, 5′-cag tag act cat aag caa cta t-3′). A standard 3 step thermocycler program is run for 35 cycles (4). Less commonly used methods for antigen detection include antigen-capture ELISA (54, 81, 108, 121) and *in situ* DNA hybridization (112).

Serology

Hemorrhagic enteritis virus antibodies can be detected in plasma or serum of recovered birds 2–3 weeks PI by AGID using known positive splenic material diluted 1:1 v/v with PBS as the test antigen (23, 24, 93). It is advisable to run both acute and convalescent sera if a diagnosis is to be made based on serology. Maternal antibody may be detected using AGID, but this method generally lacks sufficient sensitivity beyond 1 week of age (121). More sensitive ELISA techniques have been developed (12, 54, 80, 81, 121). These are capable of detecting maternal antibody in turkeys up to 4–6 wk of age, although most birds in the field are seronegative by 3 weeks of age (13, 121). An active immune response can be detected as early as 3 DPI (121). HEV ELISA kits are available commercially and should be useful for MSDV and AASV as well.

Differential Diagnosis

In turkeys an enlarged mottled spleen without demonstrable HEV antigen on AGID and the absence of intestinal bleeding warrants consideration of reticuloendotheliosis or lymphoproliferative disease as differential diagnoses. Enlarged, congested spleens in turkeys are often mistakenly attributed to HEV, but are commonly the result of bacterial septicemias e.g., colibacillosis, salmonellosis, and erysipelas. Additional signs and lesions usually accompany these diseases. Gastrointestinal bleeding and mucosal hyperemia may be associated with acute septicemic, viremic, or toxemic conditions. However these would rarely be observed without other lesions or signs consistent with the etiology. Coccidiosis and toxic substances e.g., heavy metals and chemicals, should also be considered.

Pheasants and chickens that die acutely with signs of respiratory distress but without enlarged mottled spleens should be tested for other respiratory pathogens including Newcastle disease virus, avian influenza virus, infectious laryngotracheitis virus, and in the case of chickens, infectious bronchitis virus. Respiratory signs with splenic enlargement and congestion should prompt consideration of bacterial pathogens like *Pasturella* and *E. coli*. Carbon monoxide, carbon dioxide, and natural gas should also be considered in confinement operations. Splenic enlargement and mottling without evidence of MSDV or AASV antigen on AGID should warrant histopathologic evaluation for neoplastic diseases such as Marek's disease, lymphoid leukosis, or reticuloendotheliosis. In chickens, hepatitis E should also be a consideration.

Intervention Strategies

Management Procedures

Effective prevention and control of HE, MSD, and AAS begin with adherence to Best Management Practice guidelines, especially biosecurity protocols, because movement of infectious litter or feces from flock to flock is the most common mode of transmission. Contaminated facilities may be cleaned and then disinfected with 0.0086% sodium hypochlorite solution or other common viricidal agents plus drying at 25°C for 1 week (17, 18). However in most commercial operations, especially those having multiple ages of birds, total elimination of the virus is considered impractical. In such cases vaccination remains the most effective means of disease control and prevention.

Vaccination

Types of Vaccine

Avirulent isolates of HEV and MSDV have been successfully used as live, water-administered vaccines (22). Two forms of vaccine are currently in widespread use for turkeys. One is a crude homogenate prepared from spleens (1:1 v/v spleen:PBS) of 6-week-old turkeys inoculated PO or IV with HEV avirulent I (Domermuth strain) or HEV avirulent II. The other is produced *in vitro* using MDTC-RP19 cells in suspension culture (33). Both vaccines appear to produce adequate seroconversion and protection (3) and are used extensively in the United States, but only the latter is commercially available. A third method of vaccine pro-

duction involving propagation of HEV avirulent I in peripheral blood leukocytes has also been described (123) and was temporarily used in Canada. A recombinant fowl pox vaccine expressing native HEV hexon has been shown to prevent mortality and gross intestinal lesions in challenged turkeys and appeared to produce less immunosuppression when compared to virulent HEV or commercial tissue culture-attenuated HEV as measured by lymphoblastogenesis assays(7). Other vaccines, including a purified hexon subunit (125) and a recombinant penton fiber-knob subunit, have been developed and are known to confer protection (97). The use of transgenic plants (tobacco) as feed grade, oral delivery vehicles for recombinant HEV fiber has also been explored (116,117).

Field Vaccination Protocols and Regimes

Successful *in ovo* vaccination of specific-pathogen-free turkeys has been described (1), but water vaccination of healthy turkeys is currently the method of choice and is usually performed between 3.5 and 6 weeks of age. The addition of a vaccine stabilizer to the water and the elimination of any water-line disinfectants including chlorine is essential to the survival of the virus and successful vaccination. Interestingly, stress applied on the day of vaccination e.g., social disruption through the movement of birds, appears to enhance the response to vaccination, either because it stimulates cell mediated immunity or permits more efficient viral replication (74). Flocks experiencing less than 100% protection from initial vaccination usually are protected by lateral transmission within 2–3 weeks. Despite this, a second vaccination 1 week after the first is occasionally employed. Not surprisingly, turkeys which have previously been exposed to immunosuppressive diseases such as avian pneumovirus exhibit a reduced response to vaccination (10).

Live, avirulent, water-administered vaccines are also effective for controlling MSD of pheasants (26, 30) but none are commercially available in the US. Vaccines for AAS of chickens have not been developed.

Treatment

Prior to the advent of effective vaccines, HE was treated by subcutaneous or intramuscular injection of 0.5–1.0 mL of convalescent antiserum obtained from healthy flocks at slaughter (19). Treatments have not been described for MSD of pheasants or AAS of chickens. However, due to the immunosuppressive nature of HE and related viruses, treatment for secondary bacterial infections, primarily colibacillosis, must be considered. Selection of an appropriate antimicrobial based on culture and sensitivity is always advised. Correction of management deficiencies and vaccination for other primary agents that may be exacerbated by exposure to field or vaccine challenge with HEV e.g., *Bordetella avium* and Newcastle disease virus, must not be neglected.

Quail Bronchitis

Willie M. Reed and Sherman W. Jack

Introduction

Quail bronchitis (QB) is a naturally occurring, acute, highly contagious, fatal respiratory disease of young bobwhite quail (*Colinus virginianus*). The disease is of major economic significance to gamebird breeders and has a worldwide distribution (1, 2). Quail bronchitis is characterized by rapid onset, high morbidity, and high mortality and mainly affects captive-reared birds. The etiologic agent is QB virus (QBV). Quail bronchitis and chicken embryo lethal orphan (CELO) viruses—both serotype I avian adenoviruses—are considered to be the same agent and are not distinguishable using conventional techniques (3, 20). Both viruses produce similar disease and lesions in bobwhite quail and chicken embryos.

Few type I avian adenoviruses, other than QBV and CELO, have been evaluated for pathogenicity in bobwhite quail, with the exception of Indiana C adenovirus. Recent studies (11) have demonstrated that young bobwhite quail are susceptible to infection with Indiana C adenovirus, and the clinical disease and pathologic manifestations are indistinguishable from both naturally occurring and experimental infection with QBV.

Although QBV is infectious for domestic poultry, including chickens and turkeys, as well as other avian species, resulting in seroconversion, the infection is generally asymptomatic. Although QB/CELO virus has induced neoplasms in laboratory animals, there is no known public health significance (15).

History, Incidence, and Distribution

Quail bronchitis was first described by Olson (16) from a 1949 outbreak in West Virginia. A similar disease in quail had been reported as early as 1933 by Levine, however, and an agent similar to QBV was isolated by Beaudette in 1939. Following Olson's report, several outbreaks were reported in Texas in 1956–1957 and in Virginia in 1959 (4, 5). Infection occurred in 3-week-old to mature bobwhite quail, with mortality in some pens reaching 80%. Chukar partridges on the gamebird farm did not develop the disease. Circumstantial evidence indicated transmission of QBV from inapparently infected chickens or captive gamebirds other than quail to the affected bobwhite quail.

Since the early descriptions, QB has been frequently diagnosed as the cause of mortality in captive-reared bobwhite quail. The true incidence and distribution of infection are unknown, but asymptomatic infection in older birds is believed to be widespread. Infection had not been identified in wild bobwhite quail until 1981, when King *et al.* (14) reported antibodies against serotype 1 avian adenovirus in 23% of mature, free-ranging bobwhite quail collected from a research station.

Etiology

Quail bronchitis is caused by an avian adenovirus. It contains a DNA genome and is icosahedral, nonenveloped, and ranges in size from 69–75 nm in diameter (6). Based on virus neutralization, QBV is a group I/serotype 1 adenovirus indistinguishable from the Phelps strain of CELO virus (8, 15, 20). QBV/CELO serves as the type strain for group I/serotype 1 avian adenoviruses. Other techniques have been used to classify avian adenoviruses (e.g., physicochemical properties, hemagglutination, and restriction endonuclease mapping), but they have failed to further clarify the taxonomy of these agents. As with other adenoviruses, avian adeno-associated virus (AAAV) may occur with QBV (23).

Laboratory Hosts and Pathogenicity

Quail bronchitis virus is readily propagated in embryonating chicken eggs and in cultures of chicken kidney or liver cells. Although QBV will grow in chicken fibroblasts, this system is less suitable for cultivation because virus multiplication is poor. Propagation may be interfered with by concurrent AAAV infection (15, 23) or by maternal antibodies in yolk of embryonating eggs (21, 22).

In most diagnostic laboratories, initial isolation is performed in embryonating chicken eggs, sometimes requiring several blind passages before typical lesions and mortality patterns develop. A common and proven route of inoculation is via the allantoic cavity. High yields of virus can be detected in allantoic fluid 48–96 hours postinfection (PI). Isolation and propagation of QBV using the yolk sac route in antibody-free embryonating eggs is also an effective method. Infection of the embryo by the yolk sac or allantoic cavity results in dwarfing, curling, and stunting of the embryo in 2–4 days. Examination of affected embryos reveals widespread congestion and hemorrhage and enlargement of the liver, with varying degrees of necrosis and hepatitis with intranuclear inclusion bodies.

Experimental inoculation of hamsters leads to various kinds of neoplasms, depending primarily on the route of inoculation. Subcutaneous inoculation results in fibrosarcomas, hepatomas, or hepatic carcinomas, and intracranial inoculation leads to the development of ependymomas (1, 15). Quail bronchitis virus/CELO has not been found to be oncogenic in mice or chickens (15).

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Bobwhite quail are the principal species that develop clinical signs and mortality due to infection with QBV. Clinical disease has been reported in Japanese quail. Chickens and turkeys may be experimentally infected but develop few or only mild clinical signs. Inapparent infections of chickens are suggested by serologic evidence (19, 20).

Transmission, Carriers, and Vectors

Quail bronchitis is highly contagious, as demonstrated by explosive morbidity and mortality in susceptible flocks. Most signs are

seen in quail younger than 6 week of age. Although not experimentally documented, transmission is probably by aerosol. However, fecal-oral or mechanical transmission has been documented for other avian adenovirus, and QBV has been isolated from cecal tonsil during experimental infections (12). Serologic evidence of infection of other gallinaceous birds may suggest that, even though they fail to develop clinical signs, these species may serve as a vector for QBV.

Incubation Period, Signs, Morbidity, and Mortality

Quail bronchitis is often a catastrophic disease of captive-reared bobwhite quail, which is manifested by respiratory distress that leads to death in young quail. Morbidity and mortality from field cases frequently exceed 50% and may be much higher in flocks affected at younger than 3 weeks of age. In experimental infections of 1-week-old quail, mortality began 2 days following intratracheal infection and subsided by day 9 (7). Mortality in quail inoculated at 3 weeks of age occurred between 6 and 11 days PI. Death is uncommon in birds older than 6 weeks of age.

Frequently, the first reported sign in the flock is a sudden increase in mortality. Closer inspection, however, frequently reveals that sick birds that demonstrate decreased feed consumption, ruffled feathers, huddling under brooders, wing droop, open-mouthed breathing, "snicks," and nasal-ocular discharge. Following infection, signs may develop at as early as 2 days but generally develop in 3–7 days. Severity of infection varies depending on the age at which the bird is infected. Quail bronchitis is most severe in quail less than 3 weeks of age. Older birds frequently are asymptomatic but develop antibodies to group I/serotype 1 adenovirus. This suggests that survivors may be immune to subsequent virus exposure, but the persistence of these antibodies and the level of immunity have not been investigated. Antibodies against QBV have been identified in recently hatched quail that did not exhibit adverse signs of infection. These antibodies were lost at between 4 and 6 weeks of age, suggesting that there were maternal antibodies.

Gross Lesions and Histopathology

The principal lesions of QB are in the respiratory tract (9). Nasal-ocular discharge may also be noted. Opacity and filling of the trachea by pale, moist, necrotic, and sometimes hemorrhagic exudate is common (Fig. 9.11A). On cross section, the mucosa is markedly thickened (Fig. 9.11B). Similar exudate may be found in the anterior air sacs. Histologically, tracheal lesions may include epithelial deciliation, cell swelling, karyomegaly, necrosis, desquamation, and leukocyte infiltration (Fig. 9.11C). Basophilic, intranuclear viral inclusions are common in intact or desquamated tracheal epithelium. Electron microscopic changes are similar to those seen histologically but also demonstrate phagocytosed viral particles.

In the lungs, red, consolidated areas surround the bronchial hilus (Fig. 9.11D). On section, bronchi frequently contain exudate similar to that in the trachea, indicative of a necrotizing, proliferative bronchitis. Inflammatory exudates consisting of lymphocytes, heterophils, and fluid may extend into the surrounding pulmonary parenchyma, but the intensity of the leukocyte response varies and may be confounded by secondary bacterial infections. Histologically, bronchial changes are similar to those in the trachea, except that bronchi may demonstrate more epithelial proliferation. Most lesions are associated with large basophilic intranuclear inclusions (Fig. 9.11E).

Lesions in the liver include multifocal pale, pinpoint to 3 mm necrotic foci. Histologically, these foci are characterized by hepatocellular necrosis, infiltrated to varying degrees by lymphocytes and fewer heterophils. Inclusion bodies are occasionally seen in hepatocytes adjacent to necrotic foci and/or biliary epithelium.

Lesions occur in the spleen and bursa of Fabricius but can be difficult to identify in quail less than 3 weeks of age. The spleen may be mottled and slightly enlarged. Histologically, affected spleens have multifocal, often extensive zones of necrosis, characterized by lymphocytolysis with increased fibrillar eosinophilic intercellular material, with minimal leukocyte infiltration. Adenoviral inclusions are rare in the spleen. Histologic lesions of the bursa of Fabricius include necrosis of lymphocytes, frequently accompanied by generalized lymphoid depletion and follicular atrophy. Intranuclear viral inclusions are common in bursal epithelium. Experimentally, some quail also develop necrotizing pancreatitis associated with adenoviral inclusions.

Immunity

The duration of immunity in QB is not known, but survivors of both naturally occurring and experimental infections were refractory to challenge with QBV for at least 6 months, and significant antibody levels developed in serum of quail following infection (2, 3, 16). Young chicks with maternal antibody are also refractory to challenge with QBV, but maternal antibody is not believed to prevent virus multiplication.

Diagnosis

In quail chicks, sudden onset of rales, sneezing, or coughing that spreads rapidly through the flock and results in mortality suggests QB. Excess mucus in the trachea, bronchi, and air sacs is added evidence of the disease. Severity of signs, rapidity of spread, and the presence of lesions are less marked in older quail. Isolation and identification of an agent indistinguishable from QBV (or CELO virus) would confirm the diagnosis. Inoculation of 9–11-day embryonating chicken eggs via the chorioallantoic sac with suspensions of trachea, air sacs, or lungs has been used for isolation of the virus. Yates et al. (23) recommended suspensions of fecal samples or homogenates of the posterior small intestine (ileum) or colon. Jack et al. (12, 13) reported good success in isolating QBV from the liver of naturally infected birds and from the bursa of Fabricius and cecal tonsils of experimentally infected birds. Three to five blind passages are made with allantoamnionic fluid harvested from chilled eggs up to 6 days or more PI or earlier from embryos that died 24 hours PI or later or that exhibit signs of stunting in daily candling. According to Yates et al. (23), a few strains seem to require inoculation via the yolk sac in 5–7-day embryos.

Embryo mortality (increasing with number of passages), stunting, thickening of the amnion, necrotic foci, or mottling of the liver, and accumulation of urates in the mesonephros are typical changes caused by QBV or CELO virus. Neutralization of the isolated virus by specific QBV or CELO virus antiserum would confirm identification of the virus and the diagnosis.

In general, information pertaining to isolation, propagation, and identification of CELO or any group I/serotype 1 avian adenovirus would be applicable to QBV. Yates *et al.* (23) noted preference for chick embryo kidney or kidney cell cultures, and Jack and Reed (10, 11) have described propagation of QBV in chicken embryo liver tissue. The agar gel precipitation (AGP) test may be used to place an isolated virus in the avian adenovirus group, but it does not identify the serotype. Serotype classification is based on virus neutralization (10). In the absence of virus isolation or with failure to isolate a virus, the AGP test, using stock antigen on paired sets of serum samples, may be of value. A markedly higher percentage of positive precipitin tests among samples collected during convalescence (2–4 weeks after initial signs) than among sera collected during the acute phase (first few days of signs) should add weight to a presumptive diagnosis of QB based on clinical observations.

Pulmonary aspergillosis may be differentiated from pox by the presence of caseous plugs in lungs or deposits in air sacs with pockets of grayish or greenish spore accumulations. Although bacterial infections might complicate the disease, none is known to cause rapid development of signs, lesions, and mortality typical of QB. DuBose (2) suggested that Newcastle disease might present a clinical picture similar in part to QB, but clinical Newcastle disease has not been described in bobwhite quail. Histologic identification of intranuclear inclusion bodies morphologically characteristic of adenovirus in tracheal or bronchial epithelium is highly suggestive of infection with QBV (9).

Treatment, Prevent, and Control

No specific treatment exists for QB. Increased warmth in the brooder house, adequate ventilation but no drafts, and avoidance of crowding are suggested supportive measures during an outbreak. Prevention is based on protecting susceptible quail from all possible sources of QBV or CELO virus. In addition to the usual sanitation procedures and measures to prevent entry of infectious agents onto the premises, care should be taken to keep adult quail, as well as other avian species, away from young quail. Control measures on a farm should be started immediately, when even a tentative diagnosis of QB has been made. In addition to general measures to prevent transmission from group to group, hatching operations may need to be deferred until 2 weeks after signs have disappeared in order to prevent an outbreak in the presence of highly susceptible young quail.

Attempted eradication of QBV from bobwhite quail on a large gamebird farm was unsuccessful but may have been responsible for preventing losses and clinical QB over a 2-year period (3). In that effort, 80% of the 10,000 quail hatched during the previous year died from the disease. In addition to measures described previously, older quail were marketed, and only survivors from hatches that had been affected at less than 4 weeks of age were kept for breeders. Virus-neutralization antibody at a high level was detected in 3-month-old quail hatched 2 years later, but no signs of QB were detected in the intervening period up to the time the farm closed the following winter. Winterfield and Dhillon (17) used a type 1 adenovirus serotype in quail chicks as a vaccine against QB. The isolate, designated Indiana C virus, was isolated from chickens (18). It proved nonpathogenic for quail in a laboratory trial and was subsequently used on a farm where QB was endemic and losses were extensive. It was reported that the disease quickly subsided. In recent studies (11), however, experimental inoculation of quail at 1 or 3 weeks of age resulted in mortality rates of 33–100%. In quail inoculated at 6 or 9 weeks of age, mortality ranged from 0–10%. Gross and histologic lesions included necrotizing tracheitis and bronchitis with pneumonia, necrotizing hepatitis and splenitis, and lymphoid depletion of the bursa of Fabricius. Based on these findings, Indiana C appears to be highly pathogenic for bobwhite quail and is not recommended for use as a vaccine to prevent QB. More studies on potential use of vaccines to prevent QB are needed.

Chapter 10

Pox

Deoki N. Tripathy and Willie M. Reed

Introduction

Definition and Synonyms

Pox is a common viral disease of commercial poultry (chickens and turkeys) as well as of pet and wild birds. Of the approximately 9000 birds species, about 232 in 23 orders have been reported to have acquired a natural pox virus infection (11). Fowl pox is an economically important disease of commercial poultry because it can cause a drop in egg production and mortality. Synonyms that have been used for avipox infections are contagious epithelioma; avian diphtheria; variole aviaire [Fr.]; difteria aviar [Sp.]; bouba aviaria [Port.]; Geflugelpocken [Ger.]; virula aviar; and variola gallinarum. Pox is a slow-spreading disease characterized by the development of discrete nodular proliferative skin lesions on the nonfeathered parts of the body (cutaneous form) or fibrino-necrotic and proliferative lesions in the mucous membrane of the upper respiratory tract, mouth, and esophagus (diphtheritic form). A concurrent systemic infection may also occur.

Economic Significance

Mortality in flocks exhibiting the mild cutaneous form of the disease is usually low. However, it may become high with generalized infection, especially when lesions are primarily diphtheritic or when the disease is complicated by other infections or poor environmental conditions. The systemic form of disease in canaries causes high mortality.

Public Health Significance

Avian pox is not of public health significance. It does not cause productive infection in mammalian species. However, a pox virus isolated from a rhinoceros by Mayr and Mahnel (62) was characterized as fowl pox virus (FPV).

History

Pox has long been observed in several avian species. The term *fowl pox* initially included all pox virus infections of birds, but now it is primarily used to refer to the disease in commercial poultry. Initially, Woodruff and Goodpasture (146,147,148) presented evidence that the virus particles (Borrell bodies) within the inclusion bodies (Bollinger bodies) were the etiologic agent of fowl pox. Later, Ledingham and Aberd (57) demonstrated that antisera produced against FPV after immunization or following recovery from infection agglutinated a suspension of elementary bodies of FPV.

Etiology

Avian pox viruses (fowl, turkey, pigeon, canary, junco, mynah, psittacine, quail, sparrow, crow, peacock, penguin, alala, apapane, condor, and starling) are members of the genus *Avipoxvirus* of the family Poxviridae (74,130). FPV is the type species of the genus. Because of its economic importance, more basic and applied studies have been done on FPV than any other member of this genus.

Morphology

Like members of other genera of the Poxviridae family, all avian pox viruses have a similar morphology. The mature virus (elementary body) is brick shaped and measures about $330 \times 280 \times 200$ nm. The outer coat is composed of random arrangements of surface tubules (Fig. 10.1A). FPV consists of an electron-dense centrally located biconcave core or nucleoid and two lateral bodies in each concavity and surrounded by an envelope (Fig. 10.1B).

Chemical Composition

The main components of FPV are protein, DNA, and lipid. The virus has a particle weight of 2.04×10^{-14} g and contains 7.51×10^{-15} g protein, 4.03×10^{-16} g DNA, and 5.54×10^{-15} g lipid (84); nearly one-third of FPV is lipid. Squalene as a major lipid component and elevation of cholesterol esters were detected in virus preparation from infected chick scalp epithelium (60,141). The average weight of the inclusion body is about 6.1×10^{-7} mg, 50% of which is extractable lipids. The protein content per inclusion body is 7.69×10^{-8} mg, and the average weight of DNA per inclusion is 6.64×10^{-9} mg (83).

Virus Replication

The cytoplasmic site of DNA synthesis and packaging within the infectious virus particle is characteristic of pox viruses. Detailed information on replication of pox viruses may be found elsewhere (13, 18,73).

FPV contains genes that encode for a DNA ligase, ATP-GTP binding protein, uracil DNA glycosylase, DNA polymerase, DNA topoisomerase, DNA processing factor, and replication-essential protein kinase (1). In addition, FPV possesses a gene that encodes for the DNA repair enzyme, CPD photolyase that

The scale on the lefthand side of the gel represents the position of the l HindIII fragments (kb).

repairs UV-induced damage to the DNA by using visible light as a source of energy. It is assumed that the presence of this enzyme helps the virus prolong its survival in external lesions in poultry and in the environment (107, 109).

Replication of avian pox viruses appears to be similar in dermal or follicular epithelium of chickens, ectodermal cells of the chorioallantoic membrane (CAM) of developing chicken embryos and embryonic skin cells. Differences in the host cell and virus strain, however, may be reflected in the time scale of replication and virus output.

Biosynthesis of FPV in dermal epithelium involves two distinct phases: a host response characterized by marked cellular hyperplasia during the first 72 hours and synthesis of infectious virus from 72–96 hours postinfection (PI) (20, 21).

The replication of viral DNA in dermal epithelium begins between 12 and 24 hours PI and is followed by the appearance of infectious virus later. Epithelial hyperplasia between 36–48 hours PI ends in a 2.5-fold increase in cell number by 72 hours PI. The rate of viral DNA synthesis is low during the first 60 hours of infection. Enhancement in the rate of viral DNA synthesis occurs between 60 and 72 hours PI concomitantly with a sharp decline of cellular DNA synthesis. Between 72 and 96 hours PI, the synthesis of viral DNA becomes progressively more prominent, and no further hyperplasia is observed (20, 21). Swallen (111) demonstrated by using autoradiography that chicken epidermis infected for 48 hours with FPV showed a three-fold increase in labeled nuclei as compared with controls, indicating that infection is associated with an increased incidence of intranuclear DNA synthesis. Based on positive hybridization signals, both viral RNA and DNA were detected in the nucleus of infected cells by 24–72 hours after infection (34).

Infection of chicken embryo skin cell culture results in an increase in virus titer at 16 hours after infection with evidence of cytopathic effects (CPE). Although the viral titer continues to increase during the next 20 hours, it then declines between 36 and 48 hours PI. A total increase in FPV titer of 100-fold is observed during the growth period. FPV DNA replication in these host cells occurs between 12 and 16 hours PI and continues through 48 hours PI (80).

The genome of FPV contains six genes with putative protein modification functions. These include three serine/threonine protein kinase (PK), one tyrosine PK, a metalloprotease, and a tyrosine/serine protein phosphatase. These are involved in phosphorylation of virus proteins during virion assembly, viral protein processing, and virion morphogenesis (1).

Based upon recent sequence analysis, FPV encodes homologues of at least 31 known vaccinia virus structural proteins (1), and the majority of them are associated with the intracellular mature virus particle (IMV). Of these proteins, 12 are located within the core, and 7 are associated with the membrane. Three proteins also are associated with extra-cellular enveloped virions (EEVs). In addition, homologues of 5 proteins, which represent 2 conserved pox virus gene families and have putative structural functions, are present in FPV. Also, FPV contains homologues of pox virus A-type inclusion (ATI) proteins. These inclusions protect mature virions from environmental insults and assist in pro-

longed survival in nature. Stability of the virus in the environment may be further supported by the presence of photolyase and glutathione peroxidase (1, 107).

Ultrastructural studies have focused on the morphogenesis of the virus in various developmental stages that lead to mature virions (4,5,87). After adsorption to and penetration of the cell membrane by FPV, and within 1 hour after infection of dermal epithelium (5) and 2 hours after infection of CAM (4), there is uncoating of the virus before synthesis of new virus from the precursor material. A few small virus factories containing crescents and a few isolated immature viruses (IV) are observed at 12 hours PI. The virus factories increase in size and contain more IV by 16 hours PI. Although between 16–66 hours PI, the majority of viral particles appear as IV, all subsequent steps of morphogenesis may also be observed. Only a few isolated intracellular mature viruses (IMV) are detected by 47 hours PI, some of which appear completely or partially wrapped and in the process of becoming intracellular enveloped virus (IEV). IMV particles are also found in clusters associated with membranes. Accumulation of viral particles near the plasma membrane suggests that FPV exits the cell mostly by budding (13). Inclusion bodies are present at 72 hours after infection of dermal epithelium (5) and at 96 hours after infection of the CAM (4). The A type inclusions may contain virions within or toward the periphery (Fig. 10.1C). Similar inclusions have been observed in cells infected with fowl, canary, and pigeonpox viruses and perhaps are made by all avian pox viruses.

Although pox viruses are assembled exclusively in the cytoplasm of infected cells, Gafford and Randall (34) found that the nucleus participates in the complexities of FPV replication, because viral RNA and DNA were detected in the nucleus of infected cells at 24–72 hours PI. Interestingly, an avian pox virus isolated from *Junco hyemalis* produced nuclear inclusions in addition to cytoplasmic inclusions (10). However, the intranuclear inclusions were devoid of viral particles.

Susceptibility to Chemical and Physical Agents

Resistance to ether treatment is listed as one of the taxonomic criterion for pox viruses (74). While some authors (84) stated that the virus was sensitive to both ether and chloroform, others (116) reported that a pigeon pox virus and two derived mutants were resistant to both chloroform and ether. FPV is known to withstand 1% phenol and 1:1000 formalin for 9 days but is inactivated by 1% caustic potash when freed from its matrix. Heating at 50°C for 30 minutes or 60°C for 8 minutes also inactivates the virus (3). Trypsin has no effect on the DNA or whole virus. When desiccated, the virus shows marked resistance. It can survive in dried scabs for months or even years.

Strain Classification

A nucleoprotein precipitinogen is common to all pox viruses (146). Avian pox viruses are antigenically and immunologically distinguishable from each other, but varying degrees of cross relationships do exist. Attempts have been made to differentiate strains by immunologic methods (e.g., complement-fixation, passive hemagglutination, agar gel precipitation, immunoperoxi-

dase, ELISA, virus neutralization, and immunofluorescence). Antigenic characterization of immunogenic proteins by immunoblotting (Fig. 10.1D) and genomic characterization by restriction fragment length polymorphism (RFLP) of DNA (Fig. 10.1E) have been useful to some extent in detecting minor differences among the strains tested (38, 77, 88, 101, 112). A monoclonal antibody against a unique antigen of FPV has been used to differentiate FPV strains (100,102). In recent years, FPVs have been isolated in all regions of the United States from previously vaccinated chicken flocks experiencing high mortality due to the diphtheritic form and/or cutaneous form of pox. Cross-protection studies revealed that some of these isolates have a limited immunologic relationship to strains of pox viruses used in commercial vaccines, indicating that currently available vaccines are not effective in providing adequate protective immunity against challenge with these "variant" pox viruses (31, 32, 101).

Polypeptides

Twenty-eight polypeptides were detected in purified FPV by Obijeski *et al*. (78). Likewise, Mockett *et al*. (67) observed about 30 structural polypeptides in FPV, most of which were immunogenic. Twenty-one FPV-coded polypeptides were resolved by ^{35}S methionine pulse labeling, and 57 major structural polypeptides were identified in purified FPV preparations (80). Several major and minor immunogenic polypeptides of FPV strains have been resolved by immunoblotting (77, 88, 100). Antigenic differences among the vaccine and field strains of FPV have been observed. Quail pox virus showed distinct antigenic differences from FPV based on immunoblotting, although some common proteins were also detected (38). A pox virus isolated from the spleen of a condor was genetically, antigenically, and biologically different from FPV (46). Antigenic profiles of avian pox viruses isolated from endangered Hawaiian forest birds also show differences from those of fowl pox virus (47, 48).

Genomic Differences in Avian pox Viruses

Like other pox viruses, the FPV genome is composed of a single linear double-stranded DNA molecule with a hairpin loop at each end. Although the overall genomic organization of FPV appears to be similar to that of other members of the Poxviridae family, some genomic rearrangement has occurred. The electrophoretic profiles of restriction enzyme-digested FPV and vaccinia virus DNAs are distinct (75,88). Although the DNAs of fowl, pigeon, and junco pox virus have similar genomic profiles, restriction endonuclease analysis profiles of quail, canary, and mynah pox virus DNAs reveal marked differences from those of FPV.

Two strains of avian pox viruses from endangered Hawaiian forest birds, 'alala pox isolated from Hawaiian crows (*Corvus hawaiiansis*) and apapane pox [isolated from an Apapane species (*Himatoine sanguinea*)] are genetically and biologically different from FPV (132). Similarly, avian pox virus strains isolated from endangered Hawaiian forest birds (palila and Hawaiian goose) are biologically different from fowl pox virus (48).

The FPV genome contains a central coding region and two identical, inverted terminal repeat (ITR) regions of 9,520 bp at both termini. The complete sequence of the genome of a vaccine-like strain of FPV has been determined. (1). It contains 288,539 bp, which is slightly smaller than some previous estimates and encodes for 260 putative genes of 60 to 1,949 amino acids in length. The genome of a tissue culture passaged FPV strain FP9 is approximately 260 kb in size (55). Based upon homologies with other viral or cellular genes, 101 open reading frames (ORFs) of FPV have been assigned similar or putative functions. The nucleotide composition of FPV is 69% A + T, which is uniformly distributed over the entire length of the genome. Six small regions with higher G + C content (50%) are located in the terminal genomic regions. Because of the presence of multiple and in some cases large gene families, the genome of FPV is larger than other completely sequenced pox virus genomes. In this regard, 32% of the FPV genome is composed of 31 genes in the ankyrin repeat family, 10 genes in the N1R/p28 family, and 6 genes in the B22R family. The B22R ORFs alone comprise 12% of the viral genome. Because fewer ankyrin genes were found in the genome of fowl pox virus after extensive passage in tissue culture, it is likely that in other avian pox viruses the number of ankyrin repeat genes may vary. As pox virus ankyrin repeat genes have been associated with host range functions, loss or disruption of many of these genes may be associated with the narrowing of host range (1). Interestingly, the genomes of field isolates causing outbreaks of fowl pox in vaccinated flocks contain an integrated, nearly intact provirus copy of reticuloendotheliosis virus (REV). In contrast, only a variable-length, REV long terminal repeat (LTR) remnants are present in the genome DNA of all FPV vaccine strains. These remnants are also retained, presumably after the loss of the REV provirus, by a minor proportion of each field strain population (35, 69, 104, 105, 113).

Although a ubiquitin gene has been identified and sequenced in the genome of an avian pox virus isolated from Hawaiian forest birds (92), only fragmented remains of this gene were observed in the FPV genome (1).

Analysis of the sequence of a 4.5 kb HindIII fragment of condorpox virus DNA with corresponding region of FPV genome showed differences. In FPV 11 ORFs are confined in this region including sequences related to REV integration. Condor pox virus, however, contains only 8 ORFs and does not have any REV sequences (46). Complete nucleotide sequence of canary pox virus has been determined (136). Nucleotide sequences of a 5.3 kb Pst-HindIII fragment of the genome of an avian pox virus from a Hawaiian goose (HGP) revealed very high homology with canarypox virus and homologs of three fowl pox virus ORFs including REV sequences were not present in its genome (47).

The complete nucleotide sequences of the genomes of other members of the avipox virus genus are not available at this time. However, based upon RFLP comparisons and nucleotide sequence analysis of selected genomic fragments, it is clear that genetically different strains of pox viruses infect domestic, pet, and wild birds. In this regard, the genomic profiles of canary pox, mynah pox, 'alala pox, apapane pox, condor pox, goose pox and quail pox viruses are markedly different from those of FPV (38, 46, 47, 88, 132). Moreover, the sequence analysis of the thymidine kinase (TK) gene of quail pox virus revealed only moderate homology to the corresponding FPV TK gene.

Nonessential and Immunomodulatory Genes

Based on the information available on vaccinia virus, it is clear that many of the genes of FPV may not be essential for virus replication in tissue culture, and some of them may be associated with immunomodulatory functions and may interfere with normal immune surveillance or host responses. The functions of the proteins encoded for by more than half of the genes of FPV are not known (1) and thus their role in virus replication is only speculative. Some putative genes and the probable functions of their encoded proteins are briefly described here: (a) A homologue of the eukaryotic transforming growth factor ß (TGFß), a multifunctional peptide that stimulates connective tissue growth and differentiation, is encoded by the genome of FPV. Because TGFß also exhibits a range of immunomodulatory effects, including suppression of cellular and humoral immune mechanisms, the FPV version may have a role in suppression of the host immune response and/or cell growth and differentiation. (b) Two ORFs encoding proteins similar to the cellular ß nerve growth factor (ß-NGF) have been identified in the FPV genome. These proteins may play some part in inhibiting antiviral immune responses in virus-infected cutaneous and respiratory tract infections. (c) Four ORFs of FPV show similarity to the CC class of small soluble chemokines. CC chemokines are known to attract T lymphocytes and NK cells to sites of infection. These CC chemokine homologues could function as antagonists and cause a broad-range inhibition of normal CC chemokine function during host antiviral immune responses. (d) Three genes encoding proteins homologous to G-protein-coupled receptors are present in the FPV genome. It is likely that the encoding proteins may bind to chemokines involving cell signaling that affect viral replication and pathogenesis in the host. (e) An ORF of FPV encodes a putative IL-18 binding protein. Because IL-18 homologues have been found to inhibit IL-18 dependent gamma interferon production, it may have an anti-inflammatory function during fowl pox virus infection. (f) An ORF of FPV with homology to semaphorins is likely to be associated with immunomodulatory function. (g) The FPV genome has eight ORFs that encode proteins similar to C-type lectins NKG2 and CD94 proteins present on NK cells and CD69 located on the surface of lymphocytes. C-type lectin cellular NK cell receptors bind class I major histocompatibility complex antigens and promote or inhibit immune activity through intracellular signaling pathways. It is likely that the expression of these proteins in FPV-infected cells interferes with normal immune surveillance or host responses. (h) Five homologues of serine proteinase inhibitors (serpins) encoded by FPV may be associated with host-range functions involving anti-inflammatory activity and/or regulation of cellular apoptosis in specific cells (1).

One of the characteristic features of avian pox virus infection is cellular hyperplasia of affected tissue. In this regard, a gene encoding a protein similar to epidermal growth factor (EGF) is present in the genome of FPV. Although this virus protein is not essential for virus replication, it may influence virulence, stimulate cell proliferation, and contribute to the hyperplasia observed in infected tissues. Further, a homologue of the T10 gene that encodes a protein expressed at high levels in epithelial cells in the trachea, esophagus, and lung of vertebrates is present in the genome of fowl pox. This T10 homologue may be required to extend the virus's host range to epithelial cells of the respiratory tract (1).

FPV DNA contains an ORF that encodes for a putative protein with similarity to the protein encoded by Marek's disease virus and fowl adenovirus indicating its role in avian host range function. Interestingly, a natural dual viral infection of trachea by FPV and herepesvirus has been reported previously (33). Because homologues of FPV open reading frames were detected in the genome of Marek's disease virus (17), the likelihood of exchange of genetic material from one virus to other and emergence of a different virus is possible. In this regard, integration of REV sequences in the FPV genome indicates "natural genetic engineering" in viruses. The FPV genome also contains a homologue of the glutathione peroxidase gene whose product may provide protection from oxidative stress, allowing efficient replication of virus under environmental conditions. Interaction of this enzyme and other proteins (e.g., photolyase) may have a synergistic effect on prolonging the survival of the virus in the poultry environment (1,107,109).

Hemagglutination (HA) activity has been detected in a few strains of pigeon pox virus (36,116) and in one strain of FPV (138). Although such HA activity is not present in most avian pox viruses, recently, the sequence of a putative HA gene has been identified in the genome of FPV (1). A similar nucleotide sequence is also present in the DNAs of other strains of FPV, but functional HA activity could not be demonstrated when using chicken red blood cells. The gene appears to be nonessential for virus replication in tissue culture, and its functional role is not known at this time.

Laboratory Host Systems

Birds

Avian pox viruses affect a wide range of birds of various families by naturally occurring or artificial infection. These viruses productively infect only avian species, indicating a significant degree of adaptation to the avian host. In this regard, a number of genes showing similarity to cellular genes have been found in the genome of FPV (1). Some of these (e.g., those encoding for TGb and b-NGF) may be involved in immune modulation.

A substantial degree of host specificity exists among some avian pox viruses, especially those that infect wild birds. A pox virus from a flicker (*Colaptes auratus*) (49) revealed strict host specificity when several species of wild and domestic birds were tested for susceptibility. Avian pox virus strains isolated from various species of thrushes (*Turdidae*) did not protect chickens against FPV (51). Differences in host susceptibility were also observed when a pox virus isolated from parrots was inoculated into susceptible parrots and chickens. Although it was more pathogenic for parrots than chickens, it did not provide protection against FPV. Further, vaccination of chickens with either fowl or pigeon pox virus vaccine did not provide protection against challenge with psittacine pox virus (12). A pox virus from a Canada goose (*Branta canadensis*) could be transmitted to domestic geese but not to chickens or domestic ducks (25).

Sparrows and canaries were highly susceptible to a pox virus isolated during an outbreak in sparrows but produced a mild, local cutaneous reaction in chickens, turkeys, and pigeons (39). Chickens and pigeons were found to be refractory to infection with an avian pox virus isolated from a buzzard (*Accipiter nisus*) (117). In an aviary housing more than 100 birds of a variety of species, only Rothchild's mynahs (*Leucospar rothchildii*) were infected with an avian pox virus. The virus, however, was pathogenic for starlings in the surrounding area but did not infect chickens. Mynahs and starlings are members of the family Sturnidae, and starling pox has been reported to be specific for birds in that family (56). Pox virus strains isolated from magpies (*Pica pica*) and great tits (*Parus major*) did not infect young chickens (42). Pox virus strains from various species of grouse immunized chickens against a FPV challenge (50). An isolate of pox virus from previously vaccinated turkeys was antigenically different from FPV (145). Pox virus isolated from cutaneous proliferative lesions of greater hill mynah (*Gracula religiosa*) imported from Malaysia produced severe necrotizing and proliferative lesions in chickens and bobwhite quail previously vaccinated with fowl, pigeon, or quail pox viruses (85, 86). In an outbreak of avian pox, canaries and house sparrows were affected, although 10 species of passerine birds were housed within the facility (27).

Avian pox virus infections have been considered to be important factors in limiting the population of Hawaiian forest birds. Three isolates of pox viruses from Hawaiian forest birds (alala and apapane species) produced mild lesions in chickens, and only two of them could be adapted to chicken cell lines. A comparison of their genomic profile by RFLP revealed that the two Hawaiian bird pox viruses appeared to be more related to each other than to FPV, indicating that genetically distinct pox viruses exist in Hawaiian forest birds (132). Two avian pox viruses from endangered Hawaiian forest birds (Hawaiian goose and Palila) produced only a localized lesion in susceptible chickens. The lesion persisted for a short duration and the birds were not protected against challenge with fowl pox virus (48)

Studies on the differentiation of fowl, canary, turkey, and pigeon pox viruses based on pathogenicity for chickens, turkeys, pigeons, ducks, and canaries (26, 37, 61) have been summarized. Canaries are highly susceptible to canary pox virus but show resistance to turkey, fowl, and pigeon pox viruses. Pigeon pox virus produces a mild infection in chickens and turkeys but is very pathogenic for pigeons. Susceptibility of ducks to turkey pox virus and not to FPV has been suggested for differentiation of these two closely related viruses.

Avian Embryos
Developing chicken embryos from a specific-pathogen-free supply (SPF) are commonly used for initial isolation and propagation of avian pox virus by inoculation of the CAM (93, 129, 130, 147). Ten–twelve day-old developing chicken embryos are appropriate for virus isolation. Duck and turkey embryos have been used, as well as embryos of other avian species. The inoculated embryos are incubated at 37°C for 5–7 days. Typically, infection of chicken embryo CAM results in compact, proliferative pock lesions that may be focal or diffuse (Fig. 10.2D). Quantitative assay of viral infectivity may be performed by using the embryo infective dose-50% (EID_{50}) method or by the "pock counting enumerative dose" response (139). Occasionally, isolates from wild birds fail to grow on the chorioallantoic membrane CAM of chicken embryos.

Cell Culture
Avian pox viruses can be propagated in cell cultures of avian origin (e.g., chicken embryo fibroblasts, chicken embryo dermis and kidney cells, and duck embryo fibroblasts). A permanent cell line "QT 35" (88) of Japanese quail origin as well as the chicken liver cell line LMH (44) will support growth of some avian pox viruses after adaptation. However, some isolates, especially from turkeys and wild birds, fail to grow in these cell lines even after repeated passages. While avian pox virus infections of mammalian cells are believed to be abortive, in a recent study (141) Syrian baby hamster kidney (BHK-21) cells were found permissive for three avian pox virus strains.

Cytopathic Effects
Characteristic CPE produced by the avian pox viruses in chicken embryo fibroblasts and QT 35 cells is characterized by an initial phase of rounding of the cells followed by a second phase of degeneration and necrosis. Quantitative assay is by the cell culture dose-50% method based on CPE (139).

Plaque Formation
Differences in the plaque-forming ability of avian pox viruses have been observed. Adaptation of the virus in cell culture is necessary, because not all strains produce plaques (71). Plaque formation in monolayers of chicken embryo fibroblast cell cultures by some avian pox viruses was shown to be characteristic and is considered as an aid in differentiation (61). Plaques are evident by 3–4 days PI in quail cells with certain avian pox viruses after adaptation (88).

Pathobiology and Epidemiology
Incidence and Distribution
Avian pox viruses infect birds of both sexes and all ages and breeds. The disease has been reported in more than 200 avian species (11). Fowlpox, in commercial poultry, is worldwide in distribution (79). The incidence, however, is variable. In high-density areas where multiple age birds are raised under confined conditions, the disease tends to persist for a long time despite preventive vaccinations. In recent years, several outbreaks of the diphtheritic form of fowl pox have been encountered in previously vaccinated chicken flocks.

Natural and Experimental Hosts
Fowl and turkey pox virus infections are economically important diseases in domestic poultry. Among companion birds, avian pox virus infections most often occur in blue-fronted Amazon parrots and in large aviaries of canaries where the disease is likely to be enzootic because of intimate contact. Canary pox and psittacine

pox are, therefore, of special significance for aviculturists, as the disease can result in high losses in a short time. Severe outbreaks of quail pox in pen-raised quails have been reported.

Because of convenience, reasonable cost, and ready availability, susceptible chickens of various ages are used widely as experimental hosts in biological characterization of avian pox virus isolates. Most of the pathogenesis studies, however, have been conducted with FPV. Pathogenesis of FPV infection, in chickens inoculated intradermally or intratracheally, was similar with only minor differences. In chickens infected intradermally, the virus was first detected in the skin at the inoculation site on day 2 and in lungs on day 4, followed by detectable viremia on day 5 PI. In chickens infected intratracheally, the virus was first detected in the lungs on day 2, followed by viremia on day 4 PI. The virus was recovered from the liver, spleen, kidney, and brain of birds of both groups (99). In chickens inoculated intravenously, miliary nodules were observed in the kidneys at 10–18 days PI in addition to cutaneous lesions and diphtheritic lesions on the mucous membrane of the upper respiratory tract. Characteristic microscopic changes including inclusion bodies were observed in the epithelial cells of renal tubules 4–14 days PI, and in the epithelial reticular cells of the thymic medulla 4–10 days PI (115).

Transmission

Pox virus infection occurs through mechanical transmission of the virus to the injured or lacerated skin. Individuals handling birds at the time of vaccination may carry the virus on their hands and clothing and may unknowingly deposit the virus in the eyes of susceptible birds. Insects also serve as mechanical vectors of the virus, resulting in ocular infection. The virus may reach the laryngeal region via the lacrimal duct to cause infection of the upper respiratory tract (30). In a contaminated environment, the aerosol generated by feathers and dried scabs containing pox virus particles provide suitable conditions for both cutaneous and respiratory infection. Cells of the mucosa of the upper respiratory tract and mouth appear to be highly susceptible to the virus as initiation of infection may occur in the absence of apparent trauma or injury. Detection of lesions only in the lungs in the absence of other afflicted areas is suggestive of aerosol infection (64). A homologue of T10, which is specifically expressed at high levels in epithelial cells of the respiratory tract, is encoded by a gene present in the genome of FPV. Its presence may be related to host-range function.

Mosquitoes can infect a number of different birds after a single feeding on a bird infected with avian pox virus. Eleven species of Diptera have been reported as vectors of avian pox virus (2). The mite, *Dermanyss gallinae,* has been implicated in the spread of FPV (96). Mechanical transmission of FPV from infected toms to turkey hens through artificial insemination has been reported (65).

In some flocks, the virus may persist for extended periods. This is common in large multiple age complexes. Kirmse (49) observed persistent cutaneous lesions of avian pox virus infection in a yellow-shafted flicker over a period of 13 months during which intracytoplasmic inclusions were demonstrable in the lesion. In an experimental study, Duran-Reynals and Bryan (28) showed that cutaneous treatment of chickens and pigeons with methylcholanthrene activated a latent FPV infection.

Incubation Period

Incubation period of the naturally occurring disease varies from about 4–10 days in chickens, turkeys, and pigeons and is about 4 days in canaries.

Clinical Signs

The disease may occur in one of the two forms, cutaneous or diphtheritic, or both. In addition, a systemic form of infection with high mortality is usually seen in canaries. The signs vary depending upon the susceptibility of the host, virulence of the virus, distribution of the lesions, and other complicating factors. The cutaneous form of the disease is characterized by the appearance of nodular lesions on the comb, wattle, eyelids, and other nonfeathered areas of the body (Fig. 10.2A, C). Cutaneous eye lesions will interfere with the bird's ability to reach food and water. In the diphtheritic form (wet pox), cankers or diphtheritic yellowish lesions (Fig. 102B) occur on the mucous membranes of the mouth, esophagus, or trachea with accompanying coryza-like mild or severe respiratory signs similar to those caused by infectious laryngotracheitis virus infection of the trachea. Lesions in the corner of the mouth, on the tongue, throat, and upper part of the trachea interfere with eating, drinking, and breathing. In pullets coming into lay and in older birds, the disease often runs a slow course accompanied by unthriftiness and reduced egg production.

Morbidity and Mortality

Morbidity rate of pox in chickens and turkeys varies from a few birds being infected to involvement of the entire flock if a virulent virus is present and no control measures are taken. Birds affected with the cutaneous form of the disease are more likely to recover than those with the diphtheritic form involving oral mucosa and the respiratory tract.

Effects of pox in chickens usually involve emaciation and poor weight gain; egg production is temporarily retarded if layers are infected. The course of the mild cutaneous form of disease is about 3–4 weeks, but if complications are present, duration may be considerably longer. With virulent strains of fowl pox virus, both primary and secondary cutaneous lesions may persist for more than 4 weeks. In such cases, cutaneous lesions around the eyes or diphtheritc lesions in the mouth and upper respiratory tract interfere with normal functions resulting in significant mortality.

In turkeys, the retardation of growth development of market birds is of greater financial importance than mortality. Blindness due to cutaneous eye lesions and starvation cause most of the losses. If pox occurs in breeding birds, decreased egg production and impaired fertility may result. In uncomplicated mild infections, the course of the disease in a flock may be 2–3 weeks. Severe outbreaks often last 6, 7, or even 8 weeks.

Flock mortality in chickens and turkeys is usually low, but in severe cases it may be high. In pigeons and psittacines, morbidity and mortality rates are similar to those in chickens. Pox in canaries can cause mortality as high as 80–100%. Significant mortality has been observed in quail infected with quail pox virus. Pox virus infections have been considered as a population limiting factor for Hawaiian forest birds.

Pathology

Gross

The characteristic lesion of the cutaneous form of pox in chickens is a local epithelial hyperplasia involving epidermis and underlying feather follicles, with formation of nodules that first appear as small white foci and then rapidly increase in size and become yellow. In chickens infected intradermally, a few primary lesions appear by the fourth day. Papules are formed by the fifth or sixth day. This is followed by the vesicular stage, with formation of extensive thick lesions (66). Adjoining lesions may coalesce and become rough and gray or dark brown. After about 2 weeks or sometimes sooner, lesions have areas of inflammation at the base and become hemorrhagic. Formation of a scab, which may last for another 1–2 weeks, ends with desquamation of the degenerated epithelial layer. If the scab is removed early in its development, there is a moist, seropurulent exudate underneath covering a hemorrhagic granulating surface. When the scab drops off naturally, a smooth scar may be present; in mild cases, there may be no noticeable scar. Attenuated vaccine viruses produce localized lesions, which are mild in comparison to the severe ones due to the pathogenic strains. The secondary lesions produced by pathogenic strains may persist for several weeks (124)

In the diphtheritic form, slightly elevated, white opaque nodules or yellowish patches develop on the mucous membranes of mouth, esophagus, tongue, or upper trachea. Nodules rapidly increase in size and often coalesce to become a yellow, cheesy, necrotic, pseudodiphtheritic, or diphtheritic membrane (Fig. 10.2B). If the membranes are removed, they leave bleeding erosions. The inflammatory process may extend into sinuses, particularly the infraorbital sinus (resulting in swelling) and also into the pharynx and larynx (resulting in respiratory disturbances) and esophagus. It is not uncommon to find cutaneous infection characterized by the development of lesions on the comb and wattles as well as diphtheritic lesions in the mouth and/or respiratory tract of the same bird. Often involvement of the eyes and eyelids may accompany the formation of lesions in other areas of skin as well as diphtheritic lesions.

Although in some cases, avian pox virus infection may be characterized by cutaneous, diphtheritic, systemic and oncogenic manifestations (135), in others the infection may be localized and characterized by the presence of small pale firm nodules in some internal organs (64). In a natural pox virus infection in Galapagos doves (*Nesopelia g. galapagoensis*) small (1–6 mm), pale firm nodules in the lungs were characterized by lobulated and nonlobulated nodular foci, located mainly in the airways, originating from primary and secondary bronchi. The etiologic agent, pox virus particles were detected by electron microscopy (64).

In a dead 3-month old fledging Andean condor no lesions were found on the entire skin. However, the oral cavity, esophagus and crop had multifocal raised yellow plaques. Most internal organs including heart lungs, liver, kidney, small intestine, pancreas and spleen had single to multiple soft white nodules ranging in size from 0.2 to 0.8 cm in diameter. Cytoplasmic inclusion bodies were observed on histopathological examination of tissues. Also, particles with distinct pox virus morphology were observed in

ultrathin sections of the oral cavity, spleen and liver when viewed by transmission electron microscopy (46).

The first indication of pox in turkeys is appearance of minute yellowish eruptions on the dewlap, snood, and other head parts. They are soft and easily removed in this pustular stage, leaving an inflamed area covered with a sticky serous exudate. The corners of the mouth, eyelids, and oral membranes are commonly affected. Lesions enlarge and become covered with a dry scab or a yellow-red or brown wartlike mass. In young poults, the head, legs, and feet may be completely covered with lesions. The disease may even spread to the feathered parts of the body. In an unusual outbreak of pox virus in breeding turkeys, proliferative lesions occurred in the oviduct, cloaca, and skin surrounding the vent (65).

Microscopic

The most important feature of infection (whether the lesion is cutaneous, diphtheritic, or from infected CAM) is hyperplasia of the epithelium and enlargement of cells, with associated inflammatory changes. Expression of an epidermal growth factor (EGF)-like domain present in the genome of FPV perhaps plays an important role in hyperplasia observed in FPV-infected tissues. Characteristic eosinophilic A-type cytoplasmic inclusion bodies (Bollinger bodies) are observable by light microscopy (Fig. 10.2E) in infected cells. Because pox viruses are the largest among viruses, the elementary bodies can be observed in smears prepared from the lesions and stained by the Gimenez method (126).

Histopathologic changes of tracheal mucosa include initial hypertrophy and hyperplasia of mucus-producing cells, with subsequent enlargement of epithelial cells that contain eosinophilic cytoplasmic inclusion bodies (Fig. 10.2E). These inclusion bodies appear green after staining with acridine orange, indicating DNA in the inclusions (Fig. 10.2F). Inclusion bodies may be present in various stages of development, depending on the time after infection and may occupy almost the entire cytoplasm, with resulting cell degeneration. Often, clusters of epithelial cells resembling a papilloma (114) may be observed.

Ultrastructural

Ultrastructural features of avian pox viruses are briefly described in the virus replication and diagnostic sections. Because of their large size, typical morphology, and characteristic ultrastructural details, diagnosis of avian pox viruses is relatively easy under electron microscopy by negative staining or in ultrathin sections (Fig. 10.1A, B, C).

Diagnosis

Diagnosis of avian pox virus infections is also described elsewhere (26, 127, 130, 133, 134).

Microscopy

Elementary bodies (Borrel bodies) of fowl pox virus can be detected in smears prepared from lesions, which are stained with Wright's stain or by the Gimenez method (126). Tissue sections from cutaneous or diphtheritic lesions may be processed by con-

ventional methods or by using a solution that fixes and dehydrates the tissues simultaneously (94) for detection of cytoplasmic inclusions (Fig. 10.2E). Various histochemical and histopathologic techniques have been described by Thompson and Hunt (121). Cutaneous lesions typical of avian pox (Fig. 10.2A, C) and diphtheritic lesions in upper respiratory and oral mucosa (Fig. 10.2B) must be confirmed by either histopathology (presence of cytoplasmic inclusions as shown in Fig 10.2E) or virus isolation.

Electron microscopy can be used for the demonstration of virus particles in lesions and exudate by negative staining or in ultrathin sections (Fig. 10.1A, B, C) of the infected tissues (22, 87). Type A inclusions with virions around the periphery or virus-filled inclusions may be observed during electron microscopic examination (Fig. 10.1C).

Isolation and Identification of Virus

Bird Inoculation
Avian pox viruses can be transmitted to susceptible birds by applying a suspension of the lesion material from infected birds to their scarified comb or denuded feather follicles of the thigh, or by the wing-web stick method. FPV can be transmitted readily from chicken to chicken, with typical cutaneous lesions developing in 5–7 days. In atypical cases, microscopy of lesion specimens, as well as bird inoculation, may be advisable.

Avian Embryo Inoculation
A suspension of a pox virus suspected specimen from a dermal or diphtheritic lesion is inoculated on the CAM of 9–12-day-old developing chicken embryos from a SPF flock; 5–7 days after inoculation, the CAM is examined for pock lesions (see Fig. 10.2D). Occasionally, some isolates fail to grow on the CAM of chicken embryos (25, 49).

Cell Culture
Cell cultures generally are not employed for initial isolation of avian pox viruses. Adaptation of the virus to this host system is sometimes necessary, because not all strains produce CPE on initial inoculation. For antigenic and genetic characterization of an isolate, propagation in cell culture is more convenient than the use of CAM.

Serology and Protection Tests
Actively acquired immunity against avian pox viruses results after recovery from naturally occurring infection or following vaccination. Both cell-mediated and humoral immunity following vaccination or naturally occurring infection provides protection (70, 125). Cell-mediated immunity develops earlier than the humoral antibody response. A lymphoproliferative response was observed following inoculation of chickens with fowl pox vius strains (103).

Immune responses against avian pox viruses can be determined by serological tests, such as ELISA, virus neutralization, or protection tests. Protection tests generally are used to determine immunogenicity of fowl and pigeon pox vaccines. For this purpose, at least 20 SPF chickens are vaccinated according to

manufacturer's directions. An additional 20 nonvaccinated and isolated birds of the same source and age are kept as controls. At 3 weeks after vaccination, vaccinated and control birds are challenged with a different strain of FPV capable of causing clinical signs of pox in the control birds. The challenge virus may be applied to the skin of denuded feather follicles of the thigh, to scarified comb, or by the wing-web method at a site opposite to that used for vaccination. The birds should be examined for takes (see Immunization). For satisfactory immunization, at least 90% of the controls should have lesions of fowlpox and at least 90% of the vaccinated birds should not.

Cross-protection tests for the antigenic relationship of the avian pox viruses generally are not practical for routine diagnosis but may be necessary for their biological characterization (16, 48, 86, 101, 144).

Immunodiffusion
Immunodiffusion has been used for the identification of fowl pox and pigeon pox viruses and also to differentiate antibody responses due to fowl pox and from those of other avian viral diseases (43, 137). Although the test is easy and simple to perform, its sensitivity is low and because of cross-reacting antigens differential diagnosis may not be easy. As precipitating antibodies are detectable for only a short duration after infection, serum must be collected at the appropriate time, usually within 15–20 days after onset of infection.

Passive Hemagglutination
A passive hemagglutination test will detect antibodies in the serum of FPV infected chickens earlier than the immunodiffusion test (122). Although this test is very sensitive, its use has been limited because it requires sheep or horse red blood cells for sensitization with soluble pox virus antigens. Further, differentiation of viruses is not possible because of cross-reacting antigens.

Neutralization
Virus neutralization in cell culture (72) or chicken embryos may be used; however, this procedure is not convenient as a routine diagnostic test.

Fluorescent Antibody, Immunoperoxidase, and Enzyme-Linked Immunosorbent Assay (ELISA)
Direct or indirect immunofluorescence or immunoperoxidase tests will reveal specific staining of intracytoplasmic inclusions in virus-infected cells. In the indirect test, first, the antibody against FPV is incubated with the antigen present in the infected cells and then the bound antibody is reacted with a secondary fluorescein-isothiocynate-labeled or peroxidase-labeled antibody against chicken gamma globulin (e.g., goat anti-chicken) (19, 123).

Currently, ELISA is the test of choice to determine humoral antibody responses. An antibody response is detectable in 7–10 days PI.

Immunoblotting
Immunogenic proteins of vaccine and field strains of fowl pox virus can be compared by immunoblotting. Although common

antigens are detected (Fig. 10.1D), strains can be differentiated to some extent by the presence of unique proteins of differing electrophoretic mobilities (38, 77, 88, 97). Recently, two monoclonal antibodies have been used to characterize field isolates and vaccine strains of FPV (100, 102).

Molecular Methods

Molecular techniques for diagnosis of pox virus infections have also been summarized elsewhere (134).

Restriction Endonuclease Analysis of Avian Pox virus DNA. Restriction fragment length polymorphism (RFLP) can be used for comparing the genomes of avian pox viruses by examination of the relative mobilities of restriction endonuclease generated fragments of their DNAs (24, 88, 112). The genetic profiles of FPV strains are similar, with a high proportion of comigrating fragments, although most strains could still be distinguished by the presence or absence of one or two DNA fragments (Fig. 10.1E). The characteristic electrophoretic profile of restriction endonuclease digested DNA has facilitated comparison of other members of the *Avipoxvirus* genus. In this regard, genomic profiles of fowl pox, quail, canary, and mynah pox viruses are distinct (91). Similarly, the Hawaiian bird pox viruses, 'alala pox and apapane pox, have genetic differences that distinguish each other as well as from FPV (46, 47, 132).

Genomic Fragments as Diagnostic Probes. Selected genomic fragments or oligonucleotides (89) designed from the published sequences of FPV have been used as probes in detecting FPV-specific DNA in the test samples. Crude DNA isolated from the skin or diphtheritic lesion is transferred to a solid surface (e.g., nitrocellulose membrane) and then hybridized with either a cloned fragment or an oligonucleotide, which has been radioactively labeled (usually with ^{32}P dCTP) or with a nonradioactive substance (e.g., digoxigenin). This procedure is sensitive and specific and can be used in mixed infections. For example, using virus-specific genomic probes, a dual fowl pox and infectious laryngotyracheitis virus infection was confirmed (33).

Polymerase Chain Reaction. Genomic FPV DNA sequences of various sizes can be amplified by polymerase chain reaction (PCR) using specific primers (45, 58, 59, 82, 106, 112). This technique is useful when an extremely small amount of virus is present in the sample. In case of mixed infections, fragments of different sizes can be amplified in a single PCR reaction using pathogen-specific primers. For example, the diphtheritic form of fowl pox and infectious laryngotracheitis produce similar clinical signs and tracheal lesions. Using virus-specific primers, either of these infections could be detected (52). Currently, PCR is being used to differentiate vaccine and field strains of FPV because the latter contain intact REV provirus, and the vaccine strains contain only REV LTR sequences (45, 101, 104, 112).

Differential Diagnosis

Because similar tracheal lesions in chickens can be produced by fowl pox and infectious laryngotracheitis virus, the diphtheritic form of fowl pox in chickens with associated respiratory signs must be differentiated from infectious laryngotracheitis. In the case of infectious laryngotracheitis, intranuclear inclusions are detected in the tracheal epithelium.

Lesions caused by pantothenic acid or biotin deficiency in young chicks (6) or by T-2 toxin (23, 151) could be mistaken for pox lesions. Similarly, diphtheritic pox lesions in doves and pigeons may be mistaken for lesions caused by *Trichomonas gallinae,* which are diagnosed by microscopic examination of smears or by culture.

Intervention Strategies

Management Procedures

Because of its genetic make-up and inherent stability, FPV can persist in scabs in the poultry environment and become a source of infection for the susceptible replacement young birds. The greater frequency of the disease is perhaps due to closer confinement of chickens, especially in multiple age large complexes. Such conditions provide opportunity for the transmission of the disease from bird to bird as well as through aerosol. Close confinement and unclean houses increase the opportunity for spreading the disease.

Immunization

Live virus vaccines are used for immunization of birds against pox. Vaccines of fowl pox and pigeon pox virus origin are routinely used for vaccination of chickens and turkeys in areas where the disease is endemic. These should contain a minimum concentration of 10^5 EID$_{50}$/ml (37, 143) to establish satisfactory takes for good immunity. Fowl pox and pigeon pox virus vaccines labeled "chick embryo origin" are prepared from infected CAM. FPV vaccine labeled "tissue culture origin" is prepared from infected chicken embryo fibroblast cultures.

The success of a vaccination program depends on the potency and purity of the vaccine and its application under conditions for which it is specifically intended. Vaccination essentially produces a mild form of the disease. Directions for use of vaccine as supplied by the producer should be followed explicitly. Vaccine should not be used in a flock affected with other diseases or in generally poor condition. All birds within a house should be vaccinated on the same day. Other susceptible birds on the premises should be isolated from those being vaccinated. If pox appears in a flock in an initial outbreak with only a few birds being affected, nonaffected birds should be vaccinated.

A vaccine vial should be opened immediately before use. Only one vial should be opened at a time, and the entire contents should be used within 2 hours. After vaccine is prepared, the vaccinator's hands should be washed thoroughly. Vaccine should contact the bird only at the site of immunization. Extreme precautions should be taken not to contaminate other parts of the bird, the premises, or miscellaneous equipment.

All contaminated vaccine equipment, unused vaccine, empty vials, etc., should be decontaminated, preferably by incineration. No prepared vaccine should be saved for later use.

Fowl Pox Vaccine

The "chick embryo origin" vaccine contains live FPV capable of producing serious disease in a flock if used improperly.

Fowl pox vaccine is commonly applied by the wing-web method to 4-week-old chickens and to pullets about 1–2 months before egg production is expected to start. It is also used to revaccinate chickens held for the second year of egg production. The vaccine is not to be used on hens while they are laying.

Attenuated FPV vaccines of cell culture origin can be used effectively on chicks as young as 1 day of age and have been used at times in combination with Marek's disease vaccine (29, 98).

Oral vaccination with an attenuated cell culture vaccine was reported to be effective in Germany by Mayr and Danner (63). Successful immunization required 10^6 to 10^8 TCID$_{50}$ depending upon the vaccine virus used. Comparative immunity of FPV vaccines by intramuscular, feather follicle, oral, and intranasal routes in chickens of different age groups was evaluated by Sharma and Sharma (95). They reported that oral vaccination did not provide protection over 50%, and the other methods provided 80–100% protection. Nagy *et al.* (76) demonstrated that 1-day-old chicks can be vaccinated effectively against fowlpox through drinking water when the vaccine contains a sufficiently high concentration of virus (10^6 cell culture infective dose$_{50}$ per ml).

Turkeys may be vaccinated by the wing-web method, but the virus may spread and infect the head region. The site of choice for vaccination is about midway on the thigh. Initially, turkeys are vaccinated when they are 2–3 months old, but those to be used as breeders should be revaccinated before production. Revaccination at 3–4-month intervals during the laying season might be of some advantage, depending on the level of risk. Fowlpox vaccine is not to be used on pigeons.

In recent years, several outbreaks of fowl pox have occurred in all regions of the United States in chickens that had been vaccinated with either fowl pox or pigeon pox virus vaccines, indicating their inability to provide adequate immunity (31, 32, 101). Often combined fowl pox and pigeon pox virus vaccines have been used in chicken flocks with variable results. In this regard, field isolates of FPV from vaccinated flocks show variable pathogenicity in chickens. Most of the field strains contain full-length REV in their genome. Experimental studies indicate that FPV containing integrated REV provirus induces profound, but selective immunosuppressive effects on infected chickens of younger age (140). A comparison *in vivo* of a field strain of FPV, its genetically modified progeny (in which all REV sequences were deleted) and a rescue mutant (in whose genome the REV provirus was inserted in its previous location) indicated that elimination of the provirus sequences correlated with reduced virulence (105)

Pigeon Pox Vaccine

Pigeon pox vaccine contains live, nonattenuated, naturally occurring virus from pigeons. If used improperly, the vaccine can cause a severe reaction in these birds. The virus is less pathogenic for chickens and turkeys.

Pigeon pox vaccine may be applied by the wing-web method and can be used on chickens of any age. It is generally applied to chickens at 4 weeks of age and about 1 month before egg production is expected to start. When birds younger than 4 weeks are vaccinated, they should be revaccinated before the start of production. Birds held for the second year of production should be revaccinated.

Turkeys can be vaccinated at any age by the wing-web or thigh stick methods. Day-old poults can be vaccinated if necessary, but it is better to wait until they are about 8 weeks old so that a better immune response is obtained. Revaccination may be necessary and advisable during the growing period. Turkeys retained as breeders should be revaccinated.

Pigeons can be vaccinated by the wing-web method. The vaccine can be applied by the feather follicle method, but this is not generally employed. Differences in the immunizing properties of pigeon pox vaccines have been observed (150).

Canary Pox Vaccine

A live chicken embryo-attenuated canary pox virus vaccine has been used effectively in canaries under experimental conditions (40). A modified live canary pox virus vaccine to be administered cutaneously by the wing-web method is currently available commercially in the United States. Vaccination of birds at weaning age is suggested, and booster vaccinations are recommended every 6–12 months and 4 weeks prior to laying or vector season.

Quail Pox Vaccine

A live vaccine of quailpox virus origin is available commercially. It does not appear to provide adequate protection against FPV infection (32,144).

Turkey Pox Vaccine

A live nonattenuated vaccine is commercially available for use in turkeys. The vaccine does not provide adequate protection against fowl, pigeon, or quail pox viruses (145).

Vaccine Takes

The flock should be examined about 7–10 days after vaccination for evidence of "takes." A "take" consists of swelling of the skin or a scab at the site where the vaccine was applied and is evidence of successful vaccination. Immunity will normally develop in 10–14 days after vaccination. If the vaccine is properly applied to susceptible birds, the majority of the birds should have takes. In large flocks, at least 10% of the birds should be examined for takes. The lack of a take could be the result of vaccine being applied to an immune bird, use of a vaccine of inadequate potency (after the expiration date or subjected to deleterious influences), or improper application.

Prophylactic Vaccination

Immunization against pox consists of vaccinating susceptible birds prior to the time the disease is likely to occur. Usually this is done during spring and summer in areas where the disease occurs in fall and winter. However, in large complexes containing multiple age birds and in tropical climates, where the disease may occur throughout the year, vaccination may be performed at any time when warranted without regard to the season.

Vaccination against FPV is indicated under three conditions: a) When a flock on the premises was infected the previous year, all young stock produced on the premises or introduced from other sources should receive fowl pox vaccine. b) If pox was present the previous year and pigeon pox vaccine was used, birds should be revaccinated with fowl pox vaccine, because immunity from pigeon pox vaccine is not of long duration. c) In areas where pox is prevalent, fowl pox vaccine should be used for protection against infection from neighboring flocks.

In ovo *Vaccination.* Recent success with *in ovo* administration of FPV vaccines to 18-day-old chicken embryos has provided encouraging results (7, 8). With increasing use of *in ovo* vaccination, the cost of vaccination and stresses associated with handling the birds will be reduced significantly.

Recombinant Fowl Pox Virus Vaccines
Potential of FPV as a Polyvalent Vaccine
The pox viruses have some unique features (e.g., cytoplasmic site of multiplication, large genome, and unique viral enzymes and transcription system), which allow the expression of a foreign gene in a faithful manner. Thus, a large variety of genes encoding antigenic proteins of specific pathogens have been inserted into the genome of fowl pox virus. The genome of FPV is large enough to accommodate a significant amount of foreign DNA without a corresponding reduction in virus infectivity. The physical and biologic characteristics of FPV endow it with several advantages for use as an expression vector. First, fowl pox virus vaccines have been used in commercial poultry for more than 70 years. The vaccine virus causes a mild, localized self-limiting infection. In addition, FPV has a narrow host range affecting only avian species. The virus can be propagated in primary cultures of chicken embryo fibroblasts, chicken-embryo kidney cells, or skin cells, and also in permanent cell lines such as the Japanese quail cell line, QT35. Finally, because of its large size, genes from more than one pathogen can be inserted into its genome in order to create a polyvalent vaccine.

In order to develop a live recombinant FPV, it is important to insert stably the foreign gene(s) of interest from a poultry pathogen into the FPV genome, express the gene(s) optimally, and still maintain the infectivity of the virus. Thus, the generation of a FPV expression vector requires a) a suitable nonessential region in the FPV genome for insertion of foreign genetic material so that virus replication is not disrupted, b) a foreign gene that encodes for a protective antigen of a poultry pathogen, c) a strong pox virus promoter that will optimally regulate the expression of the inserted foreign gene(s), d) a donor plasmid that incorporates these three features, and e) a method for the selection and/or detection of recombinant progeny virus.

Nonessential Region
Several nonessential regions, including some in the terminal inverted repeats, have been identified in the FPV genome (1). One such commonly used insertion site for foreign sequences in the FPV genome is the TK gene (14, 89). Because TK activity is not re-

quired for avian pox virus multiplication, the encoding gene provides a convenient site for the insertion of a foreign gene(s). In addition, insertional inactivation of the TK gene reduces the virulence of the recombinant fowl pox virus (9) as compared to the unaltered parental virus. Other nonessential genes (e.g., those encoding photolyase, ATI protein, and a homologue of hemagglutinin) appear to be additional potential sites for the insertion of foreign genes.

Regulatory Sequences (Promoters)
Strong pox virus promoters are necessary for the expression of the inserted foreign genes. Pox virus promoters are relatively conserved and, thus, are recognized by heterologous pox viruses (14, 15, 90, 128). Initially, therefore, vaccinia virus promoters were used in lieu of FPV transcription regulatory elements in creating recombinant fowl pox viruses. Although homologous FPV promoters have since been identified (53, 54, 81) and a synthetic, early-late transcriptional regulatory element has been utilized, two vaccinia virus promoters, the early-late P7.5 and the late P11, have been used for the construction of recombinant avian pox viruses. In this regard, sequence analysis of the FPV genome (1) indicates the presence of 56 early, 3 intermediate, and 55 late putative promoters. Recently, several homologous FPV promoters, including a bidirectional one, have been evaluated (108, 110). Because some of these promoters appear to be as strong as the vaccinia virus ones, it is believed that their availability will assist in the development of a new generation of polyvalent FPV-vectored vaccines.

Donor Plasmid for Generation of Recombinant Virus
To create a recombinant virus, a donor plasmid that directs the insertion of foreign DNA into the FPV genome must be constructed. In such a plasmid, contiguous FPV DNA sequences are interrupted by a foreign gene(s) regulated by pox virus promoter(s). Following introduction of this plasmid into fowl pox virus-infected cells, *in vivo* recombination occurs in the cytoplasm between the homologous sequences of the replicating FPV genome and those that flank the foreign genes in the plasmid DNA. This interaction results in the insertion of the foreign transcriptional unit into the FPV genome.

Procedure for Selection of Recombinant Viruses
Because more than 99% of the progeny virus from a transfection is of parental type, a method for the selection and/or identification of recombinant virus is required. The recombinant viruses usually are identified and/or screened based on the expression of a marker gene that is inserted adjacent to the other foreign gene. The *Escherichia coli lac*Z gene has been widely used for this purpose, and the recombinant viruses are identified based on their ability to express ß-galactosidase (*lac*Z gene product) by the inclusion of the enzyme's histochemical substrates, X-gal or Bluo-gal, in agarose overlays of infected cells (81, 90). Plaques arising from infection by recombinant viruses appear blue, due to hydrolysis of these compounds, against a background of colorless plaques generated by nonrecombinant viruses. Alternatively, recombinants carrying the *E. coli* xanthine phosphoribosyl transferase gene as a marker can be selected due to their resistance to mycophenolic

acid (15). The green fluorescent protein (GFP) marker (41) can also be used for screening. In addition, recombinant viruses have been identified by plaque hybridization using a DNA probe specific for the inserted foreign gene.

Recombinant FPV Vaccines

Using the molecular techniques described previously, recombinant fowl pox or pigeon pox virus vaccines capable of producing proteins from the genes of several poultry pathogens have been created. Some of these antigens include the hemagglutinin of avian influenza virus, the fusion protein and the hemagglutinin-neuraminidase of Newcastle disease virus, the glycoprotein B of Marek's disease virus, the viral protein (VP) 2 of infectious bursal disease virus, and the nucleoprotein of infectious bronchitis virus. In most cases, foreign genes of avian pathogens inserted into the genome of avian pox virus are expressed, and the resultant proteins induce the generation of specific immunity against the respective pathogen.

Currently, a live FPV vectored vaccine "Avian Influenza-Fowl pox Vaccine" containing a cDNA copy of the H5 hemagglutinin gene of avian influenza is available commercially. It is recommended for immunization of chickens of one day of age or older birds by subcutaneous injection. Vaccinated birds remain immune to fowl pox for 10 weeks and immune to avian influenza subtype H5 for 20 weeks after the initial vaccination. It has been used rather extensively in Mexico.

A live FPV vectored vaccine "Newcastle Disease-Fowl pox Vaccine" for subcutaneous or wing-web stab immunization of one-day-old chickens is also available commercially. Similarly, a recombinant FPV vaccine expressing genes of infectious laryngstrocheitis virus has also become available.

Avian Pox Viruses as Expression Vectors for Genes from Mammalian Pathogens

The natural host range of avian pox viruses is limited to avian species. However, these viruses can initiate an abortive infection *in vitro* in cell lines of nonavian origin. Although infectious progeny virus is not produced, foreign antigens are synthesized authentically, processed, and presented on the cell surface. In this regard, expression of the rabies virus glycoprotein in recombinant FPV and canary pox viruses (118,119,120) provided a great impetus toward the use of avian pox viruses for the development of vaccines for both man and animals. For example, a canary pox virus-vectored vaccine expressing rabies virus glycoprotein G is currently available commercially for use in cats. Similarly, a recombinant canary pox virus vaccine expressing antigens of West Nile virus has been licensed for equines.

Treatment

No specific treatment exists for birds infected with avian pox viruses.

Chapter 11
Reovirus Infections

Introduction

Richard C. Jones

Avian reoviruses are members of the Orthoreovirus genus in the family Reoviridae (5, 7). Members of the genus Orthoreovirus, family Reoviridae, share common physico-chemical properties and morphological characteristics (8). These include a double-stranded RNA (dsRNA) genome consisting of 10 segments packaged into a non-enveloped icosahedral double-capsid shell. The name "reovirus" derives from respiratory, enteric orphan, since they were first isolated from these sites in humans with initially, no apparent association with disease.

Orthoreoviruses can be classified based on distinct biological properties, most notably their host range and the unusual ability of certain members to induce cell-cell fusion, resulting in syncytia in cell culture. The Orthoreovirus genus consists of four species that separate into three distinct subgroups (15). The non-fusogenic mammalian orthoreovirus (MRV) species represents subgroup I. The fusogenic reoviruses separate into subgroup II, containing the avian reovirus (ARV)-type species and the Nelson Bay virus isolated from a flying fox, and subgroup III occupied by the baboon reovirus (BRV). Two syncytium-inducing isolates from snakes are defined as tentative species in the genus and form subgroup IV.

In addition to their fusogenic properties, avian reoviruses differ from mammalian reoviruses on the basis of their host pathogenicity and the lack of hemagglutinating ability (6). Avian reoviruses can be differentiated by antigenic configuration, pathotype, relative pathogenicity, growth in cell culture, sensitivity to trypsin, and host specificity (2, 3, 4, 5, 6, 10, 11, 12, 13, 14).

Although they are considered to be ubiquitous in commercial poultry and for the most part appear harmless, avian reoviruses have been isolated from a variety of tissues and organs in chickens affected by assorted disease conditions, including viral arthritis/tenosynovitis, stunting syndrome, respiratory disease, enteric disease, immunosuppression, and malabsorption syndrome (11, 12, 13, 14). They are frequently found in chickens that are clinically normal. The nature of the disease that occurs following reovirus infection is very much dependent upon host age, immune status, virus pathotype, and route of exposure. Interactions with other infectious agents have been documented (11, 13, 14) and may result in differences in both the nature and severity of reovirus-induced disease expression.

Reoviruses have also been associated with diseases in turkeys,

ducks and geese and infection has been detected in several wild species of birds and these are dealt with in a separate section later in this chapter.

In young meat-type chickens, economic losses related to reovirus infections are frequently associated with increased mortality, viral arthritis/tenosynovitis (3, 11), and a general lack of performance including diminished weight gains, poor feed conversions, uneven growth rates, and reduced marketability of affected birds due to downgrading at slaughter (1). Breeder flocks that develop viral arthritis just prior to the onset of or during egg production may in addition to lameness be characterized by increased mortality, decreased egg production, suboptimal hatchability/fertility, and vertical transmission of virus to progeny. All of these can contribute to increased costs for poultry producers.

The best defined and most readily diagnosed reovirus-associated disease in chickens is viral arthritis (11), sometimes refered to as tenosynovitis (9). The disease has been recognized in virtually all major poultry-producing areas worldwide mainly as a disease of heavy meat-type chickens, but also in light breeds. Other disease conditions associated with reovirus infections can sometimes be demonstrated experimentally or are inferred by isolation from clinical accessions. However, these conditions are often difficult to recognize and conclusively diagnose in the commercial setting. Furthermore, experimental reproduction of the clinical condition is often difficult or impossible, so the reovirus-disease association is frequently tenuous. Because of the clear association between virus and disease and differences in disease expression, viral arthritis will be described separately in this chapter from other reovirus-associated diseases in poultry and other species.

Viral Arthritis

Richard C. Jones

Introduction

Viral arthritis is an economically important disease of chickens that can be caused by different serotypes and pathotypes of avian reovirus (36, 46, 47, 55, 102, 105). The disease is considered to be most important in meat-type chickens but has from time to time been diagnosed in commercial layers (53, 116, 129). Although viral arthritis has been reported in turkeys (1, 2, 26, 83, 92, 119, 136, 149), experimental reproduction of joint lesions has not always been successful (1, 136).

The disease in chickens typically is controlled by vaccination with live attenuated and/or inactivated whole virus vaccines. Derivatives of the S1133 strain of reovirus are most commonly used as vaccines and have proven to be efficacious in most parts of the world. However, antigenically different reoviruses can break through vaccinal immunity. Autogenous vaccines can be used to provide protection against different serotypes (36, 109, 130). Turkeys and other avian species are not routinely vaccinated for viral arthritis.

Public Health Significance

No implications of public health significance have been reported.

History

In 1954, Fahey and Crawley (24) made what was later confirmed by Petek *et al.* (94) to be the initial isolation of avian reovirus from the respiratory tract of chickens with chronic respiratory disease. The Fahey-Crawley virus, when inoculated into susceptible chickens, produced a moderate respiratory disease, liver necrosis, and an inflammation of the tendons and synovial membranes.

Olson *et al.* in 1957 (91) described a naturally occurring synovitis in chickens from which they were able to isolate an agent insensitive to chlortetracycline and furazolidone and serologically unrelated to either *Mycoplasma gallisepticum* or *M. synoviae*. This agent, later named the "viral arthritis agent" by Olson and Kerr (87), eventually was identified as a reovirus by Walker *et al.* in 1972 (143). Dalton and Henry (15) used the term *tenosynovitis* (sometimes used synonymously with viral arthritis) to define the changes in the tendons and tendon sheaths associated with a condition they considered different from that caused by *M. synoviae*. This difference was substantiated by Olson and Solomon (89) when they reported tenosynovitis in commercially produced chickens that had been derived from *M. synoviae*-free broiler chickens. An isolate obtained from these birds had characteristics identical to those described for the "viral arthritis agent" and was shown to be antigenically similar to the Fahey-Crawley virus (90). Since the first reports of tenosynovitis in the United States and England, the disease has been described in many other countries. Several reviews document the incidence of reovirus-induced tenosynovitis (61, 99, 129).

Control of viral arthritis was greatly facilitated by recognition of the role of maternal antibodies in conferring protection to progeny (131, 135). Both viable and inactivated vaccines were subsequently developed to induce antibodies in breeder flocks for the protection of progeny from contact and transovarian transmission (131, 37, 138). The first commercially available live vaccines were developed by van der Heide *et al.* (133, 137) from the S1133 strain of avian reovirus. This same strain has been extensively used as an inactivated vaccine alone or in combination with other reovirus pathotypes.

Reoviruses that cause viral arthritis also have the potential to induce other pathological changes in chickens, particularly if introduced via the transovarian route or shortly after hatch (16, 48,

55, 78, 79, 101, 102). Disease conditions associated with some reoviruses that have arthrotropic characteristics include ruptured gastrocnemius tendons, pericarditis, myocarditis, hydroperi-cardium, uneven growth, and mortality (37, 53, 60, 101, 102, 124, 129).

Incidence and Distribution

Reovirus infections are prevalent worldwide in chickens, turkeys, and other avian species. Viral arthritis is observed primarily in meat-type chickens but can be found in lighter breeds (53, 116) and turkeys (1, 5, 26, 83, 92, 119, 136, 149). It should be recognized, however, that reoviruses are commonly found in the digestive and respiratory tracts of clinically normal chickens and turkeys (58, 94, 1119, 149) and have been identified as a vaccine contaminant. It is estimated that greater than 80% of reoviruses isolated from chickens are non-pathogenic (130). This fact has implications in relation to diagnosis of reovirus infections.

Etiology

Virus Morphology and Structure

Reoviruses replicate in the cytoplasm, are nonenveloped with an icosahedral symmetry and a double-shelled capsid. Intact virus particles have a diameter of approximately 75 nm and a density in cesium chloride of 1.36–1.37 g/mL (29, 113, 114, 122). Their genomic dsRNA segments can be divided, on the basis of electrophoretic mobility, into three size classes: large (L1–L3), medium (M1–M3) and small (S1–S4). They code for at least 11 primary translation products separated into λ, μ and σ classes (142, 118).

ARV proteins have been less well characterized than their MRV counterparts. Most of the reported studies have concentrated on chicken strains of reovirus and concern σ proteins and S class-encoded genes. S1 encodes predicted polypeptides of 10, 17 and 35kDa, respectively. The p10 protein was recently described to be a non-structural protein responsible for the fusogenic property of the virus (118). The second has been suggested to play a role in pathogenicity (117). The 3′-terminal ORF encodes the minor outer capsid component expressed and located at the vertices of the spikes, σC displays cell-binding activity and inducing type-specific neutralizing antibodies (110). S2 encodes the major core protein, σA, suggested to play a role in resistance of ARV to interferon (73). S3 encodes the major outer capsid protein σB which reacts with an anti-reovirus polyclonal serum and is one of the group-specific neutralization antigens (110). Finally, S4 encodes the small non-structural protein, σNS, which may play an important role in the earliest stages of particle assembly (8, 159).

Gene M1 encodes a minor core protein μA, gene M2 a major capsid protein, μB, and M3 μNS, a non-structural protein (85, 125). Proteins encoded by the L-class genes have received lesser attention.

Sequence analysis of selected S genes has led some authors to suggests that turkey and duck reoviruses should be ascribed to separate subgroups of avian reovirus from the chicken types (115), while the goose reovirus has similarities with the duck viruses (6).

Replication

The replication of avian reoviruses has been reviewed by Benavente and Martinez-Costas (9). Avian reoviruses enter cells by receptor-mediated endocytosis and acidification of virus-containing endosomes is necessary for the virus to uncoat and release transcriptionally active cores into the cytosol. They replicate within cytoplasmic inclusions of globular morphology, termed viral factories, which are not microtubule-associated, and which are formed by the nonstructural protein NS. This protein also mediates the association of some viral proteins (but not of others) with inclusions, suggesting that the recruitment of viral proteins into avian reovirus factories has specificity. Avian reovirus morphogenesis is a complex and temporally controlled process that takes place exclusively within viral factories of infected cells. Core assembly takes place within the first 30 min after the synthesis of their protein components, and fully formed cores are then coated by outer-capsid polypeptides over the next 30 min to generate mature infectious reovirions.

In the bird, replication of avian reoviruses has been described in various tissues but the chief targets appear to be the intestine (55), the tibiotarsal-tarsometatarsal (hock) joint (53) and the liver (62, 35).

Biophysical Factors

Reoviruses are heat resistant, being able to withstand 60°C for 8–10 hours, 56°C for 22–24 hours, 37°C for 15–16 weeks, 22°C for 48–51 weeks, 4°C for more than 3 years, −20°C for more than 4 years, and −63°C for more than 10 years (74). The titer of semipurified virus at 60°C is reduced, but not completely inactivated, in 5 hours. Heat treatment in the presence of magnesium chloride results in increased titers. The ability of avian reoviruses to survive on or in materials associated with the poultry house has been studied by Savage and Jones (112). They found that reoviruses survived for at least 10 days on feathers, wood shavings, egg shells and in feed but in drinking water virus was detectable for at least 10 weeks with little loss of infectivity.

Reoviruses are not sensitive to ether but are slightly sensitive to chloroform. They are resistant to pH 3; hydrogen peroxide when incubated for 1 hour at room temperature; 2% lysol; 3% formalin; and the DNA metabolic inhibitors actinomycin D, cytosine arabinoside, and 5-fluoro-2-deoxyuridine. They are inactivated by 70% ethanol, 0.5% organic iodine and a 5% solution of hydrogen peroxide (82). Sensitivity of avian reovirus to trypsin varies but is not related to antigenic configuration nor species of origin (47). The significance of trypsin sensitivity to relative pathogencity is unclear, but reoviruses sensitive to trypsin replicate poorly in the intestine following oral exposure and are not readily disseminated to other tissues sites (47, 81). Interestingly, S1133 derived vaccine viruses are inactived by trypsin treatment.

Avian reoviruses induce cell fusion, which differentiates them phylogenetically from most other animal reoviruses (18). Syncytia formation in cell culture increases the rate of reovirus

associated cytopathicity and virus released from infected cells but is not essential for either activity (19).

Despite two early reports to the contrary (19, 20), it is generally accepted that avian reoviruses, unlike their mammalian counterparts, do not demonstrate hemagglutination.

Strain Classification

Reoviruses can be classified using serologic procedures or grouped according to their relative pathogenicity for chickens. Kawamura and Tsubahara and Kawamura *et al.* (57, 58) identified five serotypes of reovirus from 77 isolates originally obtained from feces, cloacal swabs, and tracheas. Sahu and Olson (108) found four serotypes from intestines, respiratory tract, and synovial isolates. Wood *et al.* (147) calculated the relatedness of reoviruses originating from the United States, the United Kingdom, Germany, and Japan and found at least 11 serotypes, although there was considerable cross neutralization among heterologous types. Hieronymus *et al.* (37) grouped five reovirus isolates into three serotypes, and Robertson and Wilcox (98) assigned 10 Australian isolates into three groups with considerable cross-reactivity. It is apparent that reoviruses may frequently exist as antigenic subtypes, rather than distinct serotypes and reassortment can occur (98).

Rosenberger *et al.* (104) and Sterner *et al.* (124) inoculated specific-pathogen-free chickens by various routes with plaque-purified, antigenically similar viruses and demonstrated clear strain differences based on relative pathogenicity and virus persistence.

Laboratory Host Systems

Reoviruses grow readily in the embryonating chicken egg following inoculation via yolk sac or chorioallantoic membrane (CAM). The yolk sac is preferred for original isolation and generally results in embryo mortality 3–5 days after inoculation, with affected embryos exhibiting a purplish discoloration due to massive subcutaneous hemorrhage. Mortality in CAM-inoculated embryos usually occurs on day 7–8 PI; embryos are slightly dwarfed with occasional enlargement of the liver and spleen. Necrotic foci may occur in both the liver and spleen, particularly in embryos that survive longer than 7 days PI. Small, discrete, slightly raised white lesions may be found on the CAM. Histologically, areas of necrosis of the ectoderm with only moderate stimulation of the epithelial cells are seen. Mesoderm adjacent to the lesion is edematous and contains numerous inflammatory cells. Edema alone may be found. Embryo mortality is less consistent following inoculation via the chorioallantoic sac.

The virus grows in primary chicken cell cultures of embryo, lung, kidney, liver, macrophages, and testicle. Primary chicken kidney cells from 2–6-week-old chickens are satisfactory, but for plaques and isolation, primary embryo liver cells are preferred (30, 32). Chicken embryo fibroblasts are suitable for reovirus growth, but the virus often requires adaptation (7, 32, 54). Chicken-origin cell cultures infected with reoviruses are characterized by the formation of syncytia, which may occur as early as 24–48 hours, followed by degeneration, leaving holes in the monolayer and giant cells floating in the medium. Infected cells exhibit intracytoplasmic inclusions that may appear either eosinophilic or basophilic (99). Of many established cell lines tested, virus has been grown successfully, usually after adaptation, on Vero (108), BHK 21/13, 1TT, feline kidney (CRFK), Georgia bovine kidney (GBK), rabbit kidney (RK), porcine kidney (PK) (7), a Japanese quail cell line (QT35) derived from an induced fibrosarcoma (14), chicken lymphoblastoid cells (117), and subpopulations of chicken lymphocytes (80).

Pathogenicity

Although normally associated with arthritis, reoviruses have been strongly associated with other disease conditions in chickens as well, including growth retardation, pericarditis, myocarditis, hydropericardium, enteritis, hepatitis, bursal and thymic atrophy, osteoporosis and acute and chronic respiratory syndromes (24, 26, 47, 60, 83, 84, 101 124, 136). The pathogenicity of selected reovirus isolates was shown to be enhanced by coinfection with *Eimeria tenella* or *E. maxima* (106, 107). Exposure to infectious bursal disease virus or particular dietary regimes increased the severity of tenosynovitis resulting from infections with the WVU-2937 isolate (12, 13, 123). Reoviruses may also exacerbate disease conditions caused by other pathogens including chicken anemia virus (23, 76), *Escherichia coli,* and common respiratory viruses (97, 105). The increased susceptibility to other infectious agents following or concomitant with reovirus exposure may result from immune system compromise (97, 101, 105, 106, 107).

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Although reoviruses have been found in many avian species, chickens are the only recognized natural or experimental hosts for reovirus-induced arthritis. The situation with turkeys is unclear. Reoviruses have been isolated from turkeys with arthritis (92), and Van der Heide *et al.* (136) found a turkey isolate to be pathogenic for chickens. The turkey isolate was neutralized by chicken reovirus S1133 antiserum. High mortality in turkey poults has also been associated with reovirus (119), although turkeys were shown by Al-Afaleq *et al.* (1) to be more resistant than chickens to reovirus-induced tenosynovitis. McFerran *et al.* (75) identified a reovirus in turkey feces that shared the group-specific antigen with chicken isolates but was not neutralized by available reference antiserum.

Reoviruses have been found in clinically affected ducks, pigeons, geese, American woodcock, and psittacine species, but a firm etiologic relationship was not always established (17, 75, 111). A disease in Muscovy ducks characterized by a general malaise, diarrhea, and stunted growth has been reported in several countries (25, 56, 71) and reproduced experimentally with isolated reoviruses (25, 71). Attempts to establish active infection in the canary, pigeon, guinea pig, rat, mouse, hamster, and rabbit failed; however, Phillips *et al.* (95) reported liver lesions in neonatal mice after oral and nasal infection, and Nersessian *et al.* (83) produced stunted growth and incoordination in suckling mice inoculated intracerebrally with several turkey isolates. Al-Afaleq *et al.* (3) showed that arthrotropic reovirus R2 caused

nervous signs and oiliness of the coat in mice, resembling the effect of mammalian reoviruses. Reoviruses in other avian species are discussed further in the second part of this chapter.

Age-Associated Resistance

Kerr and Olson (59) were the first to report an age-related resistance to reovirus-induced arthritis. The disease can be readily reproduced in 1-day-old chickens free of maternal antibody (48, 135), whereas older chickens are infected, but the disease is generally less severe, and the incubation period is longer. Similar results were reported by Rosenberger (104) with reoviruses isolated from birds with an apparent stunting syndrome and arthritis. Jones and Georgiou (48) suggested the age-associated susceptibility may be related to the inability of young birds to develop an effective immune response.

Transmission

Horizontal transmission of reovirus has been extensively documented (99, 129). There is considerable variation, however, among strains of virus in their ability to spread laterally. Although reovirus may be excreted from both the intestinal and respiratory tracts for at least 10 days postinoculation, virus generally appears to be shed from the intestine for longer periods, suggesting fecal contamination as a primary source of contact infection (53, 70). Roessler et al. (101) demonstrated that 1-day-old chickens are more susceptible to reovirus introduced via the respiratory route than orally. Virus may persist for long periods in the cecal tonsils and hock joints, particularly in birds infected at a young age (51, 72), implicating carrier birds as potential sources of infection for contacts.

Menendez et al. (78), Van der Heide and Kalbac (132) and Al-Mufarrej et al. (4) have clearly demonstrated that avian reoviruses can be vertically transmitted. Menendez et al. (78) showed that following oral, tracheal, and nasal inoculation of 15-month-old breeders, virus was present in chicks from eggs laid 17, 18, and 19 days postinfection. Reoviruses were also isolated from chicken embryo fibroblast cell cultures prepared from embryonated eggs derived from experimentally infected hens (102). Al-Mufarrej et al. (4) reported that virus-infected eggs were laid by virus-infected SPF hens between 5 and 17 days post infection and virus was isolated from the liver, intestine and hock joints of hatched chicks. Despite this, virus was never isolated from cloacal swabs taken from the hens. All reports suggest that the rate of egg transmission is low.

The possibility of avian reoviruses entering through broken skin in the foot and localizing in the hock joint was demonstrated using a trypsin-sensitive strain (2).

Incubation Period

The incubation period differs depending upon the virus pathotype, age of host, and route of exposure (99, 129). For inoculated 2-week-old chickens, the incubation period varied from 1 day (foot pad inoculation) to 11 days (intramuscular, intravenous, intrasinus inoculation). The incubation period following intratracheal inoculation and contact exposure was 9 and 13 days, respectively (89).

Often, infections are inapparent and demonstrable only by serology or virus isolations. Mature birds inoculated by oral and respiratory routes with the FDO isolate had virus in all organs tested at 4 days postinfection. The number of virus isolations was greatly reduced by 2 weeks, and no virus was present 20 days postinfection. There was frequent localization of virus in the flexor and extensor tendons of the pelvic limb, although gross lesions were not evident (79). Foot pad inoculation of 1-day-old chickens with an arthrotropic reovirus (R2) produced a more rapid progression of disease than either the oral, subcutaneous, or articular routes (43). When infected by the oral route, which appears to be a likely mode of naturally transmitted virus, the initial site of viral replication, which occurred within 2 to 12 hours postexposure, was the epithelium of the intestine and the bursa of Fabricius. This was followed by virus distribution in a wide range of tissues, including the hock joint, within 24–48 hours (55). Many reoviruses cause microscopic inflammatory changes in the digital flexor and metatarsal extensor tendons without development of gross lesions (88).

Chicks are most susceptible to reovirus infection when they are very young and the development of joint lesions is a slow process. When viral arthritis does result from naturally occurring infection, it is usually not seen in young birds before 4–7 weeks old but may be seen in much older chickens as well (129). In view of the increased resistance with age, the development of lesions at maturity is difficult to explain, unless persistent virus is reactivated by the stress of sexual activity. Morbidity can be as high as 100%, and mortality is generally less than 6%. The virus can persist in the tendons for at least 22 weeks (102).

Clinical Signs

In acute infections, lameness is present, and some chickens are stunted. With chronic infection, lameness is more pronounced, and in a small percentage of infected chickens, one or both hock joints are immobilized, preventing mobility. In a flock of 36,000 broilers, the infection, first diagnosed as infectious synovitis, appeared in 8 of 16 pens when the chicks were 3–4 weeks old. Approximately 550 birds died or were removed because of lameness by 7–8 weeks. Another 4,500 birds were stunted.

In another flock of approximately 15,000 broilers, no clinical signs of viral arthritis/tenosynovitis were observed, but approximately 5% of the birds had enlargement in the area of the gastrocnemius or digital flexor tendons when observed at slaughter. At 9 weeks, birds from this flock had an average weight of only 3.66 lb; feed conversion was 2.45; mortality totaled 5%; and the condemnation rate was 2.6%. Virus was isolated from two birds condemned for toxemia; of 80 serum samples obtained from this flock, 89% had reovirus antibodies detected in a precipitin test. This inapparent infection probably caused the poor performance of these broilers.

Similar observations have been made by other workers (229, 45). Rupture of the gastrocnemius tendon, especially in male roaster birds 12–16 weeks old, is often associated with reovirus infection (45, 54). A similar lesion has been seen in 5–8-week-old turkeys (92). The typical uneven gait in bilateral rupture of the tendon results from the inability of the bird to immobilize the

metatarsus. The latter is often accompanied by ruptured blood vessels.

Gross Lesions

Gross lesions in naturally infected chickens are observed as swellings of the gastrocnemius, digital flexor and metatarsal extensor tendons. The first lesion is evident by palpation just above the hock and may be readily observed when feathers are removed (Fig. 11.1). The affected joints usually feels warm. If the gastroc-

11.1. An 8-week-old broiler showing marked swelling of digital flexor and metatarsal extensor tendons. Diagnosis frequently can be made on the basis of the bilateral swelling of these tendons.

11.2. Marked edema of digital flexor tendon sheaths (left); normal (right).

nemius tendon is ruptured, this can often be perceived as a greenish discoloration of the skin due to extravasation of blood. Removal of the skin will reveal the broken end of the tendon (51).

Swellings of the foot pad and hock joint are less frequent. The hock usually contains a small amount of straw-colored or blood-tinted exudate; in a few cases, there is a considerable amount of purulent exudate resembling that seen with infectious synovitis. Early in the infection, there is marked edema of the tarsal and metatarsal tendon sheaths (Fig. 11.2). Petechial hemorrhages are frequent in the synovial membranes above the hock (Fig. 11.3A).

Inflammation of tendon areas progresses to a chronic-type lesion characterized by hardening and fusion of tendon sheaths. Small pitted erosions develop in the articular cartilage of the distal tibiotarsus. These erosions enlarge, coalesce, and extend into underlying bone (Fig. 11.3B,C). An overgrowth of fibrocartilaginous pannus develops on the articular surface. Condyles and epicondyles are frequently involved (60). In inoculated chickens, the diaphysis of the proximal metatarsal of the affected limb is enlarged.

Histopathology

Histologic changes have been described by Kerr and Olson (59). In general, they are the same for naturally occurring and experi-

A

11.3. Viral arthritis lesions in distal posterior tibia of inoculated chickens. A. Normal.

mental infections. During the acute phase (7–15 days following foot pad inoculation), edema, coagulation necrosis, heterophil accumulation, and perivascular infiltration are seen. There also are hypertrophy and hyperplasia of synovial cells, infiltration of lymphocytes and macrophages, and a proliferation of reticular cells. These latter lesions cause parietal and visceral layers of the tendon sheaths to become markedly thickened. The synovial cavity is filled with heterophils, macrophages, and sloughed synovial cells. Periostitis characterized by increased osteoclasts develops. During the chronic phase (starting by 15 days postinfection), the synovial membrane develops villous processes, and lymphoid nodules are seen. After 30 days, inflammatory changes become more chronic. An increase in the amount of fibrous connective tissue occurs, and a pronounced infiltration or proliferation of reticular cells, lymphocytes, macrophages, and plasma cells also can be seen.

The same general inflammatory changes develop in the tarsometatarsal and hock joint areas. Development of sesamoid bones in the tendon of the affected limb is inhibited. Some tendons are replaced completely by irregular granulation tissue, and large villi form on the synovial membrane.

At 54 days postinfection, orally infected birds showed chronic fibrosis of tendon sheaths, with fibrous tissues invading tendons and resulting in ankylosis and immobility (134).

Linear growth of cartilage cells in the proximal tarsometatarsal bone becomes narrow and irregular. Erosions on the hock joint cartilage are accompanied by a granulation pannus. Osteoblasts become active and lay down a thickened layer of bone beneath the erosion. Osteoblastic activity is present on the condyles, epicondyles, and accessory tibia, producing osteoneogenesis and subsequent exostosis (60). Ultrastructurally, the gastrocnemius tendon and sheath in broilers infected with reovirus at 1 day of age by the oral route were characterized by degenerative changes in fibroblasts including cytoplasmic vacuolization, membrane disruption, loss of ribosomes from the endoplasmic reticulum, and generalized mitochondrial and cellular disruption (39).

Lesions found in the heart have been described in detail (60, 89). An infiltration of heterophils between myocardial fibers is a constant finding. In some cases, it is accompanied by proliferating mononuclear cells, probably reticular cells. However, it is not clear whether this is pathognomonic of reovirus infection. The pathogenicity of avian reoviruses for day-old chicks revealed the arthrogenic potential for many strains and marked hepatic necrosis (32). Erythrocyte, hematocrit, and total leukocyte determinations are generally within the normal range, although there may be a rise in the heterophil percentage and a decrease in the lymphocyte percentage.

Immunity

In the relatively few reports on the mechanisms of immunity to avian reoviruses, both joint and enteric effects have been studied.

Humoral Antibodies

Avian reoviruses possess a group-specific antigen discernable with gel diffusion techniques (146) and a serotype-specific antigen demonstrable with neutralizing antibody in plaque-reduction or chicken embryo assays (99, 129). Neutralizing antibodies can be detected 7–10 days following infection, and precipitating antibodies at approximately 2 weeks. Neutralizing antibody appears to persist longer than precipitating antibody, but this may be a reflection of assay sensitivity. The importance of antibody in establishing protection is not well understood, because birds may become persistently infected in the presence of high levels of circulating antibody (52). It is clear however, that maternal antibody can afford a degree of protection to 1-day-old chickens against naturally occurring and experimental challenges (133, 135). Relative protection afforded by antibody appears to be related to serotype homogeneity, virus virulence, host age, and antibody titer (96, 104, 126, 135, 144).

Local Antibodies

Induction of intestinal virus-specific IgA, which may be important in limiting the pathogenic potential and dissemination of reovirus, is affected by route of exposure, age, and sensitivity to trypsin (81). Chickens infected at one day of age or with trypsin-sensitive reovirus by the oral route do not have a detectable intestinal IgA response.

Cell-Mediated Immunity

In an early report on cell-mediated immunity, Kibenge *et al.* (62) using immunosuppression by bursectomy and/or thymectomy of chicks showed that recovery from reovirus infection involves both B- and T- cell systems but that protection is predominantly B-cell mediated. In birds treated with both, virus infection appeared more persistent. Hill *et al.* (38) reported that the suppression of T-cell-mediated immunity by cyclosporin A resulted in increased mortality in reovirus-infected birds, but the relative severity of tendon lesions was unaffected.

In a study of the enteric activity of several strains of reovirus, Songserm *et al.* (121) showed that CD8+ T-cells may play a major role in the pathogenesis and/or reovirus clearance in the small intestine. van Loon *et al.* (139) showed that in B-cell immunosup-

pressed chicks, challenge virus is controlled in the absence of actively produced antibodies, and is independent of B lymphocytes. This suggests that cellular immunity is sufficient for protection of broilers with maternal antibodies against reovirus infection following early age vaccination with live reoviral vaccine.

Pertile *et al.* (93) used monoclonal antibodies specific for B and T lymphocytes to study the development of reovirus arthritis. T-cells and plasma cells were the predominant inflammatory cells in the synovium. In the acute phase, T-cell, mostly CD8$^+$ were present in low numbers. Most activity was in the subacute phase with increased numbers of CD4$^+$ and CD8$^+$. Aggregates of cells, IgM-positive B-cells and plasma cells were also present. The chronic stage was characterized by large numbers of predominantly CD4$^+$ cells. These changes were considered similar to those seen in rheumatoid arthritis in humans. These results indicated that a potential consequence of macrophage priming following virus infection is the protection of cells against virus-induced replication and cytopathic effects, and this protection may be mediated by the cytostatic effects of nitrous oxide on the host cell. Further studies on spleen cells from reovirus infected birds indicated that reovirus infection in chickens does not compromise the functional capabilities of T-cells but induces suppressor macrophages that inhibit T-cell functions (Pertile *et al.* (93). Supporting evidence for the rheumatoid arthritis comparison was provided by the detection of anti-nuclear and anti-collagen antibodies in some reovirus-infected birds (44).

Interferon production by avian reoviruses has been demonstrated *in vitro* and *in vivo*. The S1133 attenuated strain induced interferon in chick embryo cell cultures, and *in vivo* interferon was detected in the lungs but not in other tissues (21, 22, 145). A more pathogenic reovirus elicited the production of interferon detectable in serum samples (21, 22).

Diagnosis

A presumptive diagnosis of viral arthritis may be made on the basis of signs and lesions. However, the signs of viral arthritis are not pathognomonic and some joint lesions may resemble those caused by *Mycoplasma synoviae,* staphylococci or other bacteria. Involvement of primarily the metatarsal extensor and digital flexor tendons (see Fig. 11.2), and heterophil infiltration in the heart, assist in differentiating reovirus infection from similar disease caused by these other agents. However, demonstration of virus in clinical material is required to confirm the cause. Hitherto, this has meant virus isolation, but more recently, more rapid molecular methods and especially the polymerase chain reaction have been developed.

Detection of Virus

Virus Isolation

Avian reoviruses are normally among the easiest of viruses to grow, so it is often tempting to consider them as the cause of a clinical condition, when they may actually play little or no part in it.

It is recommended that for isolation from the joints, tissue samples are more likely to yield virus than swabs (49). Pieces of

hypotarsal sesamoid bone with the tendons that pass through it, synovial membrane and articular cartilage are the tissues of choice. Joint material should be taken from apparently normal birds in addition to those that are affected, since the number of clinically affected birds in a flock at any one time may be relatively small. Also, virus isolation from joints in advanced stages of degeneration may be impossible. It should be remembered that since avian reoviruses are ubiquitous and for the most part, harmless, isolation of virus from the intestine is likely to be meaningless in interpreting the cause of joint lesions. Specimens should be sent to the laboratory in transport medium even though the virus is relatively resistant. If a delay occurs, specimens can be stored at 4°C temporarily or for longer periods at –20°C or below.

Virus isolation is best achieved from hock joint tissue using chick embryos after 5–7 days of incubation inoculated via the yolk sac, or chicken embryo liver cells (32, 99, 129). Reoviruses typically kill the embryos within 5–6 days and in cell cultures, syncytium formation on the cell sheet is the typical effect. More than one passage in eggs or cell cultures may be needed.

Reoviruses can be readily differentiated from other viruses by their typical physicochemical characteristics and the presence of a group-specific antigen demonstrable with the agar gel precipitin test. For preparation of the antigen, 9–11-day-old embryonating chicken eggs are inoculated by the CAM route, and CAMs are harvested from dead or affected embryos within 7 days postinoculation. The CAMs then are homogenized and used as antigen (90). The precipitin test can be used to identify isolates as reovirus if known positive antiserum is available, or it can be used as an indication of antibody status in affected flocks. Isolated virus can also be identified by its typical 70–80nm diameter double-shelled morphology under the electron microscope, or by immunofluorescence staining of infected cell sheets.

Molecular Methods

Molecular approaches to identification of avian reoviruses in infected tissues have been described by several authors and are now being used in some diagnostic laboratories. These include dot-blot hybridization (66, 151) and, more commonly, reverse transcriptase-polymerase chain reaction (RT-PCR) (63, 67). Liu *et al.* (69) contended that RT-PCR followed by restriction enzyme fragment length polymorphism (RFLP) provides a simple and rapid approach for characterization of ARV isolates. Also, it is possible to determine whether a new variant strain has been introduced into a flock or a given virus strain has spread from one flock to another. Caterina *et al.* (11) developed a multiplex PCR for reovirus, adenovirus, infectious bursal disease virus and chicken anaemia virus. RT-PCRs have also been found useful for screening poultry vaccines for extraneous avian reoviruses in the quality control of biologicals used in veterinary medicine (10).

Undoubtedly the molecular methods and especially RT-PCR are rapid and combined with RFLP, enable molecular epidemiology to be investigated. However, for the routine examination of field material, it is important that their sensitivity is compared critically with that of virus isolation, which can still be considered as the "gold standard" for diagnosis of avian reoviruses. It should also be remembered that RT-PCR diagnosis does not pro-

vide the live virus, so isolation needs to be done if a new isolate is to be investigated further.

Location of Virus in Tissues

Lesion-associated reovirus proteins or nucleic acid can be detected in formalin-fixed tissue using immunoperoxidase procedures (127). Demonstration of reovirus antigens in cryostat sections of snap-frozen tendon sheaths and other tissues by fluorescent antibody staining (99) is a rapid alternative method of diagnosis but is probably useful only in the early stages of infection (66). Liu and Giambrone (66) described the use of *in situ* hybridization for tracing avian reovirus strain S1133 in tissues of infected chickens. They were able to detect virus in wax-embedded sections of liver, pancreas, heart and tendon, thus confirming the target sights for these viruses. Both immunostaining and *in situ* hybridization are of course well suited to pathogenesis studies, but could be used to determine the tissue tropism of a new isolate.

In spite of extensive molecular studies, there are no recognized markers for pathogenicity of avian reoviruses, so experimental infections are required. For a reovirus obtained from an affected joint, its arthrotropic potential can be confirmed by inoculation into the foot pad of susceptible 1-day-old chicks. If pathogenic, the virus will induce a pronounced inflammation of the foot pad within 72 hours postinoculation.

Serology

Reovirus group-specific antibodies can be detected readily with the agar gel precipitin test (57, 97) or indirect fluorescent antibody (IFA) assay (31). The IFA test is more sensitive and, therefore, better suited for quantitative evaluations. Virus neutralization, based on plaque reduction in chicken kidney or chicken embryo liver cell cultures and several cell lines, has been routinely used for determining serotype differences with rabbit or chicken antiserum and monoclonal antibodies (58, 64, 126, 144, 147). Although several serotypes have been described, considerable homogeneity exists among reovirus isolates, with many being classified as antigenic subtypes rather than distinct serotypes. *In vitro* measurements of reovirus antibody specificity may not always correlate with protection against homologous and heterologous challenge of birds with maternally derived antibody (148), and the type specificity of neutralizing antibody is less for chickens immunized with inactivated reovirus than for chickens immunized following infection (77). None of these tests is suitable for large-scale screening.

For commmercial purposes, the above tests have been superseded by enzyme-linked immunosorbent assay (ELISA) as the serological method of choice, allowing automation and rapid testing of many samples. Slaght *et al.* (120) were the first to describe an ELISA for detecting avian reovirus antibody. The S1133 strain was used as antigen and found to react with antibodies to the Reo-25 and WVU-2937 isolates, although homologous antibody gave the highest titer. Islam and Jones (42) found a significant correlation between ELISA and virus neutralizing antibodies. The ELISA systems now available from commercial sources are used widely for assessing reovirus antibody levels on

a flock basis (128). Recently reported refinements have included the use of bacterially expressed σC and σB proteins (68) as ELISA antigens to improve assessment of flock immune status and monoclonal antibody-based competitive ELISA (65).

Since reovirus infection is widespread among commercial flocks, the diagnostic value of serological profiling is often difficult to interpret, although it can be an indicator of immunity following vaccination.

Prevention and Control

Biosecurity

Avian reovirus infections (but not necessarily disease) are ubiquitous. The virus can be transmitted both vertically and horizontally and, because of its resistance to inactivation away from the host, may be frequently carried by mechanical means. In view of these properties, maintaining freedom from infection in modern intensively housed chicken flocks appears to be virtually impossible. Following the removal of an infected flock from the premises, thorough cleaning and disinfection of a poultry house can prevent infection with pathogenic virus in subsequent groups. Because of the relative stability of the avian reovirus group, commercially available disinfectants should be validated for efficacy before use. Lye and 0.5% organic iodine solutions are considered to be effective inactivating agents. Though the main approach to control of reovirus infections in chickens is vaccination, good management and biosecurity procedures which minimize reovirus infections, especially in young chickens, are essential.

Vaccination

Chickens are most susceptible to pathogenic reoviruses at 1 day of age and then develop an age-associated resistance beginning as early as two weeks. Because of this enhanced period of susceptibility, vaccines and vaccination programs have evolved that are directed at providing protection at 1 day of age. Active immunization can be achieved by vaccination with viable attenuated reovirus that is usually applied by the subcutaneous route (137), although immunization by coarse-spray application of vaccine has also been used (28). Protection from subsequent challenge can be demonstrated, but the S1133-derived reovirus vaccines may interfere with Marek's disease vaccination if administered simultaneously (103, 86). The interference is most pronounced with herpes virus of turkeys (HVT) derived Marek's disease vaccines (97, 103). A reovirus vaccine derived from a naturally apathogenic strain of reovirus (2177) isolated in the United States (101, 102, 124) may be more suitable for simultaneous day-of-age administration with Marek's disease vaccine than are several S1133 derivatives (138). The vaccine should be used with caution if Marek's disease vaccine titers are low and/or Marek's disease virus challenge is significant. Reovirus vaccination of breeding stock can be done with viable or inactivated vaccines or combinations of both. The inactivated vaccines are more efficacious if preceded by vaccination with live vaccine (130, 148).

If a live vaccine is used, it should be administered prior to the onset of egg production to prevent transovarian transmission of the vaccine virus (27). The advantages of this type of immunization program include immediate protection of 1-day-old progeny provided by maternal antibody and a limitation of the potential for vertical transmission that has been shown to be economically significant (16). Vaccination of breeders is an efficacious method of controlling viral arthritis and other pathogenic reoviruses, but it should be recognized that protection is assured against homologous serotypes only (36, 96, 109). When the field virus is clearly different from that included in commercially available vaccines, an autogenous vaccine may prove effective (36, 109).

In ovo vaccination has been investigated. Guo *et al.* (33, 34) reported that the reovirus vaccine alone should not be given to chicks without maternal antibodies but this immunosuppression could be overcome if the vaccine was given with antibody complex.

Among the novel approaches to reovirus vaccination, Wu *et al.* (151) expressed σC protein in yeast (*Schizosaccharomyces pombe*). Projection against S133 challenge was slightly superior to that of a commercial vaccine. The results supported the feasibility of plant-derived vaccines for immunization programmes. Huang *et al.* (40) in similar work, expressed the σC protein in alfalfa and possibly paved the way for an edible vaccine.

The accepted method of assessing efficacy of reovirus vaccines has been to vaccinate birds and 3–4 weeks later, challenge them with virulent virus via footpad inoculation. Results are based on interpretation of the footpad swellings. This causes suffering in the challenged birds and results can sometimes be difficult to interpret. van Loon *et al.* (141) have described an alternative challenge model which involves isolation of the challenge virus from selected tissue of vaccinated or control birds and, using monoclonal antibodies, discriminating challenge virus from vaccine virus.

Other Reovirus Infections

Richard C. Jones

Introduction

Reoviruses are recognized as a cause of tenosynovitis/viral arthritis in chickens (see preceding section, "Viral Arthritis"), but they have also been isolated from several other disease conditions in chickens and turkeys. From time to time, they have been recovered from a variety of other healthy or diseased avian species. In many cases, attempts to demonstrate that the reoviruses were the cause of the condition have been unsuccessful,

or, especially in the case of wild species, experimental work has not been possible. Thus, their association with disease has not always been established. On other occasions, serological surveys have been conducted, which have shown the presence of antibodies to at least the avian group antigens in other avian species. In these cases, the role of reovirus infection is completely unknown.

Some strains isolated from birds other than chickens and turkeys, however, have been shown capable of causing patholog-

ical changes (mainly in the hock joints) in chickens, suggesting the possibility of cross-species transmission (33). The role of other avian species as carriers and reservoirs of infection for domestic poultry has never been established.

The Viruses

In almost all cases in which reoviruses have been isolated, cultivation has been achieved using methods described for the viral arthritis strains—namely, fertile chicken eggs inoculated via the yolk sac, or chick embryo fibroblasts, liver or kidney cells, or chicken kidney cells. Isolates usually have been identified by cultural characteristics and typical reovirus morphology under the electron microscope. Few comparisons have been made of reoviruses from viral arthritis and those from other conditions of poultry or other avian species.

Rekik et al. (60) examined reoviruses isolated from 9 flocks of broiler chickens in Quebec. Serum neutralization tests showed the presence of types antigenically different from the vaccine (S1133) strain. They asserted that some reoviruses isolated from conditions other than viral arthritis could be antigenically different. Heffels-Redmann et al. (28) examined two reoviruses isolated from Muscovy ducks. Although the basic electrophoretic mobility patterns of immunoprecipitated polypeptides closely resembled those of chicken strains, considerable strain-specific variation was seen at the protein level. Based on cross-neutralization tests, the two duck strains were grouped in one serotype, with no cross-reactivity with the chicken serotype S1133.

Lozano et al. (45), using polyacrylamide gel electrophoresis, compared the genomic profiles of a total of 70 avian reovirus isolates, comprising 60 from turkeys, 8 from chickens (including strain S1133) and one each from a canary and a cockatiel. Greater heterogeneity of the migration pattern was seen among the turkey reoviruses as compared with the 8 chicken viruses, particularly in the S (small) genome fragments. A characteristic migration pattern according to species could not be determined because of the high polymorphism existing in the mobility patterns from chickens and turkeys. However, the canary and cockatiel viruses had strikingly similar migration patterns, which were different from the chicken and turkey viruses. The authors indicate the difficulty of assessing the significance of these differences, because these two viruses were processed separately, and virus isolation time was different.

Further detailed comparisons are needed between reovirus strains from different avian species.

Diseases in Chickens

Reoviruses have been isolated from a wide range of disease conditions in commercial chickens other than tenosynovitis. They include respiratory disease, enteric disease, inclusion body hepatitis, hydropericardium, hepatitis in young chicks, generalized disease, blue wing disease, and the runting/malabsorption syndrome. At the same time, they can be isolated easily from the intestines of apparently healthy chickens. In addition to differences in tissue tropism between strains, a range of virulence exists,

from high to virtually harmless. Several reports describe varying degrees of reduced weight gain due to reovirus infection, presumably indicating varying effects on function of the gastrointestinal tract.

A study by Robertson et al. (62) investigated the presence of reoviruses in healthy commercial chickens and in other flocks affected with the runting syndrome or tenosynovitis. The viruses could be isolated from almost all fecal samples from healthy flocks of 3 weeks of age or older, from several tissues of chicks aged 2 weeks or more with the runting syndrome, and from older birds with tenosynovitis. In addition, all broiler breeder flocks examined had antibodies to avian reovirus. The finding of widespread reovirus infection, apparently in the absence of disease, strongly suggests that isolation of reovirus from tissue specimens does not necessarily imply that they are causing disease.

Kant et al. (35) sequenced part of the S1 segment of the σC protein of avian reoviruses from chickens isolated from a variety of disease conditions in Germany and the Netherlands between 1998 and 2000. They were unable to correlate σC sequences with different disease conditions and did not establish temporal or geographic differences either. Thus the underlying markers that identify pathotype or tissue tropism are still to be investigated.

Reports of reoviruses being associated with conditions in chickens other than joint disease include the following.

Respiratory Disease

The so-called Fahey-Crawley virus (18), whose identity was later confirmed as the first avian reovirus (59), caused a mild respiratory disease of baby chicks (73), but older chicks were resistant. Another respiratory isolate (UGA) was unable to cause respiratory disease alone, but in combination with a strain of *Mycoplasma gallisepticum* of low pathogenicity, respiratory signs and lesions were observed (69). However, reoviruses generally are not regarded as primary agents of respiratory disease in poultry.

Enteric Disease and Systemic Infections

Several descriptions exist of reovirus-associated enteric disease. An agent characterized as a reovirus was isolated from young chicks suffering from ulcerative enteritis by Krauss and Ueberschar (40), but it was not confirmed that this virus was the cause of the disease. Further early reports described enteric disease (14) and cloacal pasting and mortality (16) in young chicks.

A commercial farm with a history of poor feed conversion and chronic feed-passage problems was investigated (3). Abnormal tissue pathology was seen in broilers from 9 days of age. Avian adenoviruses and reoviruses were isolated, and although SPF chicks were inoculated with isolated reoviruses, their relationship to the initial problem was inconclusive.

Adenoviruses and reoviruses isolated from commercial broiler chickens were tested for gastrointestinal pathogenicity in day-old chicks by Lenz et al. (43). Chickens in inoculated groups developed wet unformed fecal droppings, but although adenoviruses caused marked gizzard erosions, necrotizing pancreatitis, and proventriculitis, reovirus effects were mild by comparison, including hyperplasia of lymphoid aggregates and mild gizzard erosions.

Some reports highlight the synergistic effect of reovirus in dual infection with other pathogens. For example, reovirus and *Cryptosporidium baileyi* produced a systemic infection (26), and Ruff and Rosenberger (66) showed that reoviruses can potentiate coccidial infection, although the outcome depends on the reovirus strain used.

Other reports record more generalized infections, with several organs affected. Four outbreaks of disease in broiler chickens in Victoria, Australia, were examined by Bagust and Westbury (4). Affected flocks range from 4–38 days. Sudden deaths and starvation were variously associated with hepatitis, ascites, hydropericardium, pale kidneys, and depleted bursas. Reoviruses were isolated consistently from the tissues of the affected birds. Inoculation of these viruses into day-old SPF chicks intraperitoneally or orally induced sporadic deaths but no clinical syndromes. It was speculated that other factors may interact with the reoviruses to induce these problems.

Blue wing disease is a condition affecting broilers characterized by mortalities of 10%, subcutaneous and intramuscular hemorrhages, and atrophy of the thymus, spleen, and bursa. Engstrom *et al.* (17) showed that it was caused by a synergistic effect between chicken anemia virus and a reovirus. McNeilly *et al.* (48) also showed a synergistic effect between these two agents, so that dually infected animals had significantly lower weight gain and more severe damage in several tissues than chicks inoculated with either alone. However, the severity of effects depended on the strain of reovirus.

Avian reoviruses have also been shown to enhance the pathogenicity of other infectious agents of chickens such as *Escherichia coli* (64) and infectious bursal disease virus (51).

Inclusion Body Hepatitis; Hepatitis in Young Chicks

The liver of the chicken is considered to be one of the target organs for reovirus infection. It has been shown experimentally that reoviruses can cause hepatitis immunosuppressed chicks (38). McFerran *et al.* (47) isolated reoviruses and adenoviruses from outbreaks of inclusion body hepatitis. However, it is now recognized that adenoviruses rather than reoviruses play an important role in the pathogenesis of this disease.

Mortality in broiler chicks up to 10 days of age has been reported in Poland and attributed to reoviruses (Z. Minta, personal communication). Van Loon *et al.* (75) characterized these viruses and called them "enteric reovirus strains" (ERS). The pathogenicity, dissemination, induction of malabsorption syndrome, unusual reaction pattern with different monoclonal antibodies to more common reoviruses, and serotype properties were reported. Screening of reoviruses in the field showed that these reovirus strains were also present in other countries and were usually isolated from birds with MAS. The authors proposed that the so-called ERS are associated with MAS. Whether these viruses can be differentiated from other chicken strains by molecular methods remains to be seen.

Hydropericardium

Bains *et al.* (5) described serious mortalities (10–18%) in broiler chicks in Queensland, which occurred in birds less than 14 days old. At necropsy, hydropericardium, with in some cases up to 3 ml fluid, was a consistent feature together with small spleens. Reoviruses were isolated from the hearts of these birds in fertile eggs or cell cultures, but there was no attempt to show that reoviruses were the cause of the condition. However, Jones (32) described a similar investigation but showed that intravenous inoculation of the isolated reovirus induced hydropericardium in experimentally infected chicks. The pathogenesis of this condition in relation to reoviruses has never been studied.

The Runting-Stunting/Brittle Bone Disease/Malabsorption Syndrome in Broilers

A disease syndrome with several names that first appeared in broilers in the late 1970s and chiefly is characterized by lowered body weights and variously described as the runting-stunting, pale bird, malabsorption syndrome (MAS), brittle bone, helicopter wing syndrome has been linked with several possible causative agents, including reoviruses (12, 22, 55, 58, 63, 75, 76). However, several studies have suggested that reoviruses probably play a secondary role in these conditions rather than a primary one. Montgomery *et al.* (50) attempted to reproduce the syndrome using various infectious agents isolated from affected Mississippi broilers. These included an infectious bronchitis virus (IBV) isolate and a reovirus. Although IBV with the reovirus caused weight depression, it was concluded that none of the isolated agents was the ultimate cause.

The enteropathogencity of avian reoviruses isolated from chickens with malabsorption syndrome from the Netherlands and Germany was studied by Songserm *et al.* (71). Despite replicating in the intestinal epithelium and causing small intestine lesions including denuding of the villi, none of the viruses caused weight gain depression. The authors concluded that reovirus alone cannot induce intestinal lesions as found in malabsorption syndrome. However, this group (Songserm *et al.*, 2002) had previously shown that a combination of enteropathogenic reovirus with other agents or substances present in an intestinal homogenate from affected and healthy chickens can induce MAS in broilers. *E. coli* was not essential for induction of weight gain depression but played a part in development of intestinal lesions, which alone do not always result in weight gain depression.

Van Loon *et al.* (75) characterized the Polish reoviruses associated with mortalities in baby chicks and hepatitis. They called them "enteric reovirus strains" (ERS). The pathogenicity, dissemination in the tissues, induction of malabsorption syndrome and in particular, their unusual reaction pattern with different monoclonal antibodies to other reoviruses were reported. These viruses were found in other countries and usually isolated from birds with MAS. The authors propose that ERS reoviruses are associated with MAS. Whether these reoviruses can be differentiated from other chicken strains by molecular methods remains to be seen.

So, although several reports indicate that isolated reoviruses are sometimes capable of causing varying degrees of enteritis (65, 75), or simply reduced weight gain (65, 74), the consensus view appears to be that the most important pathogen is a small virus that can be seen in the enterocytes but which has escaped cultivation (50).

Nonetheless, some commercial reovirus vaccines are produced, which are claimed to have beneficial effects against the stunting or malabsorption syndrome. The claims may indeed have some justification, but the vaccines are unlikely to protect against the primary causes.

Diseases in Turkeys

Tenosynovitis

Reoviruses have been isolated from tenosynovitis in turkeys (44, 56), but the relationship of the viruses with this disease is unclear. Al-Afaleq and Jones (1) examined three chicken and three turkey reoviruses each isolated from hock joints. All viruses induced microscopic tenosynovitis lesions in chicks, but none produced them in turkey poults. Even when reovirus was given together with *Mycoplasma synoviae*, only minimal joint lesions were induced in experimentally infected turkeys (2).

Enteric Disease

Reoviruses have been isolated from the intestines of normal turkeys and turkeys with enteric disorders (13, 20, 53, 54, 68). When such strains have been tested *in vivo*, effects have been variable: Some have been found to be pathogenic, and others nonpathogenic or of low pathogenicity. Dees *et al.* (13) compared different isolates and found that although strain BC-7 was nonpathogenic, BC-3 induced enteritis, involving destruction of the intestinal villi. Goodwin *et al.* (21), using a brilliant red powder in the diet, found that gastrointestinal transit time in reovirus-infected turkeys was significantly longer than in normal turkeys.

In the USA a condition in young turkeys called poult enteritis and mortality syndrome (PEMS) caused major losses to the turkey industry especially in the 1990s. Little is known about its incidence outside the USA but is has recently been reported in the United Kingdom (10). PEMS was originally called poult enteritis complex (7), and its main features include stunting and poor feed utilization that result from enteritis. In the more severe forms, runting, immune dysfunction, up to 100% morbidity and mortality are reported. Gross microscopic lesions of enteritis are present in all forms but tend to be non-specific. The etiology of the disease is not completely understood but it appears to be multifactorial. While the agents thought to be most important are enteropathogenic *E. coli*, turkey coronaviruses (27) and turkey astroviruses (39) and reoviruses (29) have also been isolated. Heggen-Peay *et al.* (29) showed that while experimentally, PEMS reovirus isolate ARV-CU98 did not induce fulminating PEMS in turkey poults, it was able to cause some of the typical clinical signs including intestinal alterations and significantly lowered liver and bursa weights. The authors considered that it could also contribute indirectly to the syndrome by increasing susceptibility to opportunisitic pathogens that facilitate clinical PEMS. Sequence analysis of reovirus NC98 isolated from PEMS and other turkey strains (36) has shown that they shares limited sequence analysis with reoviruses of chicken or duck origin and should be considered to constitute a separate virus species within subgroup II of the Orthoreovirus genus.

The implied involvement of the three types of virus in PEMS led to the development of a multiplex real-time RT-PCR by Spackman et al., (72) for turkey coronavirus astrovirus and reovirus which is claimed to be as sensitive as isolation for each of the viruses.

Reoviruses in Ducks and Geese

Several early reports describe the isolation of reoviruses from different species of ducks, including mallards (46), healthy Pekin ducks (33), and diseased ornamental ducks (23). All shared a common group antigen with chicken reoviruses, but their relationship with disease in ducks was not determined. However, the strains from Pekin ducks (33) were able to cause microscopic lesions of tenosynovitis in specific-pathogen-free chicks. Heffels Redmann *et al.* (28) considered that the two duck strains they examined were antigenically distinct from standard chicken strains.

Muscovy duck reovirus is the cause of a disease first described in South Africa and then France (1972) and typically affects young ducklings 2–4 weeks of age, causing diarrhea and difficulty in movement, high morbidity and mortality of 10% or higher. Malkinson *et al.* (49) isolated a reovirus from affected ducks in which they found necrotic foci in the liver, spleen and kidneys. Intramuscular inoculation of the reovirus caused mortality without clinical signs within 2 days and necrotic foci in the liver and spleen. Kuntz-Simon *et al.* (41) and Zhang *et al.* (77) suggested separate classification for Muscovy duck reoviruses based on sequencing of the σC encoding gene. No satisfactory vaccines have been marketed for these viruses but Kuntz-Simon *et al.* (42) have shown that a baculovirus-experssed σC alone, or with expressed σB appeared to be a good candidate for vaccination of ducks against the reovirus infection.

In a die-off of common eiders *(Somateria molissima)* in the Western Gulf of Finland Hollmen *et al.* (31) isolated a reovirus in cell cultures from Pekin duck but not chick embryo fibroblasts from several tissues of affected birds. High prevalence of neutralizing antibodies in flocks corresponded to mortalities, questioning their role as the cause.

The isolation of reoviruses from geese with Derzsy's disease has been reported (9), but their role is unknown as the condition is now known to be caused by infection with a parvovirus.

Serological evidence of reovirus infection in geese has been recorded in two reports. Kaleta *et al.* (34) detected neutralizing antibodies to a virus originating from Muscovy ducks and the standard chicken strain S1133 in sera of domestic geese *(Anser anser domesticus)*. Hlinak *et al.* (30) examined sera from bean geese *(Anser fabalis)* and white-fronted geese *(Anser albifrons)* in Germany. Avian reovirus antibodies were detected in 29% of blood samples, and there was no difference in seroprevalence between the two species. The authors indicate that although the role and significance of wild geese in the epidemiology of avian diseases remains to be determined, it is possible that they could be of some importance as reservoirs and carriers of some diseases of domestic poultry.

The first description of reovirus as a cause of arthritis in geese was that of Palya *et al.* (57). The disease was characterized by splenitis with miliary necrotic foci during the acute phase and

epicarditis, arthritis and tenosynocitis during the subacute/chronic phase. Clinical sings usually appeared at 2–3 weeks of age and persisted for 3–6 weeks. The reovirus was isolated from several organs and ths disease was reproduced in young goslings.

The sequence and structural similarities between the genome segment encoding σC in goose and and duck reoviruses lead Banvai *et al.*, (6) to suggest that these viruses belong to a species distinct from other established avian reovirus species within sub-group 2 of orthoreoviruses. Kunz-Simon *et al.*, (2002) and Zhang *et al.* (2006) have also suggested separate classification for Muscovy duck reoviruses based on sequencing of the σC encoding gene.

Reoviruses in Other Avian Species

McFerran *et al.* (46) isolated reoviruses from pigeons and Gough *et al.* (23) from diseased pigeons, pheasants, parrots, and other exotic avian species. Jones and Guneratne (33) isolated a reovirus from the feces of a zoo wedge-tailed eagle *(Aquila andax)*. This virus caused microscopic lesions of tenosynovitis in SPF chicks. All these reoviruses shared a common group antigen with chicken reoviruses, but their importance as pathogens in the host species was not determined.

Graham (24) isolated a reovirus from the liver of an African grey parrot submitted for necropsy with subcutaneous hemorrhages, multiple foci, and necrosis in the liver, spleen, bone marrow, intestinal lamina propria, airsacculitis, and epicarditis. Experimental inoculation of two African grey parrots with the isolate was fatal and reproduced the hemorrhages and necrotic lesions of the original condition. Sanchez -Cordon *et al.*, (67), describing disease in the same species involving 80% morbidity and 30% mortality considered that the reovirus they isolated probably triggered the subsequent herpesvirus (Pacheco's disease) and mycosis that caused the illness.

A virus associated with mortalities in American woodcock *(Scolopax minor)* was identified as a reovirus by Doherty *et al.* (15). A consistent necropsy finding was emaciation of the carcass. The authors considered that the reovirus infection was systemic and to be responsible for the deterioration in bodily condition of the birds. Transmission was thought to be by the fecal-oral route, but again, the true association with the disease was not confirmed.

An enteric disease in bobwhite quail *(Colinus virginianus)*, which resulted in increased mortality in birds from 5 days to 5 weeks was described by Ritter *et al.* (61). A reovirus was isolated from the feces, and intestinal cryptosporidia were also present. In attempts to reproduce the condition experimentally, the reovirus induced subclinical infection, but the cryptosporidium caused changes resembling the natural disease. Infection of quail with both agents produced systemic infection (25).

An outbreak of disease in pheasants in Turkey attributed to reovirus infection was described by Mutlu *et al.* (52). Twenty-seven of a flock of 100 were affected between 3–5 months of age. In addition to being in poor condition, affected birds were short of breath, had greenish diarrhea, and died within a week. Pathological findings comprised fibrinous tracheitis, catarrhal inflammation of the gut, severe hepatic necrosis, and fibrinous perihepatitis. A reovirus was isolated from several organs, but whether this was the only agent involved was not investigated.

Curtis *et al.* (11) reported tenosynovitis in 6–7-week-old pheasants. *Staphylococcus aureus* and an avian reovirus related antigenitcally to strain S1133 were isolated from the swollen hock joints of lame birds. The association between the reoviruses as a cause of the disease was presumed but not confirmed.

Antibodies to avian reoviruses (and to other poultry pathogens) have been detected in ostriches *(Struthio camelus)* in Zimbabwe (8), rockhopper penguins *(Eudyptes chrysocomes)* in Argentina (37) and in bean geese *(Anser fabalis)* and white-fronted geese*(Anser albifrons)*in Germany (30). Again, the significance of these findings is unknown.

Conclusions

Reoviruses are very common among domestic poultry and are probably common in other avian species. They are viruses that are relatively easy to cultivate, and when they are looked for, serum antibodies are often found, so there is a temptation to implicate them as a cause of several conditions from which they have been isolated. Apart from tenosynovitis in chickens, where a clear relationship occurs between reovirus infection and the clinical disease, the role of reoviruses in avian disease is frequently unclear. In exotic birds, reports of reoviruses have been sporadic. There appears to be a wide range of pathogenicity among isolates, but most are probably harmless.

There may be differences in tissue tropism, although all appear to replicate in the gut, and pathogenic strains affect the liver. In most cases, the serologic or molecular relationship of reoviruses from exotic species to the tenosynovitis strains is unknown. Where exotic strains have been tested in chickens, a predilection exists for the hock joints or tendons, suggesting the potential for cross-species infection. However, exotic species have never been proven to be reservoirs of infection for domestic poultry.

Because of the inconsistency of disease associated with reoviruses in species other than the chicken, vaccines have not been developed.

Chapter 12
Viral Enteric Infections

Introduction
Y. M. Saif

Our knowledge of enteric viruses has increased substantially in the last three decades. Several factors have contributed to this progress. The realization that pathogens other than bacteria must be an important component of the etiology of enteric disease has fueled the search for other infectious agents with specific emphasis on viruses. The availability of diagnostic tools was another incentive. Most useful among these tools was direct and immune electron microscopy.

The morphologic identification of these viruses by electron microscopy from gut contents paved the way for attempts to purify, cultivate, and develop diagnostic reagents and to further characterize these agents. Another technique that was used successfully earlier to identify some viruses in fecal samples is electropherotyping of genomic RNA. This technique is useful for detection and differentiation of double-stranded RNA viruses, such as rotaviruses and reoviruses.

A significant finding reported in the earlier studies was the presence of a variety of viral species that could be present in different combinations in the gastrointestinal (GI) tract of young commercial poultry. That necessitated attempts to separate these viruses to facilitate the study of their role in enteric disease. The availability of specific-pathogen-free (SPF) poultry was of major value in studies on these viruses. In the last decade, more diagnostic technologies such as reverse transcriptase/polymerase chain reaction (RT/PCR) became available and currently are used routinely in some laboratories to detect enteric viruses in gut contents. Removal of inhibitors from fecal material increased the utility of the test. In addition, the use of internal controls has improved the test specificity.

Most enteric viral infections occur in the first 3 weeks of life, but some could occur later. The clinical signs and lesions induced by the different viruses have similarities; hence, it is difficult to attribute a specific enteric disease to a given virus unless laboratory studies are initiated to identify the causative agent(s). In addition, the presence of different combinations of viruses could result in varied disease presentations. In general, high morbidity and low mortality exist when only one virus is detected, but mortality could be high when several viruses are present. An example of the significant economic impact of these combinations is the condition that was designated poult enteritis and mortality syndrome that was identified in the United States.

Different terms have been used in the literature to describe different conditions/syndromes of enteric disease. Unfortunately such descriptions are not instructive and confusing at best since these descriptions do not refer to specific etiology/ies. Since diagnostic tools are available for most enteric viral infections, it is preferable to designate these conditions as enteritis with reference when available to the specific infectious agents involved.

Diarrhea is a common manifestation of the disease, and the gastrointestinal (GI) tract is usually distended with gas and liquid contents. Different viruses replicate at different parts of the GI tract and at different sites on the villi. Epidemiologic studies indicated that these viruses do not persist for long in the birds. Unfortunately, many of the enteric viruses are uncultivable which hampers research and diagnostics.

No evidence of egg transmission of enteric viruses exists, and there are gaps in our knowledge of the epidemiology of the infections. Active immunity apparently plays a role in limiting the disease, but the benefits of passive immunity are limited to the first few days of life. No commercial vaccines are available for most of these infections.

Enteric viruses are commonly the cause of most of the primary insults to the GI tract of young poultry. This provides other agents, especially bacteria, with the milieu to replicate, attach, and penetrate, leading to further damage. It has been shown that during the course of several enteric viral infections, bacteria adhere and form a membrane on the surface of the villi. Counteracting secondary bacterial involvement is probably the reason for the reported effectiveness of antibiotic treatment of some cases of enteric disease initiated by viruses in young birds.

Most of the knowledge on enteric viruses were derived from studies on turkeys because of the economic significance of the disease caused by enteric viruses in commercial turkey poults. Lately, there has been renewed interest in studying enteric viral infections in young broilers because of the emergence of enteric disease as an economically significant problem in broiler operations.

The GI tract has the most extensive exposed surface in the body, and it is continually exposed to a variety of insults and

stimulations. In food animals, the integrity of the GI tract is of paramount importance. Efficient utilization of nutrients is dependent on a healthy GI tract, and this is especially true for the young of the species. Damage to the GI tract early in life could result in irreversible damage to the flock.

The progress made in the last three decades has been remarkable, but there remain gaps in our knowledge of enteric viruses. Further information that could lead to novel methods for control of these infections should be of significant impact.

Turkey Coronavirus Enteritis
J. S. Guy

Introduction

Turkey coronavirus (TCV) is the cause of an acute highly contagious enteric disease of turkeys characterized by depression, anorexia, diarrhea, and decreased weight gain. Bluecomb disease, mud fever, transmissible enteritis, and coronaviral enteritis are synonyms of TCV enteritis of turkeys.

History

In 1951, Peterson and Hymas (59) described an enteric disease of turkeys that had been observed for several years in Washington state and was known locally as mud fever. Later, the disease became known as bluecomb disease owing to clinical similarities with avian monocytosis (bluecomb disease of chickens). Severe economic losses were attributed to bluecomb disease in the United States and Canada in the 1950s and 1960s. Between 1951 and 1971, bluecomb disease was considered to be the most costly disease affecting Minnesota turkey production (50). Economic losses were attributed to increased mortality and weight loss in affected turkeys. In 1966, 23% of all mortality in Minnesota turkey flocks was attributed to bluecomb disease (58).

Efforts to identify the etiology of bluecomb disease extended over a 20-year period beginning in the early 1950s (58). Several different infectious agents were identified in affected turkeys, including reoviruses, enteroviruses, and *Campylobacter* spp.; however, experimental attempts to reproduce the disease with these agents were unsuccessful (20, 24, 74, 75, 82). In 1971, Adams and Hofstad (1) successfully propagated a virus from bluecomb disease-affected turkeys in embryonated chicken and turkey eggs, and experimentally reproduced the disease using this embryo-propagated virus. A coronavirus was identified as the etiology in 1973 (55, 65).

Eradication efforts were begun in Minnesota in the early 1970s and these efforts led to successful elimination of the virus from Minnesota turkey flocks by 1976 (58). After this time, TCV was identified only sporadically in turkey producing areas of North America. In recent years, TCV has been increasingly identified in North America as an important cause of enteric disease of turkeys. Turkey coronavirus also has been associated with a disease referred to as poult enteritis– mortality syndrome, a disease characterized by high mortality, severe growth depression and immune dysfunction (5).

Etiology

Classification

Turkey coronavirus is classified as a member of the Coronaviridae (23). The Coronaviridae comprise a large family of RNA-containing viruses that infect a wide variety of avian and mammalian species (69). The *Coronaviridae* is in the order *Nidovirales*, an order composed of viruses having linear, nonsegmented, positive-sense, single-stranded RNA genomes with similar genomic organization and nested sets of subgenomic mRNAs (13). The coronavirus genome consists of an RNA molecule that is approximately 30 kilobases in size (69). Coronaviruses possess four major structural proteins referred to as surface ("spike") glycoprotein (90–180 kilodaltons [kDa]), integral membrane protein (20–35 kDa), small envelope protein (12.5 kDa) and nucleocapsid protein (50–60 kDa) (69). In addition, some coronaviruses also contain a fifth major structural protein, the hemagglutinin-esterase protein (120–140kDa) (33, 69).

Coronaviruses have been subdivided into three major antigenic groups based on antigenic differences identified by serological analyses, and these findings have been substantiated by nucleotide sequence analyses (33, 69). Human coronavirus (HCV) (229E strain), porcine transmissible gastroenteritis virus, canine coronavirus and feline infectious peritonitis virus are members of group 1. HCV (OC43 strain), murine hepatitis virus, porcine hemagglutinating encephalomyelitis virus and bovine coronavirus (BCV) are members of group 2. Infectious bronchitis virus (IBV) and TCV comprise group 3 (11, 12, 14, 27).

Early antigenic analyses based on immune electron microscopy, hemagglutination inhibition, and virus neutralization assays indicated that TCV and IBV were antigenically distinct from each other and mammalian coronaviruses (15, 65). Based on these studies, IBV and TCV were classified as members of coronavirus antigenic groups 3 and 4, respectively (81). Subsequently, Dea *et al.* (17) provided evidence that TCV and BCV, a group 2 coronavirus, were closely related viruses based on a variety of antigenic and genomic analyses (17, 78, 79). However, more recent studies have demonstrated that TCV is antigenically and genetically closely related to IBV, a group 3 coronavirus (11, 12, 14, 27, 39, 40, 41). Turkey coronavirus was shown to be closely related to IBV based on antigenic analyses (28, 36, 39, 42) and these findings subsequently were substantiated by nucleotide sequence analyses (4, 6, 7, 14, 36, 39, 40, 41, 73). Several different studies have indicated a high degree of sequence identity between se-

quences of the integral membrane protein, nucleocapsid protein and polymerase (ORF1b) genes of TCV and IBV; only limited sequence identity was observed with the same sequences of mammalian coronaviruses (4, 6, 7, 14, 36, 40, 41, 73).

Laboratory studies have shown that BCV can replicate in intestinal tissues of inoculated turkey poults (18, 35). Dea *et al.* (18) demonstrated replication of two different BCV strains in intestines of experimentally infected turkeys, but infection failed to produce clinically apparent disease or intestinal lesions. In a recent study, Ismail *et al.* (35) demonstrated BCV replication in intestinal tissues of experimentally inoculated turkeys with development of mild clinical disease (diarrhea, body weight gain reduction, no mortality) and mild to moderate intestinal lesions. However, naturally occurring infection of turkeys with BCV has not been demonstrated.

Morphology

Coronaviruses are roughly spherical, pleomorphic, enveloped particles, with diameters of 60–200 nm (33, 69). They possess a characteristic surface structure composed of long (12–24 nm), widely spaced, club-shaped peplomers (Fig. 12.1). These peplomers give virions the distinctive appearance of a solar corona, hence the name coronavirus. Turkey coronavirus has been shown to have a density of 1.16–1.24 g/ml in sucrose (15).

Chemical Composition

Only limited information is available regarding the chemical composition of TCV. Studies indicate the presence of a RNA genome (19), but little information is available regarding specific properties of TCV RNA. Turkey coronavirus RNA likely is similar to that of other coronaviruses: linear, nonsegmented, single-stranded and approximately 30 kilobases in size (12, 13). Nucleotide sequence analyses of TCV RNA have demonstrated that TCV, like IBV, possess surface ("spike") glycoprotein, integral membrane, and nucleocapsid proteins (6, 7, 14, 40, 41). However, the size and structural properties of these proteins have not been determined. No information is available regarding other TCV proteins.

Virus Replication

Based on immunofluorescence and immunoperoxidase staining procedures, TCV was shown to replicate primarily in enterocytes in the jejunum and ileum (3, 8, 56, 62), and epithelium of the bursa of Fabricius (28). Viral antigen in intestinal enterocytes was found predominately in enterocytes lining the upper one-half to two-thirds of intestinal villi (Fig. 12.2) (8, 28, 62). In the bursa of Fabricius, viral antigens are found in both follicular and inter-follicular epithelium of the bursa of Fabricius (Fig. 12.3); viral antigens are not found in bursal lymphoid follicles. In inoculated embryos, virus replication occurs exclusively in intestinal epithelial cells (62); virus replication has not been detected in allantoic, yolk or amniotic membranes.

Thin-section electron microscopy of intestines from TCV-infected embryos and poults (3, 62) has shown that TCV replication occurs in the cytoplasm. Turkey coronavirus acquires its envelope by a process of budding through membranes of the
12.1. Negative contrast electron micrograph of turkey coronavirus.

endoplasmic reticulum and Golgi apparatus; virus particles accumulate in cisternae of the endoplasmic reticulum.

Susceptibility to Chemical and Physical Agents

Turkey coronavirus was shown to be stable at pH 3 at 22°C for 30 min, and resistant to 50°C for 1 hr, even in the presence of 1 M magnesium sulfate (19). Chloroform treatment at 4°C for 10 min readily inactivated the virus.

Turkey coronavirus was shown to remain viable in intestinal tissues stored at –20°C or lower for over 5 years. In Minnesota, TCV was shown to survive in buildings and ranges for extended periods of time even after turkeys were removed from these premises (50). Saponified cresol and formaldehyde were shown to be effective disinfectants for eliminating TCV from contaminated buildings (58).

Strain Classification

Recent studies indicate that TCV strains are antigenically and genetically closely related (6, 7, 28, 36, 39, 41). Antigenic analyses based on cross-protection studies, cross-immunofluorescence and enzyme-linked immunosorbent assays indicate close antigenic relationships between TCV isolates obtained from different geographical locations (28, 36, 39). Similarly, nucleotide sequence analyses of surface ("spike") glycoprotein gene, nucleocapsid gene and the 3′ untranslated region of different TCV isolates have demonstrated that these viruses are genetically very similar (6, 7, 36, 41). Studies have not been done to examine differences in virulence among different isolates of TCV.

Laboratory Host Systems

Turkey coronavirus strains can be propagated in embryonated chicken eggs (>16 days of incubation) and embryonated turkey

eggs (>15 days of incubation) by inoculation of the amniotic cavity (1). In inoculated embryos, virus is recovered only from intestines and bursa of Fabricius (50).

Attempts to propagate TCV in a variety of avian and mammalian cell cultures generally have been unsuccessful (21, 50). Dea *et al.* (16) reported the cell culture adaptation and serial propagation of TCV using a human rectal adenocarcinoma (HRT) cell line; however, this has not been corroborated by other investigators (28, 35, 63).

Pathobiology and Epidemiology

Incidence and Distribution
Turkey coronavirus has been identified in turkeys in the United States, Canada, Brazil, Italy, United Kingdom, and Australia (12, 14, 15, 50). The virus has been identified in most turkey producing regions of the United States.

Natural and Experimental Hosts
Turkey coronavirus affects turkeys of all ages; however, clinical disease most commonly is observed in young turkeys during the first few weeks of life. Turkeys are believed to be the only natural host for TCV. Pheasants, sea gulls, coturnix quail, and hamsters are refractory to infection (32, 50). Chickens once were believed to be refractory to TCV infection (60, 71); however, recent studies indicate otherwise (29, 37). In two separate studies, specific-pathogen-free chickens did not exhibit clinically apparent disease after experimental inoculation with TCV; however, susceptibility to TCV infection was demonstrated by seroconversion and detection of virus and viral antigens in intestinal tissues and bursa of Fabricius on days 2–8 postinoculation (PI) (29), and by detection of virus is intestinal contents on days 1–14 PI (37). Turkey coronavirus was not detected in other tissues including trachea, lung and kidneys (29).

Transmission, Carriers, Vectors
Turkey coronavirus is shed in feces of infected birds and spread horizontally through ingestion of feces and feces-contaminated materials. Experimental attempts to infect turkeys with ho-

mogenates of liver, heart, spleen, kidney and pancreas of infected turkeys were unsuccessful. Turkeys were readily infected using filtered or unfiltered intestinal materials, or filtered homogenates of the bursa of Fabricius of infected turkeys (50, 53).

Turkey coronavirus generally spreads rapidly through a flock and from flock to flock on the same or neighboring farms. Mechanical movement of the virus may occur by people, equipment, vehicles and insects. Darkling beetle larvae and domestic house flies have been shown to be potential mechanical vectors of TCV (10, 80). Wild birds, rodents, and dogs also may serve as mechanical vectors. There is no evidence that TCV is egg transmitted; however, poults may become infected in the hatchery via contaminated personnel and fomites such as egg boxes from infected farms.

Turkey coronavirus is shed in droppings of turkeys for several weeks after recovery from clinical disease (8, 38). The virus was detected in intestinal contents of experimentally inoculated turkeys for up to 6 weeks PI by virus isolation, and up to 7 weeks PI by a reverse transcriptase-polymerase chain reaction (RT-PCR) procedure (8).

Incubation Period

The incubation period may vary from 1–5 days, but typically is 2–3 days.

Clinical Signs

In field cases, clinical signs occur suddenly, usually with high morbidity. Birds exhibit depression, anorexia, decreased water consumption, watery diarrhea, dehydration, hypothermia and weight loss. Droppings typically are green to brown, watery, frothy, and may contain mucus and urates. Flocks infected with TCV experience increased mortality, growth depression, and poor feed conversion compared with uninfected flocks (66). Mortality is variable in affected flocks; high mortality may occur depending on the age of the birds, concurrent infection, management practices and weather conditions.

Experimental studies using egg-adapted strains of TCV indicate that TCV infection results only in mild disease and moderate growth depression; mortality generally is negligible (30, 37, 51, 54, 63).

Turkey coronavirus infection of turkey breeder hens during production results in a rapid drop in egg production (50). Egg quality also is affected; hens produce eggs that lack normal pigmentation (white, chalky eggs).

Pathology

Gross

Gross lesions are seen primarily in intestines and bursa of Fabricius. Duodenum and jejunum generally are pale and flaccid; ceca are distended and filled with watery contents. Atrophy of the bursa of Fabricius may be observed. Emaciation and dehydration also may be observed in infected turkeys.

Microscopic

Microscopic lesions are observed in intestines and bursa of Fabricius of TCV infected turkeys. In intestines, microscopic lesions in experimentally infected turkeys consist of a decrease in villous length, increase in crypt depth, and decreased intestinal diameter (2, 25). The columnar epithelium of intestinal villi changes to a cuboidal epithelium and these cells exhibit a loss of microvilli. There is a decrease in number of goblet cells, separation of enterocytes from lamina propria, and infiltration of lamina propria with heterophils and lymphocytes. Epithelial repair is evident beginning at 5 days PI, and complete by 21 days PI (2, 25). By 5 days PI, columnar epithelium with microvilli begin to replace cuboidal cells, and goblet cells begin to reappear (25).

In the bursa of Fabricius, changes in epithelial cells are evident by 2 days PI and consist of epithelial necrosis and hyperplasia (30). The normal pseudostratified columnar epithelium of the bursa of Fabricius is replaced by a stratified squamous epithelium (Fig. 12.4). Intense heterophilic inflammation is observed

within and subjacent to the epithelium. Moderate lymphoid atrophy of bursal follicles is observed; however, as TCV antigens are not detected within lymphoid follicles, it is unlikely that TCV directly damages bursal lymphoid tissue. Lymphoid depletion in the bursa of Fabricius may occur secondary to damage of bursal epithelium or as a result of glucocorticoid release during infection. Epithelial repair was evident in the bursa of Fabricius by 10 days PI, with the appearance of areas of columnar epithelium replacing stratified squamous epithelium.

Ultrastructural

Ultrastructural changes in intestines of TCV-infected turkeys are confined to epithelial cells (3, 62). Ultrastructural changes include loss of microvilli, disruption of the terminal web region, degeneration of mitochondria, dilation of cisternae in the endoplasmic reticulum, increases in intracellular lipid, excessive sloughing of cells at villous tips, and shortening of villi. Coronavirus particles (80–140 nm in diamter) are observed within cisternae of the endoplasmic reticulum (62).

Pathogenesis of the Infectious Process

Turkey coronavirus replicates preferentially in enterocytes lining the apical portions of intestinal villi (30, 62) and in epithelium of the bursa of Fabricius (21). The site of intestinal TCV infection suggests that the virus may cause malabsorption, maldigestion and diarrhea in a manner similar to other enteric coronaviruses (46, 67). Malabsorption, maldigestion and diarrhea likely result from TCV-induced destruction of villous epithelium; however, it has been suggested that the virus may exert its effects in a more subtle manner through alterations in the physiology of these cells (62). Turkey coronavirus also may exert its effects by altering the normal intestinal flora (52). The intestinal flora of TCV-infected turkeys was characterized by increased numbers of putrefactive and lactose nonfermenting bacteria, and a simultaneous increase in lactobacilli.

Severe disease characterized by high mortality was a common feature of early descriptions of TCV infection (bluecomb disease) and early experimental studies using inocula composed of crude fecal/intestinal homogenates (50). More recent experimental studies using embryo-propagated TCV indicate that mortality due to TCV infection usually is negligible, at least under laboratory conditions (30, 37, 51, 54, 63). Weather conditions, management practices, crowding, and secondary infections may exacerbate the effects of TCV infection and result in increased losses. Antibiotics have been shown to reduce mortality in TCV-infected flocks, most likely because they control secondary bacterial infections (59, 70). Experimental studies with TCV and an enteropathogenic strain of *Escherichia coli* provide evidence suggesting an interaction between TCV and bacteria in the development of severe clinical disease (30, 54). In these experiments, young turkeys inoculated with only TCV developed moderate growth depression without significant mortality, and turkeys inoculated with only enteropathogenic *Escherichia coli* did not develop clinically apparent disease. However, turkeys dually inoculated with TCV and enteropathogenic *Escherichia coli* developed severe growth depression and high mortality.

Immunity
Active

Turkeys that recover from TCV infection are resistant to subsequent challenge (50, 61). Turkeys that survived experimental TCV infection at 4 days of age showed no clinical signs when challenged at 11 and 22 weeks of age (61). Field observations indicate that flocks that recover from TCV infection are resistant to subsequent infection (60).

The nature of protective immunity in recovered birds is not fully understood. Specific secretory IgA, humoral and T-cell mediated immunity have been demonstrated in recovered turkeys (33, 43, 44, 47, 48). Specific secretory IgA was shown to persist in intestinal secretions and bile of recovered turkeys for at least 6 months (47). In a recent study, TCV-specific IgA antibodies were measured in feces of TCV-infected turkeys using an enzyme-linked immunosorbent assay; these studies demonstrated that IgA antibody production peaked at 3–4 weeks postinoculation and disappeared at approximately 6 weeks postinoculation (44).

Passive

Poults passively immunized against TCV by subcutaneous inoculation of serum from immune birds were not protected from challenge (60). Poults from immune and nonimmune breeder hens were equally susceptible to TCV challenge (75).

Diagnosis

Isolation and Identification of Causative Agents

Diagnosis of TCV infection generally requires laboratory assistance as other enteric pathogens of turkeys may cause similar clinical signs and lesions. Laboratory diagnosis may be achieved based on virus isolation, electron microscopy, serology, or detection of viral antigens or viral RNA in intestinal tissues, bursa of Fabricius or intestinal contents.

Isolation of TCV may be accomplished by inoculation of embryonated chicken or turkey eggs (see Laboratory Host Systems) with suspensions of intestinal contents, dropping samples, or tissues (intestines, bursa of Fabricius) from suspect infected turkeys. Clinical samples should be homogenized in an appropriate diluent, such as minimal essential medium, clarified by centrifugation, and filtered through a 0.45 um filter. Embryonated chicken eggs (>16 days of incubation) or turkey eggs (>15 days of incubation) are inoculated by the amniotic route and returned to the incubator. Embryonated turkey eggs are the preferred substrate, as the relative sensitivity of chicken embryos to TCV has not been determined. After incubation for 2–5 days, the presence of TCV in embryo intestines is determined by immunohistochemical staining procedures. Immunohistochemical staining using either immunofluorescent antibody (FA) or immunoperoxidase (IP) procedures requires a virus-specific antiserum.

Diagnosis based on electron microscopy requires the identification of virus particles having typical coronavirus morphology. Coronaviruses must be distinguished from cell membrane fragments that may resemble coronaviruses; these cell membrane fragments commonly are identified in dropping samples from normal turkeys. Definitive identification of turkey coronavirus

may be accomplished by immune electron microscopy (64); however, this requires a source of virus-specific antisera.

Both direct and indirect FA procedures have been described for detection of TCV antigens in intestinal tissues and bursa of Fabricius of infected turkeys (8, 56, 62). The direct FA procedure is an excellent diagnostic approach with respect to simplicity and speed of diagnosis. However, sensitivity and specificity of this procedure are dependent upon the quality of the antiserum used to prepare the fluorochrome-conjugated antibody, and once this reagent is produced it has a relatively short shelf life. The direct FA procedure was shown to detect TCV antigens in experimentally infected turkeys from 1–28 days PI (56).

Indirect FA and indirect IP procedures have been described for detection of TCV antigens in tissues of infected turkeys (8); these procedures utilized TCV-specific monoclonal antibodies (MAB). These MAB-based immunohistochemical procedures detected TCV antigens in intestines and bursa of Fabricius of experimentally infected turkeys as early as 1 day PI, and as late as 42 days PI. They were shown to have high specificity (>92%), but low sensitivity (61–69%) compared with virus isolation. TCV-specific MABs represent an unlimited source of high quality antibody for TCV detection.

Reverse transcriptase polymerase chain reaction procedures (RT-PCR) have been developed for detection of TCV RNA in dropping samples and intestinal contents of infected turkeys (8, 77). These RT-PCR procedures have been shown to be highly sensitive and highly specific. In one study, RT-PCR was shown to detect TCV RNA in experimentally infected turkeys as early as 1 day PI and as late as 49 days PI; sensitivity and specificity of the RT-PCR procedure was 93% and 92%, respectively, compared with virus isolation (8). Additionally, multiplex RT-PCR procedures have been developed that allow simultaneous detection of TCV and other enteric viruses (45, 68, 72).

Serology

Detection of TCV-specific antibodies most commonly is accomplished using the indirect FA procedure. Antigen for this procedure consists of either frozen sections of TCV- infected embryo intestines (57) or epithelium exfoliated from bursae of Fabricius of infected turkeys (26). Frozen tissue sections are prepared from intestinal tissues of TCV-infected turkey embryos, 24–48 hours after inoculation with embryo-adapted TCV strains (57). Antigen preparation by this method is slow and labor intensive. However, an advantage of this serological method is that it allows discrimination of false positive staining based on determining the site of intestinal staining (i.e. TCV preferentially infects apical villous epithelium). Alternatively, antigen slides may be prepared using exfoliated epithelial cells collected from bursae of Fabricius of 2-week-old turkeys, 4 days after TCV inoculation (26). Bursae are harvested from infected turkeys, rinsed in cell culture media, and incubated at 4°C for 18–24 hours with gentle stirring to exfoliate epithelial cells. Cells are concentrated by low speed centrifugation and then spotted onto glass slides. TCV-specific antibodies may be detected in experimentally infected turkeys as early as 7 days PI using either of the indirect FA methods described above. Turkeys infected early in the brooder house have been shown to

remain serologically positive throughout the growout period (34).

Enzyme-linked immunosorbent assays (ELISA) have been described for detection of TCV-specific antibodies in turkeys (31, 42). TCV-specific antibodies may be detected in turkey sera using commercially available, IBV-coated ELISA plates. In addition, a competitive ELISA (cELISA) was developed that utilizes a recombinant baculovirus-expressed TCV nucleocapsid protein and a biotin-labeled monoclonal antibody specific for TCV nucleocapsid protein (9, 31). The IBV ELISA and cELISA were both shown to be highly sensitive (>92) and highly specific (>96%) compared with the indirect FA procedure, and both tests cross-react with IBV antibodies (31, 42).

The IBV ELISA and cELISA do not discriminate between IBV- and TCV-specific antibodies. However, this is unlikely to be an impediment to specific detection of TCV infection in turkeys, as turkeys are not believed to be susceptible to IBV. IBV, like TCV and other coronaviruses, has a limited host range. Chickens and pheasants are the only known natural hosts for IBV; experimental attempts to infect turkeys with IBV have not been successful (27, 31).

Differential Diagnosis

Enteric disease caused by TCV must be distinguished from other enteric diseases of turkeys, particularly those caused by other viruses, bacteria and protozoa.

Intervention Strategies

Management Procedures

Prevention is the preferred method for controlling TCV. Turkeys infected with TCV have been shown to shed virus in feces for prolonged periods of time after recovery (8, 38, 56); these turkeys, their feces, and the materials that their feces contact are potential sources of infection for other susceptible turkeys. Feces from TCV-infected turkeys can be carried on a variety of fomites including clothing, boots, equipment, feathers and trucks. Other potential vectors such as wild birds, rodents, dogs and flies also may be involved in transmission from infected to susceptible flocks. Sound biosecurity measures must be instituted to prevent introduction of TCV via potentially contaminated personnel, fomites, animal and insect vectors, and infected turkeys.

Elimination of TCV from contaminated premises may be accomplished by depopulation followed by thorough cleaning and disinfection of houses and equipment (58). Following cleaning and disinfection procedures, premises should remain free of birds for a minimum of 3–4 weeks.

Vaccination

No licensed vaccine is available.

Treatment

At present, there is no specific treatment for TCV enteritis. Antibiotic treatment has been shown to reduce mortality, most likely by controlling secondary bacterial infections (59, 50, 70). No beneficial effect was observed when glucose, electrolytes, or calf milk replacer was added to drinking water (22).

Management procedures that have been effective in reducing mortality include raising brooder house temperatures and avoiding crowded conditions.

Rotavirus Infections

M. S. McNulty and D. L. Reynolds

Introduction

Rotaviruses are now established as a major cause of enteritis and diarrhea in a wide range of mammalian species, including humans (50,111). Rotavirus infection in avian species was first reported in 1977 by Bergeland *et al.* (7), who found particles morphologically indistinguishable from rotaviruses in intestinal contents of poults with watery droppings and increased mortality. Since then, it has become apparent that rotaviruses infect many species of domesticated birds.

As in mammals, rotavirus infection in avian species is frequently associated with outbreaks of diarrhea. The economic significance of rotaviral enteritis to the poultry industry has not yet been defined, but by analogy with the situation in mammals, it is likely to be significant. Some mammalian rotaviruses have limited ability to infect other mammalian species, and rotaviruses from turkeys and pheasants can infect chickens (119). There is a report of the isolation of an avianlike group A rotavirus from a calf with diarrhea (10); gene sequences and other data provide convincing evidence that this virus originated from pigeons (8, 89, 90, 91). Also, mammalian-like group A rotaviruses have been detected in chickens with diarrhea (115), and experimental infection of suckling mice with avian rotaviruses has been described (74). However, interspecies transmission of rotaviruses between birds and to mammals and vice versa is probably rare. Avian rotaviruses have no known public health significance.

In this section, the term *rotavirus* includes those viruses formerly described as atypical rotaviruses, pararotaviruses, antigenically distinct rotaviruses and rotaviruslike viruses.

Etiology

Classification

Rotaviruses are classified as a genus in the family Reoviridae. This family contains 12 genera, members of which infect vertebrates, invertebrates, plants and fungi. Rotaviruses infect only vertebrates and are transmitted by the fecal-oral route. They differ in morphology from other genera within the family. Rotaviruses possess 11 segments of double-stranded RNA (85). Their morphogenesis involves the temporary acquisition of a lipid envelope and the deposition of viral-coded glycoprotein in the endoplasmic reticulum (36, 65). Rotaviruses readily undergo genetic reassortment (i.e., when two different rotaviruses belonging to the same serogroup infect the same cell, hybrid viruses containing mixtures of the genome segments from each parent are generated).

Morphology

Intact rotavirus virions appear to be approximately 70–75 nm in diameter when visualized by negative contrast electron microscopy. They are composed of 3 concentric protein layers, comprising a core about 50 nm in diameter, enclosed within a double-shelled capsid made up of inner and outer shells. They have been described as reoviruslike but can be distinguished from reoviruses by their more clearly defined smooth outer edge (Fig. 12.5). Some negatively stained intact rotavirus particles resemble a wheel with short spokes radiating from a wide hub, hence the derivation of the name rotavirus from the Latin word *rota*, which means wheel. The outer capsid shell may be lost, producing non-infectious or poorly infectious so-called single-shelled particles
12.5.   A. Rotavirus particles in chicken feces showing intact particles with smooth outer edge and particles with serrated edges (arrows), lacking outer capsid shell. B. Reovirus isolated from guinea fowl feces. Intact rotavirus and reovirus particles can be differentiated by the more distinct, smooth outer margin of rotavirus. Methylamine tungstate stain.

(9) that resemble orbiviruses and are about 10 nm smaller than intact double-shelled virions (Fig. 12.5). Intact and single-shelled particles of turkey rotavirus had densities in cesium chloride of 1.34 and 1.36 g/mL respectively (48). Intact and single-shelled group D rotavirus particles from a pheasant were reported to be larger, at 80 nm and 70 nm, respectively, than those of an avian group A rotavirus with densities of 1.347 and 1.365 g/mL, respectively (16). Advances in our understanding of the structure of the rotavirus virion have revealed that the so-called single-shelled particles are in fact double-layered. Similarly, intact virions, previously referred to as double-shelled particles, are triple layered.

Both inner and outer capsids have a T = 13(l) icosahedral surface lattice, with 132 channels spanning both capsid shells and extending inwards from the virion surface to the core; 60 short spikes extend 12 nm from the smooth surface of the outer capsid shell, so the mature infectious virion has an overall actual diameter of approximately 100 nm (65, 85).

Chemical Composition

Like their mammalian counterparts, avian rotaviruses possess a double-stranded RNA genome consisting of 11 segments ranging from about 0.2×10^6 to 2.1×10^6 in molecular weight (1, 6, 12, 18, 21, 24, 26, 27, 28, 45, 46, 53, 54, 55, 61, 64, 68, 69, 86, 87, 93, 102, 103, 104,105, 106, 107, 108, 109, 110, 114, 118).

Ten major virus polypeptides were detected in MA104 cells in-

fected with a turkey rotavirus. Three polypeptides, designated VP1, VP2, and VP6, with approximate molecular weights of 125 kD, 100 kD, and 45 kD were associated with particles lacking the outer capsid. Polypeptides VP3, VP4, VP5s, and VP7, with molecular weights of 90 kD, 88 kD, 54–55 kD, and 37 kD, formed part of the outer capsid shell. The 37-kD polypeptide was glycosylated, and two nonstructural polypeptides (30 kD and 28 kD) were also identified as glycoproteins (47).

These results were similar but not identical to those obtained with the prototype mammalian rotavirus, SA-11. Four polypeptides, designated VP1, VP2, VP3, and VP6, with approximate apparent molecular weights of 125 kD, 94 kD, 88 kD, and 41 kD, respectively, are present in SA-11 particles lacking the outer capsid shell; VP1, VP2, and VP3 comprise the core, and VP6 is the only protein in the inner capsid shell. The outer capsid shell of SA-11 is composed of 2 polypeptides, designated VP4 and VP7 (molecular weights 88 kD and 38 kD, respectively); VP7 is glycosylated. Proteolytic cleavage of VP4 to produce VP5* (60 kD) and VP8* (28 kD) results in enhancement of viral infectivity. There are 6 SA-11 rotavirus nonstructural proteins (19).

Brüssow *et al.* (11) identified putative VP1, VP2, VP3, V5*, VP6, and VP7 in purified, intact virions of rotavirus 993/83, an avianlike group A rotavirus isolated from the feces of a calf with diarrhea (10, 91) and of pigeon rotavirus PO-13, isolated in Japan (69). VP5* and VP7 were removed by EDTA treatment, indicating that they were present in the outer capsid shell (11).

The coding assignments and properties of the proteins encoded in each of the 11 genome segments of SA-11 rotavirus have been established, and the entire genome has been sequenced; this information is also available for a number of other mammalian rotaviruses (19, 85). Similarly, the complete nucleotide sequence of the avian rotavirus PO-13 pigeon isolate has been determined (40, 42). Also, sequence data and comparisons with their mammalian counterparts are available for the genes coding for VP3 (13), VP6 (18, 41, 42, 88, 90), VP7 (51, 79, 89), VP8* (91) and NSP4 (73) from a number of other avian group A rotaviruses.

Virus Replication

The replication of rotavirus has recently been reviewed in detail (19). Only those features of the morphogenesis of avian rotavirus likely to be of interest to avian pathologists are described here.

The morphogenesis of turkey, chicken, and pheasant rotaviruses has been investigated by thin-section electron microscopy (20, 34, 55, 61, 69). Virus replication occurs in the cytoplasm. Both in cell cultures and *in vivo*, virus cores are formed within granular matrices of viral precursor material (viroplasm) that lies free in the cytoplasm. Developing virus particles are liberated into dilated cisternae of rough endoplasmic reticulum. Some particles appear to bud through ribosome-free areas of endoplasmic reticulum, acquiring an envelope in the process (Fig. 12.6). The envelope is lost from particles in the interior of the endoplasmic reticulum and is replaced by a thin layer of protein that comprises the outer capsid shell. Virus is released by cell lysis.

Susceptibility to Chemical and Physical Agents

Little published information exists about susceptibility of avian rotaviruses to chemical and physical inactivation. Two isolates of turkey rotavirus were stable to treatment with chloroform for 30 minutes and to pH 3 for 2 hours. Heating at 56°C for 30 minutes decreased infectivity of both viruses 100-fold, both in the presence and absence of magnesium ions (48). A duck rotavirus had similar resistance to inactivation with chloroform and acid but was less stable to heating in the presence of magnesium ions (100). Similarly, a pigeon rotavirus was stable to ether, chloroform, and sodium deoxycholate treatment (69). Glutaraldehyde had greater inactivating capacity against avian rotavirus than sodium hypochlorite or iodophor disinfectants (71).

Strain Classification

Antigenicity

Characterization of mammalian rotaviruses has shown that the most important antigens of the virus are those proteins that make up the inner and outer layers of the capsid (i.e., VP6, VP4, and VP7), although other proteins also contribute to the antigenicity of the virus. Rotaviruses have three important antigenic specificities, namely group, subgroup, and serotype (19, 50).

The vast majority of mammalian rotaviruses share a group antigen, demonstrable by tests such as ELISA, immune electron microscopy, complement fixation, and immunofluorescence.
12.6.   Electron micrograph of chicken embryo liver cell culture 48 hours postinfection with turkey rotavirus. Part of the cytoplasm of an infected cell is shown, with viroplasm (Vp) containing virus cores and virus particles gaining envelopes by budding (arrows) from rough endoplasmic reticulum and from type 2 inclusion material. Nonenveloped virus particles are also present.

These have been termed group A or conventional rotaviruses to distinguish them from rotaviruses that were formerly termed atypical rotaviruses, which do not possess this antigen. This group reactivity resides predominantly in VP6, the protein that makes up the inner capsid shell; VP6 is also the major structural component of virions. Other terms for atypical rotaviruses include nongroup A rotaviruses, pararotaviruses, antigenically dis-

tinct rotaviruses, and rotavirus-like viruses. Atypical rotaviruses have been further divided into groups B, C, D, E, F, and G, based on possession of different group antigens and by terminal fingerprinting analysis of viral RNA (8, 36, 83, 84, 92).

Group A rotaviruses have been isolated from mammals and birds, but so far groups B, C, and E have been found only in mammals, and groups D, F, and G have been detected only in birds (36, 65).

Some avian rotaviruses show an antigenic relationship with mammalian group A rotaviruses by cross-immunofluorescence using hyperimmune or convalescent antisera (61, 64, 108, 118). Those avian rotaviruses antigenically related to mammalian group A rotaviruses are referred to as avian group A rotaviruses. This relationship originally was assumed to occur through simple sharing of the mammalian rotavirus group A antigen, but studies using monoclonal antibodies suggest a more complex situation. Some monoclonal antibodies, specific for group A avian rotavirus VP6, reacted with all mammalian and avian group A rotaviruses tested, and others recognized only avian group A rotaviruses (49, 70). Conversely, other monoclonal antibodies that recognized mammalian group A rotaviruses did not recognize avian group A rotaviruses (22, 30, 38). Thus, it appears that epitopes on VP6 of group A avian and mammalian rotaviruses exist, which are distinct from an antigenic determinant common to all group A rotaviruses.

Nucleotide sequencing and mapping of antigenic sites have provided evidence that the authentic group antigen common to mammalian and avian group A rotaviruses is located at amino acid residues 134–142 of PO-13 pigeon rotavirus VP6. In addition, another antigenic site shared by all mammalian and avian rotaviruses tested, with the exception of the Ch 1 chicken isolate, was present at amino acid residues 45–65 (39, 41). Interestingly, while VP6 from avian rotaviruses showed a low degree of nucleotide and deduced amino acid (approximately 70–75%) sequence homology with mammalian rotaviruses, Ch 1 VP6 sequences showed more than 13% amino acid differences compared to sequences from 2 pigeon and 2 turkey isolates (40, 88).

In addition to group specific antigenic domains, some domains on VP6 also mediate subgroup specificity. This has proven a useful epidemiological marker, particularly for human rotaviruses. Mammalian group A rotaviruses can be classified into subgroups I, II, I and II combined, or neither I nor II. Initial evidence suggested that group A avian rotaviruses belonged to neither mammalian rotavirus subgroup (22, 38, 49, 104), but more recent work has shown that avian rotaviruses from pigeons, turkeys, and chickens react with subgroup 1-specific group A monoclonal antibodies (70). However, additional studies are required to determine whether these avian group A rotaviruses are genuinely subtype I viruses.

In addition to group A avian rotaviruses, 3 other antigenically distinct groups of rotavirus have been identified by cross-immunofluorence in chickens (61, 64). The prototype viruses of these groups, the 132, A4, and 555 isolates have been classified as groups D, F, and G, respectively (8, 36, 84, 92). So far, groups D, F, and G have been identified only in avian species.

Rotaviruslike viruses of turkeys (93, 105, 107) are related antigenically by cross-immunofluorescence to the 132 chicken rotavirus isolate (56) and should also be regarded as group D rotaviruses. Similarly, a rotaviruslike virus of pheasants has also been classified as a group D rotavirus (16). An avian group antigenically distinct from groups A and D, designated atypical rotavirus, has been identified in turkeys in the United States (105).

Viruses belonging to groups A–E are classified as belonging to different species in the genus *Rotavirus*, designated *Rotavirus A–E*, with viruses from groups F and G categorized as tentative additional species in the genus (65,85).

Serotype specificity in group A mammalian rotaviruses resides predominantly in VP7, a glycoprotein that constitutes most of the outer capsid shell and that, next to VP6, is the most abundant protein in the virus. Serotype specificity mediated by VP7 is termed G serotype. However VP4, the spike component of the outer capsid, also contributes to serotype specificity, and such specificity is termed P serotype. At least 15 G serotypes and 14 P serotypes have been recognized, based on virus neutralization tests using hyperimmune polyclonal antisera or monoclonal antibodies (85). Monoclonal antibody-based ELISAs are also used to determine G serotype (50). The genes encoding VP7 and VP4 can segregate independently during genetic reassortment. P serotyping has been hampered by a lack of readily available typing antibodies. However, it has been found that genotypes of VP4, as defined by nucleic acid hybridization and sequence data, correlate well with serotypes, so that genotyping can be used as a surrogate for serotyping (50).

Limited information is available about avian rotavirus serotypes. Using a fluorescent focus-neutralization test, 3 serotypes were identified in a collection of 6 turkey and 2 chicken isolates of group A avian rotavirus (62). With the use of a more sensitive plaque-reduction test, however, two of the viruses classified as different serotypes had a prime strain relationship and were classified in serotype G7 (38). So far, only avian rotaviruses have been assigned to this serotype. To date, there is no information about P serotypes of avian rotavirus. However, the limited sequence data relating to the genes encoding avian VP7 (51, 89) and VP8* (91), which possesses the major antigenic site(s) for P serotype specificity, indicate that diversity of both G and P serotypes exists in avian group A rotaviruses. There is no information about serotypic variation in nongroup A rotaviruses; however, it is likely that different serotypes exist in viruses belonging to groups B, C, D, E, and F.

Some group A and group D avian rotaviruses agglutinate a range of avian and mammalian erythrocytes (16, 32, 48, 69). In mammalian group A rotaviruses hemagglutination has been shown to be due to VP8* (50). Hemagglutination and hemagglutination-inhibition tests may also provide a means of strain classification.

Genetic

Analysis of the pattern of migration of genome segments, especially segment 5; the triplet consisting of segments 7, 8, and 9;

and the doublet of segments 10 and 11, following polyacrylamide gel electrophoresis, has been extremely useful, both in preliminary characterization of avian rotaviruses and in investigating their epidemiology. An important advantage of this technique is that it does not require isolation and propagation of virus in cell cultures but can be carried out on virus in intestinal contents or feces. Five major types of RNA profiles, termed *electropherogroups*, were recognized when turkey and chicken rotavirus RNAs were electrophoresed (109) (Fig. 12.7). Rotaviruses belonging to electropherogroups 1, 2, 3, and 4 were detected in chickens, and electropherogroups 1, 2, 3, and 5 were found in turkeys.

Interestingly, 4 representative isolates, each belonging to different chicken electropherogroups, were also found to belong to different serogroups (64). Furthermore, turkey and pheasant group D rotaviruses from the United States have a similar pattern of migration of RNA segments to group D chicken rotavirus (16, 61, 64, 105, 109). This suggests that electropherogrouping may be a useful indicator of group antigenic differences. The existence of a fifth electropherogroup in avian species raises the possibility that an additional serogroup exists. Disruption of the triplet consisting of segments 7, 8, and 9 found in group A rotaviruses appears to be a useful marker for nongroup A rotaviruses. It will be interesting to see whether turkey viruses from the United States with genome profiles similar to those of electropherogroup 3 (45, 105) (i.e., so-called atypical rotaviruses) and chicken rotaviruses from Argentina (6) are antigenically related to group F chicken rotaviruses with similar profiles from the United Kingdom.

Within each electropherogroup, minor variations, termed *electropherotypes*, were described in turkey and chicken rotaviruses from the United Kingdom (109). Similar variations have also been described in turkey rotaviruses in the United States (45, 106). These variations may be useful for classifying rotavirus strains, although minor electrophoretic differences do not necessarily imply serotypic differences (48).

Laboratory Host Systems

Isolations of rotaviruses from the feces or intestinal contents of turkeys, chickens, pheasants, ducks, and pigeons have been made in primary chick kidney and chick embryo liver cell cultures (3, 26, 60, 61, 62, 100, 118). Although a chicken rotavirus grew better in chick kidney cells than in a continuous line of fetal rhesus monkey kidney cells (MA104) (75), primary isolation of turkey (46, 107), pheasant (20), and pigeon (69) rotaviruses has also been achieved in MA104 cells. The pigeon isolate also replicated to higher titer in MDBK cells than in chick embryo kidney cell cultures (69). Some group A rotaviruses can infect both nonstimulated avian splenic lymphocytes and transformed avian lymphoblastoid cell lines (96).

Serial propagation of rotaviruses in cell culture usually requires trypsin treatment of virus inoculum. Proteolytic cleavage of VP4 into VP8* and VP5* potentiates *in vitro* growth by enhancing viral infectivity and penetration of the virus into cells (19, 50). Most isolates are noncytopathic on primary isolation; several passages in cell cultures are required before a cytopathic

effect is seen. With the exception of the 132 chicken rotavirus isolate (61) and possibly isolates made from turkeys in France (3) and ducks in Japan (100), avian rotaviruses isolated and serially propagated to date in cell cultures have all been group A avian rotaviruses.

A rotavirus from lovebirds was lethal for chick embryos following yolk sac inoculation. Passage of the virus in 6–8-day-old embryos resulted in death 4–6 days after inoculation (24). Similarly, group A rotaviruses from turkey poults were isolated in chick embryos following yolk sac inoculation. Dead embryos were hemorrhagic and stunted with no other visible lesions (12). So far, no information is available concerning replication of other avian rotaviruses in embryos.

Accounts of experimental propagation of avian rotaviruses in their natural hosts are numerous (16, 20, 34, 57, 69, 81, 82, 119, 120, 121, 122). Some group A avian rotaviruses are also capable of infecting avian species other than their natural hosts (118, 119,

120, 122). In contrast, virus excretion was not detected in young chickens, turkeys, and partridges experimentally infected with an atypical rotavirus from pheasants (28).

Pathogenicity

Rotaviruses cause enteritis and diarrheal disease in avian and mammalian species. However, although rotavirus infections in avian species may be associated with outbreaks of enteric disease, subclinical infections are also common. In an extensive survey of turkey flocks with enteric disease and healthy turkey flocks in the United States, group A rotaviruses were detected slightly more commonly in healthy than diseased flocks; whereas rotaviruslike viruses were found far less frequently in healthy than in diseased flocks (86). A French study reported that 48.4% and 50% of chicks with diarrhea in 2000 and 2001 respectively were infected with rotavirus, which was found in only 20.2% and 18% of healthy chicks in the same years (94).

It has been established that mammalian rotaviruses can vary in virulence (19, 50). However, to date, no direct evidence shows that avian rotaviruses vary in virulence.

In theory, variations in virulence could arise through genetic reassortment. Genetic reassortment involving mammalian rotaviruses belonging to the same group, but not between viruses from different groups, has been described (19). *In vitro* reassortment has been documented between group A turkey and simian rotaviruses, producing a reassortant with the gene coding for VP4 originating from the simian parent and the remaining 10 genes coming from the avian rotavirus parent (52). However, if reassortment is important in generating new rotaviruses in avian species under field conditions, it is much more likely to occur between avian viruses than between avian and mammalian viruses.

Pathobiology and Epidemiology

Incidence and Distribution

Rotaviral enteritis has been described in poults in the United Kingdom (37, 60, 63), United States (7, 12, 93, 118), and France (2). Rotavirus isolation from, or detection in, chicken feces has been documented in Argentina (6), Belgium (66), Brazil (1), China (114), Cuba (21), Germany (18), India (68), the United Kingdom (59, 61, 62), the United States (118), and the former Soviet Union (4). Rotaviral antibody has been reported in chickens in Japan (95, 101), ducks in the United Kingdom (60), and pigeons in Belgium (113). Rotavirus was detected in the feces of guinea fowl with transmissible enteritis in Italy, but its etiologic role is uncertain (81). Rotaviruses have been found in feces of diseased pheasant chicks in Italy (20), the United Kingdom (27, 28), and the United States (87, 118). Rotaviruses were isolated from, or detected in, feces of clinically normal ducks in Japan (100) and the United Kingdom (112), apparently normal feral pigeons in Japan (69), diseased racing pigeons in the United Kingdom (26), diseased partridges in Italy (80) and the United Kingdom (23), diseased partridges and Japanese quail in Italy (80), a wild bird (*Melanitta fusca)* in Japan (102), and diseased ratites in South Africa (17) and the United States (35). A chicken

embryo lethal rotavirus was isolated from the liver and small intestine of a diseased lovebird in England (24). This evidence indicates that rotaviruses have a worldwide distribution in a wide variety of avian species.

Natural and Experimental Hosts

As discussed previously, turkeys, chickens, pheasants, partridges, ducks, guinea fowl, pigeons, and lovebirds naturally are infected with rotaviruses, and some have been experimentally infected. Most naturally occurring infections in turkeys, chickens, pheasants, partridges, and ducks involve birds <6 weeks old. Paradoxically, older chickens (56–119 days) and turkeys (112 days) were more susceptible to experimental infection than birds in the first few weeks of life (119, 121). This observation is interesting; however, its relevance to the field situation is questionable because available evidence indicates that most turkeys and chickens will have been infected, and presumably will have developed some immunity, well before this age. Lack of age resistance to infection, however, is illustrated by an outbreak of diarrhea associated with rotavirus infection in commercial laying hens between 32 and 92 weeks of age (43).

Longitudinal surveys have shown that flocks of broilers and turkeys frequently experience simultaneous or sequential infections with different rotavirus electropherogroups (64, 86, 108, 109).

Some avian rotaviruses have been experimentally propagated in suckling mice (74).

Transmission, Carriers, and Vectors

Rotaviruses are excreted in avian feces in very large numbers (121). No information is available concerning survival of avian rotaviruses in feces, but, by extrapolation from mammalian rotaviruses, environmental contamination is likely to be persistent. Horizontal transmission occurs readily between birds in direct and indirect contact. Evidence demonstrates that larvae of the darkling beetle acts as a mechanical vector for turkey rotaviruses (15). Egg transmission of rotaviruses has not been demonstrated, but rotavirus detection in 3-day-old turkey poults prompted speculation that transmission occurs either in or on the egg (108). No evidence exists for a carrier state in birds.

Incubation Period, Clinical Signs, Morbidity, and Mortality

Both the incubation period and the course of the disease are short. In experimentally infected turkeys, watery-to-soft droppings were passed 2–5 days postinfection. Orange-tinged mucus was observed in soft feces. Rotavirus infection caused significant impairment of D-xylose absorption from the intestinal tract at 2 and 4 days postinfection. Inoculated turkeys were depressed with loss of appetite between 1 and 5 days postinfection. Pasting of the vents of experimentally infected poults has also been described (33, 119, 121). In the majority of studies, no mortality occurred in experimentally infected turkeys or chickens, but in one series of experiments, 3 of 23 poults inoculated at 2 days of age died (98). Mild (57) or no clinical signs (67, 119) were observed following experimental infection of chickens. When signs occurred, their onset coincided with peak virus excretion about 3 days

postinfection. Chicks had mild diarrhea (61) or passed increased quantities of cecal droppings (57). Laying hens experimentally infected with rotavirus showed a drop in egg production 4–9 days postinfection (121). Rotavirus was detected in feces of experimentally infected chickens and turkeys from 24 hours postinfection, and in some birds, excretion continued for more than 16 days (57, 119, 120, 121).

Under field conditions, clinical signs associated with rotavirus infection in broilers have varied from subclinical infections to outbreaks of diarrhea severe enough to warrant attention to the litter, with associated dehydration, poor weight gains, and increased mortality (1, 6, 60, 62). In poults, variations in severity of clinical signs have also been observed, including a very mild scour in the first week of life, which caused mortality only if vent pecking occurred (37); a more severe disease in 12–21-day-old poults characterized by restlessness, litter eating, and watery droppings with mortality between about 4 and 7% (7); and profuse scouring in 2–5-week-old poults (59), with affected birds huddling together, mortalities from suffocation, and stunting of survivors. In other outbreaks, predominant signs have been diarrhea and wet litter.

Pheasant chicks 2–3 weeks old in the United States had diarrhea and increased mortality associated with rotavirus infection (87). In the United Kingdom, rotavirus infection was associated with stunting and increased mortality in pheasant chicks in the first week of life (27, 28). Six of twenty 2-day-old pheasants inoculated with intestinal contents containing rotaviruses from naturally occurring cases died 5–6 days postinfection (28); a high mortality rate was also observed in pheasant chicks inoculated with a group D rotavirus (34). In Italy, infected pheasants between 6 and 40 days of age showed depression, drooping wings, yellowish watery diarrhea, and dehydration; mortality was 20–30% (20). Diarrhea, lethargy, and loss of appetite were associated with rotavirus infection in 3–4-month-old racing pigeons in the United Kingdom (26).

Variations in severity of clinical signs associated with rotavirus infections could be due to genuine differences in virulence of avian rotavirus strains, as has been shown for mammalian rotaviruses (19, 50), and interaction of rotavirus with additional factors such as other infectious agents (33) or environmental stress.

Morbidity is high. Most fecal specimens taken randomly from birds in affected flocks will contain rotaviruses.

Pathology

Gross

The most common finding at necropsy is the presence of abnormal amounts of fluid and gas in the intestinal tract and ceca. Pallor of the intestinal tract accompanied by loss of tonicity may be evident. Secondary findings may include dehydration, stunting of growth, pasted vents, inflamed vents, anemia due to vent pecking, litter in the gizzard, and inflammation and encrustation with droppings of plantar surfaces of the feet (7, 33, 34, 37, 57, 62, 98, 122). Hemorrhages were observed in the cecal walls of some experimentally infected pheasant chicks (28), and discrete, multifocal, superficial brownish-red erosions were found in the

duodenum and jejunum of turkeys experimentally infected at 84 and 112 days of age (122).

Microscopic

Immunofluorescence (IF) studies using chickens and turkeys experimentally infected with rotavirus have demonstrated the principal site of virus replication to be the cytoplasm of mature villous absorptive epithelial cells in the small intestine. Infected cells were most numerous in the distal third of villi (Fig. 12.8). Small numbers of infected cells were also detected in colon epithelium, ceca, cecal tonsils, and lamina propria of some villi. No IF was observed in proventriculus, gizzard, spleen, liver, or kidney (57, 67, 119, 120, 121). Within the small intestine, different rotavirus strains may show preference for specific areas. A group A rotavirus grew best in the duodenum of experimentally infected chickens, and a group D rotavirus favored the jejunum and ileum (57). In general, experimental infections using chickens and turkeys of differing ages showed that increasing amounts of viral antigen were detected in birds of increasing age (121).

Microscopic lesions in the small intestines of turkeys experimentally infected with group A rotaviruses consisted of basal vacuolation of enterocytes, separation of enterocytes from the lamina propria with subsequent desquamation, villous atrophy accompanied by widening of the lamina propria, scalloping of the villus surface, fusion of villi, and leukocytic infiltration of the lamina propria (98, 122). In general, mean villous lengths were decreased and crypt depths were increased following experimen-
12.9.   Duodenum of SPF turkey poults. A. Normal villi of an uninfected control poult at 10 days of age. B. Villi of a 10-day-old poult infected with Tu-2 rotavirus at 7 days of age. tal infection, resulting in decreased villus to crypt ratios; morphometric changes were more pronounced in the duodenum and jejunum than in the ileum (33, 98, 122). There was infiltration of polymorphonuclear and mononuclear cells into the lamina propria of the cecum and colon in some birds (122). Scanning electron microscopy demonstrated roughened villus surfaces, irregularly shaped and sized villi (33, 122), and loss of microvilli in enterocytes located at the tips of villi (122). In experimentally infected chickens, only minimal leukocytic infiltration of the lamina propria, with minimal loss of microvilli on cells at villus tips, was found in one study (122). Moderate villus atrophy, mainly in the ileum, however, has also been described by other workers in experimentally infected chickens (67). Microscopic changes observed in experimentally infected SPF turkeys are shown in Figure 12.9.

Similar lesions to those found in turkeys were reported in pheasant chicks experimentally infected with a group D rotavirus. However, when microscopic lesions were most severe, at 7 days PI, viral antigen was detected along the entire length of villi and occasionally in the crypts. Lesions were most severe in the duodenum and jejunum (34).

No histopathologic changes were observed in poults with naturally acquired rotavirus infection (37). Degeneration and inflammation of villi of the duodenum and jejunum have also been reported, however, in poults with rotaviral enteritis (7). Lesions were not found in ileum, cecum, colon, cloaca, or other organs.

Neither gross nor microscopic lesions are pathognomonic for rotavirus infection.

Ultrastructural
No detailed, sequential studies of the ultrastructural pathology associated with avian rotavirus infections have been published. The major ultrastructural changes are illustrated in Figure 12.6.

Pathogenesis of the Infectious Process
Little information about the pathogenesis of avian rotavirus infections exists, but inferences can be drawn from what is known about mammalian rotaviruses. With both avian and mammalian rotaviruses, the target cells are mature columnar absorptive cells that are located in the villous epithelium. Studies with whole virus and with purified VP8, the cell attachment protein, indicate that when initiating infection, avian rotaviruses utilize sialic acid-

containing molecules as receptors on the surface of MA104 cells (99). It is not known if a similar mechanism operates *in vivo*.

Under normal circumstances, villous epithelial cells have a relatively short life in mammals and birds, and they desquamate from the tips of the villi. They are replaced by a process of cell division in the crypts, followed by migration of cells up the sides of the villi to the tips. Crypt cells are immature and poorly differentiated. As they migrate up the villi, they differentiate and start to produce disaccharidases, alkaline phosphatase, and mechanisms to transport sodium. In rotavirus-infected piglets, infection and destruction of mature villous epithelial cells results in increased division and accelerated migration of crypt cells, so that the villi are clothed with immature, poorly differentiated cells, deficient in disaccharidases, alkaline phosphatase, and (Na^+-K^+)-ATPase. Glucose-stimulated sodium transport and the net absorption of sodium, potassium, chloride, and water are also decreased, producing a rapid-onset, severe, watery diarrhea with loss of electrolytes in the feces (31).

It is assumed that broadly similar mechanisms operate in rotavirus-infected birds. Decreased absorption of D-xylose from the intestinal tract has been observed in experimentally infected turkeys (33, 98, 121). However, shortening of the villi in experimentally infected turkeys (33, 98, 122) and chickens (122) was less severe than in infected calves and piglets. It has been suggested that the differences in lesions between infected birds and mammals and the age-related susceptibility of turkeys and chickens may result from differences in the development of intestinal villi between mammals and birds (120, 121, 122). It has been postulated that the frothy fluids found in the ceca of infected birds may result from impaired digestion and absorption of carbohydrates and sugars that, in turn, lead to their fermentation by cecal bacteria, producing metabolites that draw water into the ceca by osmosis (120).

However, malabsorption may not be the only explanation for rotavirus-induced diarrhea. NSP4 proteins of mammalian rotaviruses have been shown to be enterotoxins, causing diarrhea in suckling mice (5, 50). Avian rotavirus NSP4 glycoproteins have been shown to have similar biological activity, despite major differences in the amino acid sequences of avian and mammalian rotavirus NSP4 proteins (72, 73). It is believed that mammalian rotavirus NSP4 activates a signal transduction pathway that increases intracellular calcium levels in cells by mobilizing calcium from the endoplasmic reticulum, resulting in an increase in plasma membrane chloride permeability and potentiating chloride secretion, thereby producing a secretory diarrhea (5, 50).

There are many reports of detection of a rotavirus viremia and of extraintestinal infection/presence of rotaviral antigen in a wide variety of naturally and experimentally infected mammals. It has recently been shown that in experimentally infected rats, rotavirus infects and causes histopathological changes in cells in the liver and lungs, and replicates in macrophages in blood vessels and in the lungs, providing a possible mechanism for widespread dissemination through the body (14). However, it is not known if a similar situation occurs in infected birds.

Immunity
Active
