The *ibeA* gene contributes to invasion of brain microvascular endothelial cells (BMEC) by neonatal meningitis ExPEC. It is significantly more likely to be found in APEC than in avian commensal strains (156, 268, 435, 436). The abilities of APEC strain BEN 2908 to invade human BMEC and also cause avian colibacillosis are significantly reduced when *ibeA* is inactivated (156). These results indicate that *ibeA* is a virulence attribute of APEC. The gene *ibeA* occurs in between 14% and 20% of APEC (156, 435, 436). In at least one APEC strain, *ibeA* is found in a chromosomal PAI (GenBank accession no. NC 008563).

Other

Formation and residence within a biofilm could enhance the ability of APEC to resist cleaning and disinfection and to acquire vir-

ulence and resistance genes by horizontal gene transfer. When 105 APEC and 103 avian commensal *E. coli* strains were compared for their ability to form biofilms on plastic surfaces, formation of biofilms by APEC was induced by nutrient poor conditions. In contrast commensals formed biofilms in both nutrient poor and rich conditions (476).

Genomic Location of Virulence Genes

Much progress has been made on localizing various virulence genes in the APEC genome, providing insight into their organization, regulation, and evolution. Such progress is expected to accelerate with recent completion of the genomic sequence of an APEC strain (GenBank accession no. NC008563). Sequences of several APEC chromosomal PAIs and two APEC virulence plasmids are currently available. Both virulence plasmids contain PAIs (257, 258). During conjugation, these virulence plasmids transfer from donor to recipient strains with large multi-drug resistance-encoding plasmids (256, 259), and genes encoding virulence and resistance can be found on the same APEC plasmids (personal communication with Timothy J. Johnson). This close association between resistance and virulence genes in APEC may offer a means by which APEC persist in the production environment (255).

Common features of most PAIs include encoding one or more virulence factors, size between 10–200 kb, introduction into the genome via horizontal transfer, which may result in deviation of G-C ratios and codon usage from the organism's typical pattern, and usually being flanked by small directly repeated sequences (262). PAIs may contain mobility elements, such as integrons, transposons, and insertion sequences. If they themselves move they are likely carried on plasmids, conjugative transposons, or phages, whose loss may spontaneously convert a virulent organism into an avirulent one (262).

Chromosomal PAIs identified among APEC include the VAT-PAI (404), PAI I$_{APEC-O1}$ (269), and AGI-3 (76). VAT-PAI is a 22-kb PAI that includes the *vat* gene, which encodes Vat (see Virulence Factors:Toxins). Another chromosomally located APEC PAI, PAI I$_{APEC-O1}$ (269), is 56 kb in size and harbors the complete *pap* operon and other *E. coli* genes (*tia* and *ireA*). Also, PAI I$_{APEC-O1}$ lies immediately upstream of the *kps* gene cluster, which is required for biosynthesis of polysialic acid capsule. Although the role of this PAI in virulence has yet to be elucidated, study of 95 APEC and 95 avian commensal isolates for possession of 6 genes of this PAI revealed that they occurred more often in APEC of high and intermediate virulence than in isolates of low virulence. None of the commensals contained all 6 of these targets; whereas, 7.2% of APEC strains had all of the genes (267). The most recently described APEC chromosomal PAI, AGI-3 (76), is 49.6 kb in size and is arranged in 5 modules. Deletion analysis of AGI-3's module 1 demonstrated that it contributed to an APEC strain's carbohydrate uptake and virulence for chickens. Studies of its prevalence among 249 ExPEC strains, including 205 APEC and 36 nonpathogenic strains of avian origin, showed that about 12% of all strains tested contained this region. All 15 APEC strains of the O5 serogroup contained this PAI, suggesting that it might be serogroup-associated.

APEC PAIs also have been found on large transmissible plasmids. A 180-kb ColV plasmid, known as pAPEC-O2-ColV, was sequenced and analyzed (258), and its role in virulence was evaluated (475). In addition to regions devoted to plasmid transfer, maintenance, and replication, pAPEC-O2-ColV contained a 94-kb cluster of putative virulence traits, including *hlyF*, *ompT*, *iss*, *tsh*, the ColV operon, and four putative iron-related systems. The iron-related systems included those encoding aerobactin and salmochelin, the *sit* ABC transport system, and a putative iron transport system novel to APEC called *eit*. Also, this PAI contained another putative ABC transport system known as *ets*. A study of the distribution of these PAI genes in 595 APEC and 199 avian fecal commensal *E. coli* isolates revealed that a portion of this PAI was highly conserved among APEC and that the genes of the conserved region occurred more often in APEC than in commensal strains. This conserved portion, which occurred in nearly 80% or more of APEC examined, included the *sit*, salmochelin, aerobactin, and *ets* operons; *hlyF*; *iss*; *ompT*; the RepFIB replicon; and the 5′ end of the ColV operon. The variable portion of this PAI contained the 5′ end of the ColV operon, *tsh,* and the *eit* operon. The split between conserved and variable portions occurred within the *cvaB* gene of the ColV operon with the 5′ end of *cvaB* and many of its upstream genes occurring significantly more often among APEC than the 3′ end of *cvaB* and many of its downstream genes. This difference in prevalence between conserved and variable portions of the PAI among APEC suggested that there must be an alternative location for the conserved portion in APEC. Indeed, a very similar PAI was found in a 174-kb ColBM-encoding APEC plasmid, known as pAPEC-O1-ColBM (257). This F-type plasmid shares remarkable similarities with pAPEC-O2-ColV, except that it encodes for production of colicins B and M rather than ColV.

At least portions of these plasmid-linked PAIs appear to occur widely among APEC isolated from different parts of the world (9, 102, 103, 132, 243, 329, 335, 435, 436, 523, 553, 561), various avian host species (9, 335, 435, 436), and different syndromes (98, 436). These observations suggest that the conserved region of these plasmid-linked PAIs might be a defining characteristic of the APEC pathotype (436) that could be exploited in colibacillosis control. Protocols for rapid characterization of APEC, based on detection of certain virulence genes, including some from this cluster, show promise (133, 474).

Regulation of APEC Virulence

Mutational analysis of the specific phosphate transport system (*pst*) operon of an APEC strain resulted in deregulation of phosphate sensing and changes in the composition of the bacterial surface. These changes were accompanied by increased susceptibility to serum, acid shock, and polymyxin, and resulted in decreased virulence, suggesting that a functional Pst system is required for full virulence of APEC O78 strain χ7122 (297). Also, the BarA-UvrY two-component system has been shown to regulate APEC virulence. Mutants lacking *barA* or *uvrY* had impaired adherence, invasiveness, persistence in tissues, survival in macrophages, and serum resistance (211). It is likely that completion of the APEC genome will facilitate experimen- tation that will provide insight into the critical issue of virulence regulation.

Pathobiology and Epidemiology

Incidence and Distribution

Escherichia coli have a cosmopolitan distribution. The various serotypes of *E. coli* are normal intestinal inhabitants and occur in high numbers in most animals including human beings. Presence of *E. coli* in the lower intestinal tract is beneficial, aiding in growth and development (460) and inhibiting other bacteria including *Salmonella* (148, 331, 419). *E. coli* likely occur in most mammals and birds although healthy psittacines may be an exception (25, 493). It is a common inhabitant in the intestinal tracts of poultry at concentrations up to 10^6 *E. coli*/gram of intestinal contents. Higher numbers are found in younger birds, birds without an established normal flora, and in the lower intestinal tract (113, 304, 546). A diversity of *E. coli* types colonize the cecal mucosa, which may shift abruptly as birds age (247). *E. coli* strains that persist over time are considered resident strains while those that only are present for a limited period are considered transient strains. Among normal chickens, 10–15% of intestinal coliforms may belong to potentially pathogenic serotypes (204) although intestinal strains may not be the same serotype as those from extra-intestinal sites in the same bird. Intestinal *E. coli* provide a reservoir for virulence and antimicrobial resistance factors (391).

Egg transmission of pathogenic *E. coli* is common and can be responsible for high chick mortality (163, 312, 412, 440). Fluoroquinolone-resistant *E. coli* were vertically transmitted from clinically normal breeders and caused high mortality in chicks (412). Pathogenic coliforms are more frequent in the intestine of newly hatched chicks than in the eggs from which they hatched (203), suggesting rapid spread after hatching. The most important source of egg infection seems to be fecal contamination of the egg surface with subsequent penetration of the shell and membranes.

Coliform bacteria can be found in litter and fecal matter. However, *E. coli* accounts for only a small number of total bacteria in litter (382). Environmental isolates constituted a distinctly different population from APEC occurring in the flock (244). Dust in poultry houses may contain 10^5–10^6 *E. coli*/g. Dust concentrations are higher immediately outside of power-ventilated houses than they are within the houses. *E. coli* are present in the air inside of the houses and up to 40 ft outside of the houses (96). These bacteria persist for long periods, particularly under dry conditions (202). Wetting dust inside houses with water resulted in an 84–97% reduction within 7 days. Feed and feed ingredients are often contaminated with pathogenic coliforms and are a common source for introducing new serotypes into a flock (324). Rodent droppings frequently contain pathogenic coliforms. The intestinal tract of the mouse is a suitable environment for transfer of genes from resistant to susceptible strains. Exposure of mice to an antibiotic accelerates the process (205). Pathogenic serotypes also can be introduced into poultry flocks through contaminated well water (368). Presence of

E. coli in drinking water indicates fecal contamination and can serve as an indicator for the potential presence of any fecal-oral transmission of infectious agent.

Natural and Experimental Hosts

Most, if not all, avian species are susceptible to colibacillosis. Clinical disease is reported most often in chickens, turkeys, and ducks. Collectively, the various forms of colibacillosis are considered to be the most common infectious bacterial disease of broiler chickens and turkeys. Natural infections of quail (16, 64, 141, 562), pheasant (500), pigeons (56, 429), guinea fowl (199, 315), waterfowl (33, 50, 88, 239, 340, 426, 531), ostriches (85, 274, 385, 538), and emus (214, 545) have been reported.

Age of Host Commonly Affected

All ages are susceptible to colibacillosis, but young birds are more frequently affected and severity of disease is greater in young birds, including developing embryos (175, 200, 253, 348). Outbreaks can occur in caged layers (523, 560) and coliform salpingitis/peritonitis is a common cause of mortality in breeders (260).

Host Susceptibility Factors

Compared with bacterial virulence factors, host susceptibility and resistance factors are probably an equal or greater determinant of colibacillosis occurrence (Tables 18.4, 18.5). Normal, healthy birds with intact defenses are remarkably resistant to naturally occurring *E. coli* exposure including virulent strains. Infection occurs when skin or mucosal barriers are compromised (e.g., unhealed navel, wounds, mucosal damage from viral, bacterial, or parasitic infections, lack of normal flora, etc.), the mononuclear-phagocytic system is impaired (e.g., viral infections, toxins, nutritional deficiencies), there is immunosuppression (e.g., viral infections, toxins), exposure is overwhelming (e.g., environmental contamination, poor ventilation, contaminated water), and/or birds are exposed to abnormal stress or have an inappropriate response to stress. Effective control of colibacillosis depends on identifying and eliminating the predisposing cause(s) of the disease.

Colibacillosis often occurs concurrently with other diseases making it difficult to determine the contribution of each agent to the overall clinical disease. For example, colibacillosis, paraty-

phoid, and histomoniasis caused high mortality in a broiler flock maintained free of antibiotics where high ambient temperatures and humidity may have been additional factors contributing to the disease (151). High mortality in Japanese quail with signs of respiratory disease was associated with *Mycoplasma gallisepticum*, *Pasteurella multocida*, *Staphylococcus* sp., *Streptococcus* sp., *Cryptosporidium* sp., and *E. coli*; relatively high ammonia levels likely also contributed to the clinical disease (359).

Infection with infectious bronchitis virus (IBV) in chickens (83, 161, 378, 478), infection with hemorrhagic enteritis virus in turkeys (387, 416, 518), and exposure of avian species to ammonia (367, 397) are the most commonly reported factors that predispose to colibacillosis. Interactions between IBV and *E. coli* have been studied extensively and used to determine virulence of both organisms, efficacy of IBV vaccination programs, and effect of IBV vaccination on subsequent colibacillosis (84, 327, 328, 376). IBV vaccination of chicks at one day of age by spray reduced the occurrence and severity of airsacculitis following challenge with virulent IBV and *E. coli.* In contrast IBV vaccination by eye-drop reduced systemic infection and improved uniformity, but did not protect against airsacculitis (328).

Moderate stress increases resistance, possibly as a result of the development of immunity following contact of organisms with the immune system (304), or as a result of developing and exercising defense mechanisms and maintaining them in a state of readiness (185). Similarly, provoking mild, nonspecific inflammation of the respiratory system increases resistance to subsequent respiratory *E. coli* infection (511). Resistance to intra-air sac *E. coli* challenge was observed following primary NDV vaccination with the Roakin strain, which was prevented when the chickens were given corticosterone (217). Individual survival is likely promoted by diversion of feed-derived nutrients from growth and development to antibacterial defenses (187). Protein does not accumulate at the same rate in muscles of infected birds once they recover and they do not match the weight-for-age of uninfected birds (509). Inhibition of prostaglandin E2 by naproxen restored normal growth (508), which is consistent with the earlier finding that inhibition of prostaglandins with aspirin and vitamin E decreased the severity of disease resulting from *E. coli* challenge (311).

Genetic lines of chickens and turkeys vary in their resistance to *E. coli* infections (21, 469, 470, 557). Variations among genotypes in growth rate, nutritional interactions, and immune responsiveness that relate to *E. coli* susceptibility also have been identified. Consistent among studies on both chickens and turkeys is an inverse relationship between growth rate and resistance to colibacillosis (188, 218, 227, 470, 557, 558). Selection for rapid growth is believed to require redirection of nutrients towards growth at the expense of bacterial resistance (187, 428). However, no correlation between body weight at market for broilers or chick production of breeders with high early antibody response to *E. coli* vaccine was found, indicating the feasibility to select for both immune responsiveness and desirable production traits (305). Immune responses to other vaccines and antigens paralleled response to *E. coli* vaccine in selected lines (559). In general, chickens and turkeys that are more immunologically re-

sponsive (e.g., high early antibody lines) are more susceptible to colibacillosis unless they have been vaccinated or otherwise exposed prior to challenge (37, 120, 558). Genetic lines may be more resistant to colibacillosis if the challenge method uses a predisposing agent such as infectious bronchitis virus because of resistance to the predisposing agent rather than *E. coli* (63). When 5 broiler lines, a slow-growing line, and 2 line crosses were examined using a standardized pure *E. coli* challenge, substantial differences in mortality, lesion occurrence, and growth depression were found. These results indicated that selection for resistance would be feasible, but that heterosis was either negative or negligible making test crossings essential (21, 22). Evaluation of 4 broiler strains for their response to endotoxin revealed differences in weight gain and changes in bone breaking strength. Response of the strains to endotoxin with regard to changes in liver size and bone breaking strength were highly correlated with mortality prior to endotoxin exposure. Strains that had a greater loss of bone breaking strength as a result of inflammation were more likely to have higher overall mortality (227, 341). Variations in physiological and behavioral responses to endotoxin also occur among egg-laying strains (74).

Transmission, Carriers, Vectors

Escherichia coli is present in the intestinal tracts of most animals and shed in the feces, often in high numbers. Direct or indirect contact with other animals or feces can introduce new strains into the poultry flock. Free-living birds are especially important as they are colonized with strains that are already adapted to avian species. *E. coli* is readily isolated from free-living waterfowl, especially ducks (82, 135, 136), and passerine birds, especially European starlings (355). A particularly virulent O86 APEC has caused significant mortality in free-living finches in Britain, but has yet to be found in poultry (140, 410).

Trachea, ceca, and oviduct of recovered laying hens remained persistently colonized for at least 21 weeks after either oral or intra-air sac inoculation with pathogenic *E. coli.* Hens with colonized oviducts continued to lay eggs of which 2.7% contained the

organism. Interestingly, *E. coli* was not isolated from the shell surface, even when the oviduct was heavily colonized (15).

Larval and adult darkling beetles (*Alphitobius diaperinus*) likely contribute to *E. coli* transmission and its spread among poultry houses and farms following consumption of infected larvae or beetles or contact with their feces by the birds (171). Following exposure, larvae and adults were positive for *E. coli* both externally and internally for up to 12 days. The organism was shed in their feces for 6–10 days. Chicks became colonized with *E. coli* after eating infected larvae or adults, but the number of infected chicks was higher when the birds ate larvae (332).

Adult houseflies (*Musca domestica*) serve as mechanical vectors of *E. coli,* and fly larvae develop digestive tract infections with *E. coli* following ingestion of bacteria-laden material. Ingested bacteria can serve as a food source for flies; larvae have a high survival rate when experimentally fed solely *E. coli*. Once infected, *E. coli* persists through the pupal and adult stages making it possible for flies to serve as a reservoir for virulent strains (432, 433). The gut of the housefly provides a suitable environment for horizontal transfer of *E. coli* antibiotic resistance and virulence genes (413).

Incubation Period

The time between infection and onset of clinical signs varies with the specific type of disease produced by *E. coli.* The incubation period is short, generally between 1 and 3 days, in experimental studies in which birds are exposed to high numbers of virulent organisms. In the field it is more common to see colisepticemia 5–7 days after infection with a predisposing agent such as infectious bronchitis virus in chickens or hemorrhagic enteritis virus in turkeys.

Clinical Signs

Clinical signs vary from inapparent to total unresponsiveness just prior to death depending on the specific type of disease produced by *E. coli.* Localized infections generally result in fewer and milder clinical signs than systemic diseases. Coliform cellulitis is typically not detected until the birds are processed. Lameness and retarded growth are seen in birds with skeletal lesions that develop as a sequel to sepsis. Affected birds are typically undersized for the flock and found at the ends of the house, along the side walls, or under feeders or waterers. They may be victims of persecution ("cannibalism") by other birds. When joints or bones of one leg are affected, birds walk with a characteristic hopping motion to keep weight off of the affected leg. Birds with lesions in both legs are either nonambulatory or have great difficulty in standing and walking. When the thoracolumbar spine is affected, the birds have an arched back, sit on their hocks, and bear little or no weight on their feet. Occasionally they will sit back on their tail and hocks with their feet elevated off the ground. Birds with chronic lameness have caking of droppings around the vent and on abdominal feathers. Feces are green with white to yellow urates as a result of anorexia and dehydration. Young birds with omphalitis and infected yolk sacs also may have difficulty in walking because of abdominal distention, which alters weight distribution and impairs balance.

Birds with colisepticemia are often terminally moribund and the flock may be inactive and not eating. Decreased water consumption is associated with a poor prognosis. Severely affected individual birds are unresponsive when approached, do not react to stimuli, and are easily caught and handled. They sit with their eyes closed in a hunched position with drooping of the head, neck, and wings. The beak may be inserted into the litter to support the head. Dehydration is indicated by dark dry skin, which is especially noticeable in the shanks and feet. Dehydrated young chicks typically have prominent raised folds of skin along the medial and lateral sides of the shanks and toenails that appear black. Although, technically, death is not a clinical sign, this may be the main indication of an outbreak of colibacillosis in a flock.

Clinical signs of predisposing or compounding factors often are seen concurrently with signs of *E. coli* infections.

Morbidity and Mortality

Both morbidity and mortality are highly variable depending on the type of disease produced by *E. coli*. It is probable that most, if not all, commercial flocks experience some degree of morbidity, mortality, or condemnation due to *E. coli* infections.

Mortality occurring during the day indicates a more severe disease outbreak than when birds are only found dead in the morning. In flocks with highly virulent colisepticemia it is occasionally possible to watch a bird sicken and die within a few hours. A flock that appears clinically normal when examined during the day, but has an excess number of dead birds the following morning, is a common finding in mildly affected flocks. This pattern is typical for egg layer and breeder flocks experiencing coliform salpingitis/peritonitis.

Pathology

Several localized and systemic types of colibacillosis affect poultry. Often the name is based on the tissue(s) affected or disease process (Table 18.6).

Localized Forms of Colibacillosis

Coliform Omphalitis/Yolk Sac Infection. Omphalitis is an inflammation of the navel (umbilicus). In birds the yolk sac is usually involved too because of its close anatomic relationship. Infection follows contamination of the unhealed navel with APEC. Fecal contamination of eggs is considered to be the most important source of infection. Bacteria may be acquired *in ovo* if the hen has oophoritis or salpingitis or via contamination following artificial insemination (201, 348). Yolk sac infections also can result from translocation of bacteria from the chick's intestine or from the bloodstream. In these cases the navel is not affected.

It is common to recover low numbers of *E. coli* from normal yolk sacs. Between 0.5 and 6% of eggs from normal hens contain *E. coli*. Experimentally inoculated hens may shed *E. coli* in up to 26% of their eggs. Pathogenic strains accounted for 43 of 245 isolates from dead embryos (200). About 70% of chicks with "mushy chick disease" had *E. coli* in their yolk sacs (200). Other types of bacteria also can cause omphalitis, although *E. coli* is most common.

Adhesin factors characterizing omphalitis isolates of *E. coli*

included type 1 (F) fimbriae in 96%, P fimbriae in 8%, and afimbrial adhesin in 16%. Afimbrial adhesin occurred more frequently in omphalitis isolates compared to isolates from cases of salpingitis, swollen head syndrome, or respiratory disease (275). When genotyped, omphalitis isolates tended to be more similar to commensal isolates than they were to isolates from swollen head syndrome or septicemia (11, 93). A high percentage of *E. coli* isolates from eggs, dead embryos, and chicks that died between placement and 7 days of age possessed the virulence genes *ipaH* (invasion and persistence in cells), *eae* (attaching and effacing lesions), and *cdt* (cell distension and death) compared to other APEC (440).

Some embryos may die before hatching, particularly late in incubation; whereas others die at or shortly after hatching. Surviving infected chicks can be a source of *E. coli* for other chicks in the same hatch (348). The incidence of birds with omphalitis increases after hatching and declines after about 6 days with occasional losses continuing up to 3 weeks. As few as 10 organisms of serotype O1a:K1:H7 caused 100% mortality in day-old chicks following yolk sac injection (468). When birds become infected with low virulent strains there may be no embryo or chick mortality or some may survive although hatchability, chick livability, and relative yolk weights may be affected (348); the only pathologic finding being retention of infected yolk sacs containing caseated yolk (181).

Swelling, edema, redness, and possibly small abscesses characterize acute inflammation of the navel. The abdomen is distended and blood vessels are hyperemic (Figure 18.1B). In severe cases the body wall and overlying skin undergo lysis and are wet and dirty. These birds are referred to as "mushy" chicks or poults. There may be other nonspecific changes such as dehydration, visceral gout, emaciation, vent pasting, and enlarged gall bladder. The yolk sac is typically distended because yolk has not been absorbed and inflammatory products have been added. Yolk is abnormal in color, consistency, and smell, and may contain visible exudate. Blood vessels of the yolk sac are often prominent (Figure 18.1A). Chicks or poults with infected yolk sacs that live more than 4 days also may have pericarditis or perihepatitis, indicating systemic spread of the organism from the yolk sac.

Microscopically the wall of the infected yolk sac is edematous with mild inflammation. There is an outer connective tissue zone adjacent to a layer of inflammatory cells containing heterophils and macrophages, a layer of giant cells, a zone of necrotic heterophils and masses of bacteria, and then the inner, abnormal yolk contents. A few plasma cells may be found in some yolk sacs.

Omphalitis and yolk sac infection have been experimentally reproduced in ducks by exposing eggs to *E. coli* broth cultures. Dipping eggs at 18 days of incubation resulted in a higher incidence of infection than dipping at 1 day. Low brooding temperature or fasting after hatching increased the incidence of infection and mortality (459).

Consequences of yolk sac infection include deprivation of nutrients and maternal antibodies, absorption of toxins, and spread of *E. coli* by extension into the body cavity or systemically to produce colisepticemia. Survivors are usually stunted and do poorly. Subsequently the yolk sac contracts but an abscess remains for an extended period. *E. coli* often persists in the inflamed yolk sac for weeks or months. Adhesions to intestines, especially the tip of the duodenal loop, or other visceral organs are common. Rarely the elongated stalk of the yolk sac will wind around the intestine and cause strangulation.

Coliform Cellulitis (Inflammatory Process). Cellulitis is an inflammation of the subcutis that extends beneath normal skin. Cellulitis is rare in mammals but relatively common in birds. It may have many causes, but *E. coli* infection is most common in chickens. For this reason, the term cellulitis has been used synonymously with coliform cellulitis. However, cellulitis in turkeys is not frequently associated with *E. coli* infection (65, 168, 396). Cellulitis is covered separately below because this form of colibacillosis has emerged as a significant disease problem in broiler chickens.

Swollen Head Syndrome. Swollen head syndrome (SHS) is an acute to subacute cellulitis involving the periorbital and adjacent subcutaneous tissues of the head (Fig. 18.2G). SHS was first described in broilers in South Africa associated with *E. coli* and an unidentified coronavirus infection (356). The disease has subsequently been described in most intense poultry-producing areas of the world. The disease also affects turkeys and guinea fowl (315, 516).

Swelling of the head is caused by inflammatory exudate beneath the skin that accumulates in response to bacteria, usually *E. coli,* following upper respiratory viral infections (e.g. avian pneumovirus, infectious bronchitis virus). Ammonia aggravates the disease (118). The portal of entry is considered to be the conjunctiva or inflamed mucous membranes of the sinuses or nasal cavity (379). Possible infection via the eustachian tube also has been suggested (118). Microscopic lesions include fibrino-heterophilic inflammation and heterophilic granulomas in the air spaces of the cranial bones, middle ear, and facial skin. Lympho-plasmacytic conjunctivitis and tracheitis with formation of germinal centers have also been observed (238).

Although the pathogenesis of SHS has not been established, conjunctival-associated lymphoid tissue inflamed from virus infection and/or ammonia irritation may serve as the site through which bacteria gain access to subcutaneous tissues. Periorbital inflammation is typically seen early in the disease and hyperplastic lymphoid tissue has been shown to be a site where *E. coli* penetrates mucosal surfaces (184). Scarifying the conjunctival mucosa and instilling a pure culture of *E. coli* (356), or inoculation of *E coli* into submucosal or subcutaneous tissues (380), will reproduce the disease. Intranasal inoculation of avian pneumovirus and *E. coli* failed to reproduce the disease (380). SHS did not occur when day-old chicks were inoculated supraconjunctivally with either avian pneumovirus or *E. coli*, but they did develop clinical disease, which was most severe when the chicks received both agents (7).

Escherichia coli isolates from SHS cases possessed several virulence factors including fimbrial adhesins, colicin production, aerobactin, and complement resistance. In general SHS isolates had virulence attributes that were similar to isolates from cases of septicemia (93), except colicin production and iron-acquisition siderophores were more frequent in SHS isolates. The colicins produced by SHS strains often differed from ColV (92). The majority of strains were motile, but presence of K1 capsule was infrequent (401). Similar results were found in a subsequent study in which SHS isolates were more similar to isolates that cause septicemia than isolates that cause omphalitis or commensal isolates except type 1 and curli fimbriae, and temperature-sensitive hemagglutinin (tsh) were more frequent in SHS isolates (11). A transferable 60 MDa plasmid from an SHS *E. coli* isolate contained genes for cell adhesion, colicin production, and tsh (489). Adhesin factors occurring in SHS *E. coli* isolates included type 1 in 94% and P fimbriae in 28%. The P-fimbrial adhesin factor occurred more frequently in SHS isolates compared to isolates from cases of salpingitis, omphalitis, or respiratory disease (275). A unique Shiga toxin (VT2y) (454) that may be involved in the pathogenesis of SHS was identified in a high percentage of SHS *E. coli* isolates (402). Additionally another toxin, similar to one produced by *Bacillus cereus* that is highly lethal for mice following injection, was identified in SHS isolates (456).

Diarrheal Disease. Primary enteritis is a common manifestation of *E. coli* infections in mammals including human beings, but is considered rare in poultry. Diarrhea results from infections with enterotoxigenic (ETEC), enterohemorrhagic (EHEC), enteropathogenic (EPEC), or enteroinvasive *E. coli* (EIEC); each type possessing certain virulence factors that determine the characteristics for each type of enteric disease (see Virulence Factors). EHEC and EPEC strains produce attaching and effacing lesions on intestinal mucosal surfaces. Collectively, these strains are called attaching and effacing *E. coli* (AEEC). Intestinal *E. coli* in poultry have been poorly studied, except as commensal strains for comparison with APEC or reservoirs of virulence genes that occur in human strains, so our knowledge of the role that *E. coli* may play in intestinal disease is limited.

Enterotoxigenicity caused by ETEC strains is uncommon in APEC. Most surveys for heat stable and heat-labile enterotoxins either fail to find any positive isolates or identify only a few (130). ETEC that elaborated toxins capable of causing fluid accumulation in ligated intestinal loops of chickens were recovered from chickens with diarrhea (5, 261), and an O15 APEC strain that produced heat-labile toxin II was isolated from ostrich chicks experiencing severe diarrhea and high mortality (385).

Natural and experimental infections with AEEC or presence of *eae* gene have been reported in chickens (149, 264, 281, 440, 492, 495), turkeys (398, 399, 492), pigeons (530), ducks (492), psittacines (463), and other avian species (140, 293). Infections with infectious bursal disease virus in chickens and adenovirus infection in the pigeon were considered possible predisposing factors to AEEC infection. In turkey poults, coinfection of EPEC and turkey coronavirus (TCV) resulted in severe stunting and very high mortality (192). Clinical disease was most severe when poults were infected with TCV prior to inoculation with EPEC (399). Ten of 12 commercial turkey flocks experiencing high mortality because of poult enteritis mortality syndrome (PEMS) were infected with EPEC confirming the importance of natural EPEC infection as a cause of mortality in young turkeys (399).

Birds infected with AEEC may be clinically normal or have diarrhea and be dehydrated. In clinically affected birds, the intestines are pale and distended with fluid, which may contain visible flecks of mucus and exudate. Ceca are often the most obviously affected part of the digestive tract. They are typically distended with pale brown fluid and gas. Bacteria intimately attach to the surface of enterocytes causing effacement of microvilli, pitting, and pedestal formation, which are best seen by electron microscopy (Figure 18.3). Lesions are most common in the ceca. Organisms are readily identified in tissue sections using Giemsa stain or by immunohistochemical methods.

Attempts to experimentally define a role for *E. coli* in malabsorption syndrome of chickens were not successful (347, 481, 482). In contrast, specific strains of *E. coli* have been associated with PEMS (123, 124). Turkey astrovirus, an agent involved in PEMS, impairs macrophage function, which could explain the enhanced susceptibility of affected poults to secondary bacterial infections such as colibacillosis (425).

Diseases resulting from infection with EIEC have not been described but are likely, especially in the case of neonatal septicemia. EIEC possess genes such as *ipa,* which encodes a virulence factor that provides the organism with the ability to penetrate and survive within cells. The most frequently identified virulence gene in *E. coli* isolated from eggs, dead embryos, and
18.3. Attaching effacing *E. coli* bind tightly to the apical surface of enterocytes destroying the normal brush border. On light microscopy the surface epithelium appears irregular, and numerous bacteria can be seen attached to affected cells (A). By EM the organisms characteristically occupy small pits in the cell surface or are on pedestals. The number of bacteria and extent of brush border effacement can be clearly seen (B). (Courtesy of Dr. H.L. Shivaprasad)

chicks with omphalitis/yolk sac infections was *ipaH*. Most of the *ipaH*[+] isolates (62/80; 77.5%) came from liver or yolk sac of chicks that died between 3 and 7 days of age, which corresponded to a period of increased mortality (440). Further characterization of the *ipaH*[+] isolates revealed properties that did not match those of typical EIEC and the existence of specific EIEC clone complexes among avian isolates. Cell invasion was confirmed *in vitro* (440).

Venereal Colibacillosis (Acute Vaginitis). Venereal colibacillosis is an acute and frequently fatal vaginitis that affects turkey breeder hens shortly after they are first inseminated. Puncturing the hymen of young turkey hens can lead to a severe localized *E. coli* infection characterized by vaginitis, cloacal and intestinal prolapse, peritonitis, egg binding, and internal laying. The affected mucosa is markedly thickened, ulcerated, and covered with a diphtheritic, caseo-necrotic membrane, which causes obstruction of the lower reproductive tract. The marked tissue changes can lead to egg binding. The upper oviduct is grossly and histologically normal. Flocks can have losses of up to 8% because of increased mortality and culling. Egg production is decreased and there is an increased number of cull eggs due to small size. No other infectious agents have been identified as contributing to the disease (153).

Coliform Salpingitis/Peritonitis/Salpingoperitonitis (Adult). Inflammation of the oviduct caused by *E. coli* results in decreased egg production and sporadic mortality. It is one of the most common causes of mortality in commercial layer and breeder chickens (48, 49, 260) and also affects other female birds, especially ducks and geese (50). Accumulations of caseating exudate in the body cavity resemble coagulated yolk, which is the reason for the common name "egg peritonitis." Salpingitis and egg binding may occur concurrently. They are often confused with each other because they both result in an obstructive mass within the oviduct. Yolk peritonitis is a mild to moderate diffuse peritonitis that results from free yolk in the body cavity. Marked exudation, extensive inflammation, and positive cultures characterize coliform peritonitis and serve to distinguish it from yolk peritonitis.

Infection occurs when *E. coli* ascends the oviduct from the cloaca. Injecting large (10^9) numbers of bacteria into the reproductive tract will reproduce the disease. Mucosal infections with viruses (*e.g.* infectious bronchitis virus) or mycoplasmas also may predispose a bird to salpingitis. Co-infection with *E. coli* and *Tetratrichomonas* occurred in Pekin duck breeders with salpingitis (88). Heavy egg production and associated estrogenic activity predispose hens to salpingitis by relaxing the sphincter between the vagina and cloaca. Spread to the oviduct from an airsacculitis is also possible but this form of salpingitis occurs more frequently in young birds as part of a systemic infection.

Isolates of APEC from birds with salpingitis have similar virulence characteristics to those that cause airsacculitis. In a study of 30 isolates, 11 belonged to serogroups O2 and O78 while 10 were untypeable. Twenty-seven of the isolates were of either high or intermediate virulence in a day-old chick assay. Most isolates possessed type 1 fimbriae and adhered to oviduct epithelium, especially in adult breeders, and they had the ability to acquire iron when grown in iron-deficient medium. Isolates were resistant to serum from young breeders, but sensitive to serum from older breeders (346). In a separate study type 1 fimbriae also were identified in 49 of 50 isolates from broiler breeders with salpingitis; few isolates possessed other fimbrial types (275). Therefore presence of type 1 fimbriae can be considered characteristic of APEC salpingitis isolates.

In chronic cases the oviduct is markedly distended and thin-walled with single or multiple masses of caseous exudate in the general form of the oviduct (Figure 18.2A). The mass of exudate may expand to the point that it fills most of the body cavity (97). Exudate is laminated, often contains a central egg, shells, and/or membranes, and is malodorous. Spread of the organism into the body cavity through the compromised oviduct wall leads to con-

current peritonitis, which is termed salpingoperitonitis when there is involvement of both the oviduct and peritoneum. Peritonitis in the absence of salpingitis also can occur, but is uncommon. Acute cases have less exudate in the oviduct or peritoneum that tends to be soft and not as caseated (Figure 18.2B). Affected birds are incapable of producing and laying eggs. Abdominal laying and misovulated ova may accompany salpingitis and contribute to peritonitis.

Microscopically the tissue reaction in the oviduct is surprisingly mild in view of the marked gross lesions. It primarily consists of multifocal to diffuse heterophil accumulations subjacent to the epithelium and caseous exudate in the lumen, which often contains bacterial colonies. Lymphoid foci develop in the mucosa with time and indicate chronicity.

Coliform Orchitis/Epididymitis/Epididymo-orchitis. An ascending *E. coli* infection of the male reproductive tract, analogous to that resulting in salpingitis in the hen, occurs infrequently in roosters. Testicles are swollen, firm, inflamed, irregularly shaped, and have a mosaic of necrotic and viable tissue when opened. Heavy growth of *E. coli* can be obtained from the testicle and epididymis (345).

Systemic Forms of Colibacillosis

Colisepticemia. Presence of virulent *E. coli* in the blood stream defines colisepticemia. Virulence and number of organisms balanced against efficacy of host defenses determine duration, degree, and outcome of the disease, as well as the pattern and severity of lesions (420, 421). Colisepticemia progresses through the following stages: acute septicemia, subacute polyserositis, and chronic granulomatous inflammation (75). While lesions are typical of colisepticemia, other bacteria capable of producing septicemia also can cause similar changes. Characteristic features of colisepticemia at necropsy are tissues that develop a green discoloration following exposure to air and a characteristic odor, possibly related to indole produced by the organism. The bursa of Fabricius is often atrophic or inflamed as a result of colisepticemia. It should not be interpreted that a small bursa is evidence of a prior immune suppressing disease such as infectious bursal disease (114, 370, 371).

Pericarditis is common and is a characteristic of colisepticemia. It is usually associated with myocarditis, which results in marked changes in the electrocardiogram (182), often before gross lesions appear. Vessels in the pericardium become increasingly prominent because of hyperemia and the pericardium becomes cloudy and edematous. Initially fluid and soft masses of pale exudate accumulate within the pericardial sac followed by fibrinous exudate (Fig. 18.1C). Exudate can be seen loosely adhering to the epicardium when the pericardial sac is opened. As the disease progresses exudate increases, becomes more cellular (fibrinoheterophilic), and undergoes caseation. The pericardial sac adheres to the epicardium with chronicity.

Microscopically the same progression of lesion development is seen. Serous and serofibrinous exudate is seen initially followed by increasing numbers of heterophils and subsequently macrophages. Within the myocardium, particularly close to the epicardium, there are accumulations of lymphoid cells and by 7–10 days there also are many plasma cells. Subsequently, exudate in the pericardial sac undergoes organization (Fig. 18.1G), which, in survivors, eventually results in constrictive pericarditis and liver fibrosis due to chronic passive congestion. Cardiac lesions reduce arterial blood pressure from a norm of about 150 mmHg to about 40 mmHg just before death.

Several distinct clinical forms of colisepticemia can be distinguished depending on how the organism gains access to the circulation and the age and type of bird.

Respiratory-Origin Colisepticemia. Respiratory-origin colisepticemia affects both chickens and turkeys and is the most common type of colisepticemia. *E. coli* gains access to the circulation following damage to the respiratory mucosa by infectious or noninfectious agents (161, 180). Infectious bronchitis virus (IBV) and Newcastle disease virus (NDV), including vaccine strains, mycoplasmas, and ammonia, are the most common predisposing agents. Avian pneumovirus infection increases susceptibility of turkeys to colisepticemia (7, 246, 514, 516). Severity of the resulting disease, which is commonly referred to as air sac disease, chronic respiratory disease (CRD), or multicausal respiratory disease (215), is directly related to the number of agents that are involved. A diversity of *E. coli* serotypes can be identified in a disease outbreak. Those in the tissues are usually different from those in the intestinal tract of the same bird but can be found in the intestinal tracts of other birds and the environment.

Susceptibility is increased when only IBV or NDV infection occurs. Five days after administration of a vaccine strain of NDV, clearance of aerosol-administered *E. coli* is reduced. Microscopically 3–8 layers of immature, nonciliated cells replace the pseudostratified, columnar epithelium of the trachea (139). Mixed IBV-*E. coli* infections are more severe than those caused by either agent alone (378, 478). Antibodies against *E. coli* produced by chickens infected with infectious bursal disease virus and/or IBV had a significant decrease in opsonizing ability compared to antibodies produced by normal chickens. Reduced opsonization of the organism resulted in decreased macrophage function, which may help explain the frequent infection with *E. coli* that follows IBV infection (383).

Mycoplasmal infection increases susceptibility to *E. coli* about 12–16 days postinoculation, and susceptibility persists for at least 30 days. Infection with IBV or NDV in addition to mycoplasma further decreases resistance to *E. coli* and the period of increased susceptibility begins earlier and persists longer.

Inhaled coliform contaminated dust has been implicated as one of the most important sources for infecting air sacs of susceptible birds. Exposure to chicken-house dust and ammonia results in deciliation of the upper respiratory tract of birds (367, 397) permitting inhaled *E. coli* to colonize and cause respiratory infection.

Lesions are prominent in respiratory tissues (trachea, lungs, air sacs), pericardial sac, and peritoneal cavities and are typical of the subacute polyserositis stage of colibacillosis (75, 421) (Figs. 18.1C–F). Infected air sacs are thickened and often have caseous

exudate on the respiratory surface. Microscopically the earliest changes consist of edema and heterophil infiltration. Mononuclear phagocytes are frequently seen 12 hours after inoculation. Later, macrophages become common, with giant cells along margins of necrotic areas. There is fibroblast proliferation and accumulation of vast numbers of necrotic heterophils in caseous exudate. Bacterial colonies are often present in caseous exudate and contain numerous organisms. *E. coli* colonies have a typical appearance in histologic sections. They are usually circular with concentrated bacilli forming a distinct smooth perimeter with fewer bacilli and spaces centrally. They stain negative with tissue Gram stain. Lesions of predisposing respiratory disease are usually present in the trachea and lungs and consist of lymphoid follicles, epithelial hyperplasia, and epithelium-lined air passages that may contain heterophils. Pneumonia and pleuropneumonia are more common in turkeys while chickens usually have pleuritis or pleuropneumonia with less lung involvement. Extension of the disease process into the oviduct from the left abdominal air sac may occur and cause salpingitis in juvenile birds (Figure 18.1H).

Inoculating pathogenic *E. coli* or bacteria-free culture filtrates into the air sac readily reproduces lesions of uncomplicated coliform infection (22, 105). Airsacculitis occurs within 1.5 hours. Bacteremia and pericarditis develop within 6 hours. In birds that survive, lesions are well-developed by 48 hours postinoculation. Most mortality occurs during the first 5 days. Recovery is usually rapid if birds survive the initial infection, although a few with persistent anorexia become emaciated and die. Ask *et al.* (22) have developed a defined method for determining susceptibility to colibacillosis that is reproducible and has been used to determine the relative innate (genetic) susceptibility of various broiler chicken genotypes to the disease (21).

Enteric-Origin Colisepticemia. Enteric-origin colisepticemia is most common in turkeys. *E. coli* gain access to the circulation and tissues following damage to the intestinal mucosa by infectious agents. The most common predisposing agent is hemorrhagic enteritis virus (387, 416, 518). Usually only one or two types of *E. coli* are involved in the disease outbreak and those in the tissues and intestinal tract are the same.

Lesions are typical of the acute septicemic stage of colibacillosis (75). Affected birds are in good physical condition and often have full crops containing feed and water. The most characteristic lesions are congestion or green discoloration of the liver, marked enlargement and congestion of the spleen, and congested muscles (Fig. 18.2C). Microscopically the spleen is congested with proteinaceous fluid in sinuses and has multifocal necrosis, often containing intralesional bacteria. Fibrin thrombi are present in liver sinusoids and occasionally renal glomeruli. In some cases, multiple, pale foci in the liver are seen. Microscopically these are areas of acute necrosis initially, but with time they evolve into granulomatous hepatitis in survivors (Fig. 18.2D). After a few days birds eventually develop lesions similar to those of respiratory-origin colisepticemia.

Neonatal Colisepticemia. Chicks are affected within the first 24–48 hours after hatching. Mortality remains elevated for 2–3 weeks and usually totals 10–20%. Up to 5% of the flock may be stunted and require culling. Unaffected birds grow normally and the disease does not appear to spread. Initial lesions consist of congested lungs, edematous serous membranes, and splenomegaly. The proventriculus and lungs develop a dark color that can approach black as the interval between death and necropsy increases. Microscopically bacteria are numerous in affected tissues and easily identified. After a few days the typical pattern of acute, fibrinoheterophilic polyserositis involving the pericardial sac, pleura, air sacs, and peritoneum becomes evident. Lesions are often extensive and severe in birds that survive into the second week. Occasionally birds with arthritis or osteomyelitis may be found late in the disease. Most affected birds have yolk sac abscesses suggesting the navel is the portal of entry. Alternatively, *in ovo* infection may be responsible (348).

Layer Colisepticemia. Colisepticemia is usually a disease of young birds, but occasional outbreaks of acute *E. coli* infection resembling fowl typhoid or fowl cholera occur in mature chickens and turkeys (28, 108, 520, 560). Acute colibacillosis in layers is being seen with increasing frequency (520). The majority of outbreaks are associated with onset of egg production, but less frequently they occur at an older age, or may continue as the flock ages and potentially spread to older flocks on the same farm. The disease may reoccur in the same flock or subsequent flocks placed on farms or in houses where affected flocks had been previously (520). Death usually occurred suddenly without premonitory signs although depression and/or dirty vents were observed in some affected hens in approximately half of the flocks. Weekly mortality was significantly higher in affected flocks than age-matched control flocks (0.26–1.71% vs. 0.07–0.30%). Cumulative mortality ranged up to 10% and mortality remained elevated for 3–10 weeks. Polyserositis (perihepatitis, pericarditis) and peritonitis associated with free yolk in the peritoneal cavity were present in most birds at necropsy. Oophoritis and salpingitis occurred less frequently.

Isolates of *E. coli* from outbreaks in Italy were lactose-negative, nonmotile, and belonged to serogroup O111. Intramuscular inoculation of the O111 APEC reproduced the disease whereas it developed in only a few birds following oro-nasal administration (560). In contrast, the majority of isolates from outbreaks in Belgium were serogroup O78. Outbreak isolates were more likely to have P fimbriae (F11), especially if they were serogroup O78 and recovered from the heart. Serogroup O78 isolates also had the lowest percentage of motile strains (520). A number of virulence factors were significantly more frequent in outbreak isolates compared to control isolates. However, when cecal isolates and extra-intestinal isolates within either the outbreak or control groups were compared, they were not significantly different. Collectively no virulence factors or combination of factors were found only in outbreak isolates (523).

The pathogenesis of the disease is unknown, but stress associated with onset of egg production is believed to be an important contributing factor (560). Ascending infections via the oviduct have been suggested as a means by which *E. coli* gain access to systemic tissues, but in a recent study, higher colonization rates

of the trachea, but not the oviduct, in affected flocks suggests layer colisepticemia may be aerogenous (520). Lack of recognized stressors or indications of diseases known to predispose chickens to colisepticemia suggest layer colisepticemia results from a primary *E. coli* infection (520, 522).

Risk factors for developing layer colisepticemia include close proximity to other poultry farms and higher stocking density (521). Control has been through chlorination of water or treatment of the flock with appropriate antibiotics.

Coliform Septicemia of Ducks. Coliform septicemia of ducks is characterized by moist, granular to curd-like exudate of variable thickness causing pericarditis, perihepatitis, and airsacculitis. A characteristic odor is often noted at necropsy. Liver is frequently swollen, dark, and bile stained, and spleen is swollen and dark. *E. coli* (usually O78) can be recovered from any internal organ (302, 340). *Riemerella anatipestifer* causes similar lesions, but it can be identified by appropriate cultural procedures.

Coliform septicemia occurs throughout the growing season but is most frequent in late fall and winter. All ages of ducklings are susceptible. Distribution of losses suggests individual farms, rather than hatcheries, are the source of infection (302). Poor husbandry and marked contamination of pond water used by ducklings were contributing factors to an outbreak of colisepticemia in captive mallards (340).

Colisepticemia Sequelae. Death is the usual outcome of colisepticemia, but some birds may completely recover or recover with residual sequelae. If the bird does not control *E. coli*, it can localize in poorly protected ("immunologically privileged") sites including the brain, eyes, synovial tissues (joints, tendon sheaths, sternal bursa), and bones. In immature females, salpingitis can occur when there is involvement of nearby air sacs. IBV infection of the oviduct may also be an important predisposing factor in juvenile salpingitis. After *E. coli* is no longer present, constrictive pericarditis develops as the exudate in the pericardial sac undergoes organization, and liver fibrosis may result (Figure 18.1G). Ascites may develop because of residual pulmonary damage from combined *E. coli*–IBV infection (512, 552). It also is possible for ascites to develop from the direct action of endotoxin on the pulmonary vascular system. Endotoxin causes vasoconstriction leading to pulmonary hypertension and the potential to develop ascites (pulmonary hypertension syndrome) (72).

Meningitis. Escherichia coli localization in the brain is uncommon. Meninges are affected (meningitis) but in some birds there also is involvement of the brain (encephalitis) and ventricles (ventriculitis). Meningeal lesions are evident at necropsy as zones of discoloration adjacent to major blood vessels. Fibrinoheterophilic to heterophilic exudate is seen microscopically early in the infection; the lesion becomes more granulomatous with time. Bacteria are usually numerous within lesions but may not form distinct colonies.

Panophthalmitis. As with the brain, involvement of the eye is uncommon. However, if it is infected the resulting panophthalmi-

tis is severe (179, 372). Typically there is hypopyon and hyphema, and infection is unilateral (Fig. 18.2F). The eye is swollen, cloudy to opaque, and may be hyperemic initially. Later the eye shrinks as it undergoes atrophy. Fibrinoheterophilic exudate and numerous bacterial colonies are present throughout the eye. Inflammation, especially adjacent to necrotic tissue, becomes granulomatous with time. Varying degrees of retinal detachment, retinal atrophy, and lysis of the lens also may be seen. The organism persists in the diseased eye for long periods of time.

Osteoarthritis and Synovitis. Localization of *E. coli* in bones and synovial tissues is a common sequel to colisepticemia (Fig. 18.2E). The term osteoarthritis is used when a joint is inflamed and one or more bones making up that joint have osteomyelitis. Polyarthritis refers to involvement of more than one joint. Bacterial chondronecrosis with osteomyelitis (BCO) is another name that has been used (334). For a recent review see (334).

Affected birds likely have insufficient resistance to completely clear the bacteria. Hematogenous spread of *E. coli* following hemorrhagic enteritis virus infection of turkeys resulted in synovitis, osteomyelitis, and green liver discoloration (119). Intravenous inoculation to simulate hematogenous spread to bones and joints has been used to reproduce the lesions, but mortality from the initial septicemia is often high (37). A preferable method is to inoculate the air sac of birds with low numbers of *E. coli* after a pre-treatment with dexamethasone (222).

Mild to severe lameness and poor growth are seen clinically and affected birds are more likely to be victims of persecution ("cannibalism"). Often multiple sites are involved. Bacteria colonize the vascular sprouts that invade the physis of a growing bone provoking an inflammatory response that results in osteomyelitis. Transphyseal blood vessels in birds serve as conduits for the process to spread into the joint and surrounding soft tissues. Compared to clinically normal turkeys, lame turkeys had the following: higher splenic and liver weights, lower body and bursal weights, decreased cellular immunity, normal to increased humoral immunity, decreased circulating lymphocytes, increased circulating total leukocytes, monocytes, and heterophils, normal to marginally depressed phagocyte function, increased serum protein, uric acid, and blood urea nitrogen (BUN), and decreased hemoglobin, iron, alkaline phosphatase, and gamma-glutamyltransferase (38). Bones most often affected are the tibiotarsus, femur, thoracolumbar vertebra, and humerus (362). Proximal physes of long bones are more frequently affected than distal physes. Lesions typically form where endochondral ossification is occurring and extend proximally to involve the adjacent physeal cartilage. It is common to find both osteomyelitis and tibial dyschondroplasia together, but this is most likely due to their occurrence at the same location rather than a cause and effect relationship. Osteomyelitis is easily recognized on gross examination of bones opened to expose the physes, but small lesions that can only be seen microscopically also occur (334).

Hock, stifle, hip, and wing joints and articulations of the free thoracic vertebra are sites where arthritis is most likely to occur (362). Lesions in other joints are less common. Trauma to joints
18.4.   Spondylitis involving articulating free thoracic vertebrae of two lame turkeys (fixed tissues). Pressure from the lesion on the spinal cord has caused demyelination of the ventral tracts. *Escherichia coli* is a common cause of this lesion, but other bacteria that can localize in bones and synovial tissues may also be a cause.

and growing bones may predispose to the development of lesions. Tenosynovitis frequently accompanies arthritis. Less commonly, spread of the inflammatory process from a joint into the periarticular tissues occurs. An infectious sternal bursitis is also common but must be distinguished from traumatic sternal bursitis in which fluid is seen but not exudate. When inflammatory lesions involve the shoulder joint or proximal humerus, extensive exudate can accumulate between the superficial and deep pectoral muscles (Figure 18.1E). Lesions that develop in joint spaces of the articulating free thoracic vertebra are characterized by spondylitis (spondylosis), which results in progressive paresis and paralysis (146)(Figure 18.4). Lesions in the distal articulation of the free thoracic vertebra occur more commonly than lesions in its proximal articulation or both articulations.

Turkey Osteomyelitis Complex. Turkeys with turkey osteomyelitis complex (TOC) have infectious, inflammatory lesions in bones, joints, or periarticular soft tissues and enlarged, green discolored livers that are used at processing to indicate the possible

presence of intraosseous lesions (80, 119, 221, 222). Green liver discoloration is rarely identified in the field even in lame turkeys. Most often green discolored livers are detected at processing and result in downgrading and, depending on severity, partial or whole bird condemnation. It is likely that green discoloration of the liver is more evident in processed birds because they have bled out in contrast to birds in flocks that either die or are euthanized.

In TOC, osteomyelitis and arthritis occur as described above. Spondylosis of the articulating free thoracic vertebra can be associated with green liver discoloration (30). Not all birds with green discolored livers have TOC, but generally birds with TOC have discolored livers (80). Feed and water withdrawal do not cause green liver discoloration (229), but infection with *Mycoplasma synoviae* was associated with a high percentage of carcasses with green discolored livers in the absence of TOC (30). The Food Safety Inspection Service in the United States uses green discoloration of the liver at processing to identify carcasses that may have TOC so that any abnormal tissue can be removed from the food chain. Osteomyelitis lesions can also be detected by ultrasonography (361). Tom turkeys are more affected than hens and affected birds have decreased cell-mediated immunity (38, 222).

Escherichia coli are frequently isolated from the lesions (80, 119), but other bacteria may also cause TOC lesions, especially *Staphylococcus aureus*, or *S. hyicus* (503)(see Staphylococcosis). Culturing bones and livers from affected and unaffected birds in two turkey flocks resulted in recovery of pleomorphic, Gram-variable bacteria consistent with L-forms (cell-wall-deficient forms). Positive cultures were obtained more frequently from affected birds and bones than from unaffected birds or livers. The significance of these organisms in the disease is unknown, but the high number of isolates suggests these bacterial forms may be more common in turkeys than has been generally realized (36).

A laboratory model of TOC based on injecting turkeys with dexamethasone followed by inoculation of low numbers of *E. coli* into an air sac has been developed and used to study the pathogenesis of the disease (219, 220, 222, 223, 224). Dexamethasone injections alone will reproduce the lesions of TOC by increasing susceptibility of the birds to opportunistic bacteria, particularly *S. aureus*. Exposure of turkeys to low levels of *E. coli* via air sac inoculation increases the occurrence of TOC (222). The current hypothesis is that TOC is related less to the virulence of the infecting bacteria than it is to an inappropriate response of a subpopulation of male turkeys to stress, which increases their susceptibility to opportunistic bacterial infections. The greater susceptibility of turkeys selected for rapid growth and higher body weights to experimental TOC further supports the concept of genetic susceptibility that is most likely mediated by how the birds respond to stress (218). The protective effect of vitamin D_3 (221) also suggests a possible genetic basis for TOC susceptibility related to vitamin D receptors and their function (222). However, when vitamin D metabolites were administered, TOC was reduced as with vitamin D treatment, but there were toxic effects in dexamethasone-treated turkeys challenged with *E. coli* (225).
18.5. Coligranuloma in a market-age turkey. Numerous, nodular lesions are located in gastrointestinal tissues including liver, but they do not involve the spleen. A mucoid *Escherichia coli* was isolated.

Coligranuloma (Hjarre's Disease). Coligranuloma of chickens and turkeys is characterized by multiple granulomas in liver, ceca, duodenum, and mesentery, but not spleen (Fig. 18.5). The disease also has been described in quail (91). Coligranuloma is an uncommon form of systemic colibacillosis that usually occurs sporadically in individual birds, but can cause mortality as high as 75% when a flock is affected. Serosal lesions resemble leukosis tumors. Early in the disease there is confluent coagulation necrosis involving as much as half the liver. Only scattered heterophils are seen, and at the edge of the necrotic areas there are a few giant cells. Subsequently typical heterophilic granulomas are present in the affected tissues. Pyogranulomatous typhlitis and hepatitis, which may be related to coligranuloma, have been described in turkeys with cecal cores and ruptured ceca (354).

Pathogenesis of the Infectious Process

Escherichia coli enter host tissues following mucosal colonization or directly through breaks or openings in the skin. Mucosal colonization is dependent on adhesin factors that permit the bacterium to attach to receptors and subsequently reproduce. A variety of fimbrial and non-fimbrial adhesins are produced by *E. coli,* which facilitates their attachment to host cells (see Virulence Factors). Good evidence exists that two fimbriae—Type 1 (F) and P fimbriae—are important in the initial stages of infection. Type 1 fimbriae are expressed by *E. coli* that attach to upper tracheal epithelium (422), oviductal epithelium (346), and digestive tract mucosae (121). P fimbriae are expressed in deeper tissues (422). Type 1 fimbriae bind to mucus in the digestive tract but not to goblet cells producing the mucus. In contrast, AC/I fimbriae bind poorly to mucus but attach to goblet cells (121). Flagella aid in penetrating the mucous layer in order to reach the cell surface, and curli, another adhesin factor, aids in attachment to the cell surface (288, 289).

Virulent strains are capable of traversing the mucosa, especially if an injurious agent has compromised it, and surviving within the internal milieu of the body. Air sac epithelial cells round up following inoculation with virulent strains, which causes them to separate from each other providing bacteria access to systemic tissues (105). Toxins in cell-free culture filtrates, most likely endotoxin, produce the same acute inflammatory response as the living organism (105). Other toxins that could aid or provide the same capability have been demonstrated in APEC (see Virulence Factors), but their role in disease has yet to be determined.

Once *E. coli* becomes extramucosal, the environment it has entered is extremely hostile. Unless the organism is equipped with survival capabilities (*e.g.*, "virulence" factors), it is rapidly destroyed by phagocytic cells such as heterophils, thrombocytes, and macrophages (197, 198, 542). Macrophages located primarily in the spleen and liver phagocytize bacteria that gain access to the circulation (18). Complement and antibodies to O antigens (endotoxin), outer-membrane proteins (siderophores), and fimbriae serve as opsonins to promote phagocytosis and destruction of the organism (19, 20). Endotoxin also decreases the bactericidal ability of pulmonary macrophages (129), which may aid in survival and dissemination of *E. coli.*

Immediately after *E. coli* contacts host tissues, there is an acute inflammatory response. Acute phase proteins produced in the liver and cytokines IL-1, IL-6, and tumor necrosis factor increase rapidly following exposure to endotoxin or *E. coli*, which can serve as nonspecific indicators of early disease (70, 381, 550). Acute phase effects of endotoxemia include decreased feed consumption and efficiency, body and breast weight, and tibial bone size, weight, calcium content, and breaking strength, and increased mortality, liver weight, plasma ionized calcium, and antibody responses. Increasing amounts of endotoxin in the circulation decreases body weight and bone breaking strength (341). Vascular permeability increases and fluid and protein accumulate in the tissue. Serous membranes become wet and edematous and liquid begins to accumulate in body cavities. Chemotactic factors attract heterophils, which marginate in post-capillary venules and emigrate into surrounding tissues (321). Between 6 and 12 hours soft, gelatinous exudate becomes grossly visible. Heterophils can kill *E. coli* extracellularly by substances

such as ß-defensins released as they degranulate and die (198, 496, 497). After 12 hours there is a progressive shift in inflammatory cells from heterophils to macrophages and lymphocytes.

Exudate continues to accumulate and eventually undergoes caseation to form a firm, dry, yellow, irregular, cheese-like mass. Microscopically caseous exudate consists of heterophilic granulomatous exudate containing variable numbers of embedded bacterial colonies. A palisade of multinucleated giant cells and macrophages surrounds the exudate (75). Depending on the size of the mass of exudate, an extended period of time will be required for the exudate to be slowly eroded away by the action of the surrounding phagocytic cells. Viable bacteria persist as microcolonies within the exudate. Epithelial tissue may be restored if damage has not been too severe, but usually there is some degree of fibrosis, which may be complete (scarring) if tissue destruction has been extensive. Exudate containing fibrin may undergo organization eventually being converted to scar tissue. Gross lesions are inversely related to virulence. Highly virulent strains cause mortality so quickly that gross lesions have little time to develop, whereas birds infected with less virulent strains survive longer and develop more extensive lesions.

Diagnosis

Isolation and Identification of Causative Agent

Diagnosis is based on isolation and identification of *E. coli* from lesions typical of colibacillosis. Care must be taken to avoid fecal contamination of samples. Isolation of the organism from visceral organs of birds undergoing decomposition must be interpreted cautiously as *E. coli* rapidly spreads from the intestinal tract of dead birds. Bone marrow cultures are easy to obtain and are generally free of contaminating bacteria. Material should be streaked on eosin-methylene blue (EMB), MacConkey, or tergitol-7 agar, as well as non-inhibitory media. A presumptive diagnosis of *E. coli* infection can be made if most of the colonies are characteristically dark with a metallic sheen on EMB agar, bright pink with a precipitate surrounding colonies on MacConkey agar, or yellow on tergitol-7 agar. Strains of *E. coli* can be slow or non-lactose fermenters and appear as non-lactose-fermenting colonies. Definitive identification of *E. coli* is based on the organism's characteristics (see Etiology). A flow chart for the isolation and identification of *E. coli* has been published (301). A number of manual and automated systems are available for identification of bacteria, including *E. coli.*

Antigenic identification, determination of virulence factors, or fingerprinting of the isolate might be helpful, particularly when done as part of an epidemiologic investigation. The correlation between virulence and complement resistance suggests this may be a good method for screening isolates for possible disease association. A relatively simple rapid turbidimetric assay has been described (408). A constellation of 6 virulence genes (*sitA, iroN, hlyF, iss, iutA,* and *etsA*; see Table 18.3) that appear to characterize virulent strains have been identified in >74% of APEC isolates, but only occur infrequently in commensal strains. A multiplex PCR to detect them may provide a means to distinguish between commensal and pathogenic isolates by laboratory methods without having to resort to either embryo or chick lethality tests in the future (L. Nolan, unpublished data).

Serology has not been used as a diagnostic method. However survival after challenge correlated better with antibody titers detected by an enzyme-linked immunosorbent assay (ELISA) than by the standard indirect hemagglutination procedure (303).

Procedures to detect acute phase proteins (70, 341, 381, 550) or shifts in the heterophil/lymphocyte ratio (183) can serve as nonspecific markers of the inflammation and stress that accompany colibacillosis.

Differential Diagnosis

Acute septicemic diseases may result from pasteurellae, salmonellae, streptococci, and other organisms. *Chlamydiophila*, pasteurellae (*Pasteurella, Ornithobacterium, Riemerella*), or streptococci *(Streptococcus, Enterococcus)* sometimes cause pericarditis or peritonitis and other bacteria, mycoplasmas, and *Chlamydiophila* can cause airsacculitis. Many organisms including viruses, mycoplasmas, and other bacteria can cause synovial lesions similar to those resulting from *E. coli* infection. A variety of organisms including *Aerobacter* spp., *Klebsiella* spp., *Proteus* spp., salmonellae, *Bacillus* spp., staphylococci, enterococci, or clostridia are frequently isolated (often as mixed cultures) from yolk sacs of embryos and chicks (200). Liver granulomas have many causes, including anaerobic bacteria belonging to the genera *Eubacterium* and *Bacteroides.*

Intervention Strategies

Management Procedures

Fecal contamination of hatching eggs is the most important way that *E. coli* are transmitted between flocks. Collecting eggs frequently, keeping nest material clean, not using floor eggs, discarding cracked eggs or those with obvious fecal contamination, and fumigating or disinfecting eggs within 2 hours after they are laid can reduce transmission. *E. coli* on the shell surface can be reduced or eliminated with sanitizers (465). Application of sanitizers by electrostatic spraying improves efficacy (446). Ultraviolet irradiation can reduce or eliminate *E. coli* and other bacteria on the surface of hatching eggs without altering conductance or hatchability (87). If infected eggs are broken during incubation or hatching, the contents are a serious source of infection to other chicks, especially when personnel and egg-handling equipment are contaminated. Eggs are particularly susceptible just before hatching. Methods for preventing incubator and hatcher dissemination are unknown. However, venting incubators and hatchers to the outside and having as few breeder flocks as possible represented in each unit will help reduce cross-contamination and losses. Chicks are colonized by strains of *E. coli* that they are exposed to in the hatchery from people or the environment and take the organisms with them when they are placed on the farm. Contaminated chicks survive better if kept warm and they are not deprived of food for an extended period of time.

Survival tends to be better in birds fed high protein diets, increased selenium (300), and increased vitamins A and E (226, 390, 504, 505). However, high levels of vitamin E can be detri-

mental to resistance to coliform cellulitis, colibacillosis, and antibody production (145, 307, 319, 464). Response to vitamin E is likely interrelated with the genotype of the bird (470, 554). Feeding can have an impact on severity of colibacillosis. Chickens fed on alternate days were more resistant to *E. coli* challenge than full-fed chickens (54, 423).

There are no known methods for reducing the level of pathogenic *E. coli* in the intestinal tract and feces, although consideration that 1) pelleted feed has fewer *E. coli* than mash, 2) rodent droppings are a source of pathogenic *E. coli,* and 3) contaminated water can contain high numbers of the organism should not be overlooked. Hot pelleting processes destroy *E. coli* (125), but care must be taken not to recontaminate finished feed. Adding 5–10% egg yolk powder to feed effectively reduced or eliminated *E. coli*, and other bacterial foodborne-illness pathogens in layers (270). Commercial broiler chickens and breeders were less productive when their water contained *E. coli* and nitrates (177, 178). Chlorination of drinking water and use of closed (nipple) watering systems have decreased the occurrence of colibacillosis and condemnations for airsacculitis (55, 108, 405). Pathogenic strains of *E. coli* can be competitively excluded from intestines of chicks by seeding them with native microflora from resistant chickens (535), commercial competitive exclusion products (194, 216), or *Bacillus subtilis* spores (290, 506). A similar effect was achieved following *in ovo* inoculation of *Lactobacillus reuteri* (122). Food and water deprivation increased the occurrence of spontaneous bacteremia (306).

Infection with *M. gallisepticum* and/or IBV overcomes the protective effect of native flora colonization (536). Raising mycoplasma-free birds and reducing exposure of birds to viruses causing respiratory diseases can reduce *E. coli* infection of the respiratory tract of birds. Effective vaccination to protect against respiratory tract pathogens and immunosuppressive agents that predispose to colibacillosis reduces occurrence of the disease (328).

Birds acquire nonspecific resistance to colibacillosis following moderate stress and socialization with people. Nonspecific resistance is short-lived and can be minimized by cold stress or corticosterone (326).

Maintaining good air and litter quality is fundamental to reducing risk of a flock developing colibacillosis (96). Fluctuating between cool and warm temperatures and modulating airflow have been used experimentally to produce colibacillosis in commercial chickens (245). Proper ventilation minimizes respiratory tract damage from ammonia and reduces the levels of bacterial and aerial endotoxin exposure. Ammonia, even at levels below those that can be detected by human smell, impairs mucociliary clearance of inhaled particulates (367, 397). Degree of damage to the respiratory mucosa correlates with ammonia exposure (366). Dust also increases the risk of colibacillosis (202). Bacteria preferentially adhere to dust particles because of electrostatic charges. The combination of dust and ammonia results in birds inhaling high numbers of bacteria and being unable to clear them from their respiratory tract.

Wet litter provides an excellent environment for *E. coli* to persist and reach high numbers. Higher numbers of *E. coli* and

Salmonella were found in litter that had water activity >0.9% and moisture content >35%. Air velocities across the surface of the litter of at least 100 ft/min produce drier litter and decrease the number of *E. coli* (431). Airflow across litter may not be uniform throughout a commercial broiler house. Low airflow correlated with high coliform counts in litter and litter with high numbers of coliforms was 16 times more likely to be in a low airflow area of the house (364). The incidence and severity of footpad dermatitis at processing can be used as an indicator of litter condition and air quality that were present during the production cycle (206). Maintenance of waterers is essential in eliminating wet spots in the house. Daily raking of soiled litter that builds up around feeders and waterers, removing heavily soiled litter, tilling, and replacing or covering wet litter with fresh dry litter are useful procedures for maintaining good litter quality.

Vaccination

Types of Vaccines
A variety of vaccines and vaccination methods have been developed including passive and active immunization, use of inactivated and live products, recombinant and subunit vaccines, and immunization against specific virulence factors. Most have not gone beyond the experimental investigation phase. No vaccination procedure has proved to be highly efficacious in commercial production and no product is used widely in the industry at the present time. A commercial vaccine containing F11 (PapA) fimbrial antigen and flagellar antigen (FT) is licensed in Europe for use in broiler breeders to provide natural passive immunity to progeny of vaccinated hens (Noblis E. coli Inac, Intervet).

Inactivated Vaccines. Effective inactivated vaccines against various serotypes including O2:K1 and O78:K80 have been produced (19, 68, 100, 101, 513). They provide protection against the homologous serogroups, but no significant cross-protection against heterologous serogroups. An inactivated O78 vaccine protected ducks (459). Both homologous and heterologous protection was provided by a vaccine prepared by ultrasonic inactivation of the organism followed by irradiation (336). A vaccine containing bacterial membrane vesicles was effective in protecting turkey poults against challenge with pathogenic *E. coli* by stimulating antibody production, bacterial-lysis activity of complement, T cell proliferation, and cytotoxic T cell activity (69). Multivalent vaccines made from pili containing low levels (180 μg) of protein per dose reduced the severity of challenge infection (193). Absorbed sera indicate pili of serotypes O1, O2, and O78 are antigenically different (499).

Live Vaccines. A live vaccine prepared from a naturally occurring, nonpathogenic, piliated *E. coli* strain (BT-7) was efficacious when used in chickens older than 14 days of age. Protection against both homologous and heterologous strains was demonstrated (147). *E. coli* J5, a mutant strain that has incomplete endotoxin in the cell wall exposing Gram-negative core antigen, was both safe and effective for protecting chicks (3, 4). Antibody titers to Gram-negative core antigens that develop in commercial chickens peak during the pullet period (445).

Recombinant and Mutant Vaccines. A *carAB* mutation of a virulent O2 serotype caused defective utilization of arginine and pyrimidines, increasing the requirements by the mutant. As low levels of these substances are generally available *in vivo*, the organism was unable to sustain itself, which resulted in a self-limiting infection. The mutant strain was found to be stable, immunogenic, and attenuated. Turkeys orally vaccinated with the mutant were protected against colibacillosis in a hemorrhagic enteritis virus-parent wild-type strain challenge model (286). Mutant O2 and O78 APEC with deletions of the genes *cya* or *crp*, which are involved in energy production, were used as a spray vaccine to immunize broiler chickens. The mutants were safe and immunogenic but provided only limited protection against airsacculitis following challenge (407). Similarly, strain O78 mutants with deletions of *galE*, *purA*, and *aroA* genes were found to be safe and immunogenic, but provided only moderate protection against homologous challenge with no protection against heterologous challenge (266).

In contrast to high mortality caused by the parent and wild-type strains, attenuated streptomycin-dependent (str-dependent) mutants derived from a virulent APEC did not cause mortality in challenged birds. No protection against cellulitis or systemic lesions resulted when birds were vaccinated with high numbers of the mutant strains by aerosol and oral routes. However, systemic lesions were significantly reduced when birds were given three vaccinations on days 1 (aerosol), 14 (oral), and 28 (oral) (13).

A recombinant vaccine using *Salmonella typhimurium* was constructed to produce homologous group B determinants and *E. coli* O78 antigen. Vaccinated birds seroconverted and were protected against subsequent challenge with a pathogenic *E. coli* O78 strain (437). A similar vaccine constructed to express *E. coli* type 1 fimbrial antigen in addition to O78 LPS provided protection against homologous challenge. The O78 LPS was responsible for most of the efficacy of the vaccine although presence of the fimbrial antigen did decrease the severity of air sac lesions. The fimbrial antigen did not provide cross-protection following challenge with O1 and O2 APEC serogroups (438).

A preliminary study on immunization of chickens with Iss, a surface protein common to APEC but not commensal *E. coli* that is important in complement resistance, suggests the potential to achieve cross-protection among different serotypes (317).

Fimbrial vaccines containing FimH, the adhesin of F1A (type 1) fimbriae, or PapGII, the highly conserved portion of P fimbrial adhesion, were immunogenic but did not provide protection against APEC challenge (526, 527). The results of PapGII immunization differ from the finding that passive immunization with PapG yolk-derived antibodies was protective (see Passive Immunization).

Passive Immunization. Passive immunization results in increased resistance to aerosol challenge and clearance of bacteria from blood (363). Use of inactivated vaccines in breeders provided passive protection against homologous challenge in progeny, which was complete for 2 weeks and partial for several additional weeks post-hatch (209, 442).

Antiserum prepared in rabbits against iron-regulated outer membrane proteins of *E. coli* protected turkeys against mortality following challenge. Frequency of bacteremia at 96 hours after challenge, recovery of *E. coli* from air sacs, and severity of gross lesions were significantly reduced in immunized birds compared with control birds given normal rabbit serum or saline solution (58).

Antibodies extracted from the yolk of eggs laid by immunized hens provided homologous protection against an O78 APEC. Partial protection against heterologous challenge with O1 and O2 serotypes was provided by immunizing hens with P pilus adhesin (PapG) or the aerobactin outer membrane receptor IutA. Immunizing with PapG provided the best overall protection. Breeder hens immunized by this method may provide immunity to their progeny (265).

Immunopotentiation. A problem with recombinant vaccines is low immunogenicity, which could potentially be solved by using effective immunopotentiators. Inoculation of chickens by intramuscular or subcutaneous routes and chicks by intramuscular or *in ovo* routes with cytosine-phosphodiester-guanine (CpG) oligodeoxynucleotides improved livability and reduced cellulitis lesion size following challenge with APEC (169, 170). CpG motifs are present in high numbers in bacterial DNA and enhance innate immune responses (24, 170). Modification of *E. coli* heat-labile enterotoxin (LT) resulted in a nontoxic protein (nLT) that stimulated antibody production in chickens following either oral or parenteral co-administration of an antigen to chickens (528).

Treatment

Antimicrobial Drugs

Antimicrobial drugs have been used extensively for reducing losses from colibacillosis since their first introduction for treatment of poultry in the mid-1950s. Occurring in parallel with use of an antimicrobial has been a progressive development of resistance, which was initially identified following introduction of tetracyclines (479). Antimicrobial resistance is determined genetically and is usually transferable within a species or between different types of bacteria via mobile genetic elements—plasmids, integrons, and transposons (34, 299, 553). The greatest reservoir for transferable antimicrobial resistance factors in the poultry flock environment is not *E. coli* or even Gram-negative bacteria, but gram-positive bacteria that comprise over 85% of the bacteria in poultry litter (382). The intestinal tract of the chicken is a suitable environment for transfer of genes from tetracycline-resistant to susceptible *E. coli* strains. Adding tetracycline to the chick's drinking water accelerates the process. Resistance to other antimicrobials is co-transferred along with tetracycline resistance (205).

Growing concern over antibiotic resistance, especially multidrug resistance, and the potential of bacterial strains affecting people acquiring transmissible resistance factors from bacteria in animals (see Public Health Significance), has led to changes in the way antimicrobials are used to treat colibacillosis in poultry (473). Additionally, new antimicrobials are not being developed for use in poultry and the ones that have been used previously have lost much of their efficacy due to acquired resistance.

Recently, fluoroquinolones became available in the United States and elsewhere for treatment of colibacillosis in poultry, which generally proved to be highly efficacious (165). However, societal concerns about resistance in some strains (39, 164, 252, 272, 540), development of cross-resistance among different quinolones, and importance of this class of antibiotics for treating people have led to their withdrawal for use in poultry in many countries including the United States. For a review of antimicrobial resistance of avian *E. coli* see (541).

When selecting an antimicrobial to use for treatment, it is important to determine the susceptibility of the isolate involved in the disease outbreak so that ineffective drugs can be avoided. APEC frequently are resistant to tetracyclines, sulfonamides, ampicillin, and streptomycin (339, 525, 541, 553). Multiresistance is common (525) and may occur in conjunction with virulence factors (255). Numerous recent studies on antimicrobial resistance of *E coli* isolates from chickens (12, 51, 157, 273, 299, 339, 349, 388, 517, 553, 561), turkeys (10, 86, 453, 517), ducks (344, 533), eggs (360), and poultry feed and ingredients (324) have been done in different geographic areas. All showed some level of resistance in APEC and commensal strains, but there were regional variations. Most *E. coli* isolates from shell eggs were susceptible to all antibiotics (360). Occasionally resistance is higher among commensal strains compared to APEC, *e.g.*, ampicillin resistance in turkeys (10) but, in general, resistance tends to be greatest in APEC strains. A high percentage of *E. coli* isolates from turkeys are resistant to gentamicin, which has been attributed to the widespread use of day-old gentamicin injection (10). Gentamicin resistance among chicken-origin *E. coli* was associated with significantly greater virulence in an embryo lethality assay (349).

Even a highly effective drug may not result in improvement of the flock if too little is used or it is incapable of reaching the site of infection. Therefore, underdosing may promote development of resistance. Chicks given feeds with increasingly lower concentrations of ampicillin (1.7 and 5 g/ton) developed resistance that was directly correlated to the amount of antibiotic in the feed (8). Paradoxically, certain antimicrobials and anticoccidials commonly used at subtherapeutic levels in poultry for growth promotion and coccidiosis control inhibited transfer of a plasmid that is responsible for multiresistance in *E. coli*. The basis for the inhibition was attributed to the ion-binding properties of the drugs and interference with DNA uptake channels in the organism (325). Selective pressure from exposure to an antibiotic is not always essential for resistance to develop (73). Although resistance generally occurs following prior contact with an antimicrobial, it can occur naturally in the absence of previous exposure. Resistance to florfenicol and chloramphenicol, which had never been used in poultry in the United States, was found in *E. coli* isolates from chickens in the southeastern United States (271).

Water administration of apramycin proved effective in reducing the numbers of organisms in the digestive tract and preventing bacteremia in chickens (306). Neomycin reduced mortality in turkey poults exposed naturally to litter from flocks with colibacillosis (323).

Anticoccidials also have antimicrobial activity that may be beneficial in the prevention and treatment of coliforms. Monensin reduced colonization of chickens with *E. coli* O157:H7 to undetectable levels 14 days post-exposure compared with nonmedicated controls and chickens receiving other coccidiostats (487). In a recent study TAMUS 2032, a cationic amphipathic peptide antibiotic produced by *Brevibacillus texasporus*, improved performance and reduced mortality when added to the feed of commercial broilers with or without monensin following natural environmental challenge. Improved livability and productivity also resulted from adding monensin with or without bacitracin. Bacitracin alone provided no protection against colibacillosis (245).

Other Treatments
The declining use of antibiotics for prevention and treatment of colibacillosis has stimulated interest in alternative methods including prebiotics, probiotics, enzymes, digestive acidifiers, vitamins, immune enhancers, anti-inflammatory drugs, and other antimicrobial products. Although prebiotics and probiotics are widely available for use in poultry, few studies on their effect on colibacillosis have been published. Colonization with *E. coli* begins immediately after hatching making early administration of probiotics essential (122). Administration of a bacteriocin-producing strain of *Lactobacillus plantarum* F1 or the purified bacteriocin provided chicks protection against challenge with an O2 APEC. Fermentation of coarsely ground wheat with a mixture of *L. plantarum* and *Pediococcus pentosaceus* completely eliminated *E. coli* when the pH of the mixture was <4.0 for at least 24 hours (353). *L. johnsonii* significantly reduced colonization of the small intestine with *E. coli*, but had no effect on colonization of the ceca or large intestine (294).

In addition to lactobacilli, other microbes can inhibit colonization with *E. coli*. Specific strains of *Bacillus* spp. inhibit *E. coli* colonization in the digestive tract and have potential use as probiotics (27, 290). Formation of highly resistant spores simplifies administration of these bacteria to commercial flocks through feed. Extracts prepared from *Bifidobacterium* enhanced resistance to colibacillosis following oral administration. Cell-mediated immunity was enhanced in the treated chickens (276). Inoculating young birds with nonspecific competitive exclusion products derived from healthy adults reduced intestinal colonization by APEC (216).

Essential oils often have substantial inhibitory effect on *E. coli* *in vitro* (196, 409) and in the lower intestinal tract of chickens (242). A commercial oregano oil product has been used in organic poultry production, but there are no studies on its effect on colibacillosis. Isopathic (immune enhancing) and homeopathic treatments with multiple products were unsuccessful in modifying the response of 8-day-old broilers challenged intratracheally with an O78 APEC strain (529).

Bacteriophage administration provides another possible alternative to antibiotic medication for controlling colibacillosis (32, 62). Two bacteriophages isolated from municipal wastewater that lysed an O2 APEC were effective in reducing mortality from experimental colibacillosis caused by the homologous APEC strain when high numbers of phage were mixed with the inoculum,

given as a spray up to 3 days prior to challenge, or inoculated intramuscularly up to 48 hours post-infection (230, 231, 232, 233, 235, 236). Combination of bacteriophage treatment with enrofloxacin had a synergistic beneficial effect (234). While bacteriophage treatment has been shown to be efficacious, several challenges remain before a commercial product might be realized (235).

Several studies have shown vitamin E supplementation to have both prophylactic and therapeutic benefits for *E. coli* infections (226), but not all studies support this conclusion (see Management Procedures). Differences in results likely are due to differences in experimental designs, especially severity of challenge and the timing and manner in which vitamin E is administered. Use of aspirin or sodium salicylate reduced the impact of experimental colibacillosis in turkeys (226) and chickens (311) respectively. However, if used in high levels or in combination with other products that impair the inflammatory response, a reverse response can occur (226). Feeding a beta-glucan product obtained from yeast cell walls improved the response of chickens to *E. coli* challenge, but also depressed growth of unchallenged controls (228).

Coliform Cellulitis (Inflammatory Process)

Jean-Pierre Vaillancourt and H. John Barnes

Introduction

Coliform cellulitis, also known as avian cellulitis, inflammatory process, infectious process, or IP, is caused by *Escherichia coli* and characterized by sheets of serosanguineous to caseated, fibrinoheterophilic exudate in subcutaneous tissues. Lesions, often referred to as plaques, are located in the skin over the abdomen or between the thigh and midline (see Figures 18.2H, 18.6, and 18.7). Other colibacillosis lesions or reduced productivity occasionally may accompany coliform cellulitis (11, 15, 38, 51), but usually lesions are discovered at processing when inspectors open the thickened yellow abdominal body wall of an otherwise normal carcass. Interactions among *E. coli*, the birds, and their environment contribute to the disease.

Coliform cellulitis has emerged as a significant disease since its description in 1984 (42) because of increased condemnations, downgrading at processing, and higher labor costs to process affected flocks. Between 1986 and 1996, condemnations for coliform cellulitis increased almost 12-fold in Canada. In 1996, 0.568% of all birds processed and approximately 30% of total condemnations were classified under cellulitis (24). In an Ontario study conducted in 2001, 1.11% of birds processed in federally inspected slaughter plants were condemned for cellulitis (49). Estimated annual losses to the U.S. broiler industry due to coliform cellulitis have increased from $20 million in 1991 to more than $80 million in 1998 (47).

Etiology

Escherichia coli is the most frequently isolated organism from cellulitis lesions and is considered the cause of coliform cellulitis in chickens. Other bacteria have been found (*Pseudomonas aeruginosa, Proteus vulgaris, Enterobacter agglomerans, Pasteurella multocida, Streptococcus dysgalactiae, Aeromonas, Staphylococcus aureus, Actinomyces pyogenes,* etc.) but are not believed to be significant (4, 12, 29, 31, 42, 48, 52). *E. coli* isolates from cellulitis lesions are of the same serogroups as those from birds with other forms of colibacillosis and usually produce colicin and aerobactin (40). Virulence properties and molecular characteristics are similar among isolates from cellulitis and coliisepticemic lesions and normal birds (13, 19, 30). However, iso-

18.6. Coliform cellulitis lesion at processing. Skin over the abdomen is thickened and has a yellow discoloration. Carcass is normal except for the skin lesion.
18.7. Coliform cellulitis lesion at processing. A caseous sheet of exudate, often referred to as a plaque, is located in the subcutaneous tissues beneath an area of thickened, yellow discolored skin.

lates from cellulitis lesions have a greater ability to produce cellulitis in experimentally exposed birds than *E. coli* isolates from airsacculitis lesions or feces of healthy chickens (5, 21, 41). Cellulitis-type and systemic-type strains of avian pathogenic *E. coli* can be selected that cause a predominance of either cellulitis or septicemic lesions, respectively (18). Leclerc *et al*. (2003) suggested that greater adhesive capacity of some *E. coli* strains to deep tissue layers may explain higher cellulitis prevalence in affected flocks.

A vacuolating cytotoxin produced by cellulitis *E. coli* isolates is also produced by isolates from chickens with colisepticemia and swollen head syndrome but not by isolates from healthy chickens. The cytotoxin is similar to one produced by *Helicobacter pylori*, except that *H. pylori* cytotoxin is specific for mammalian cells, and the avian *E. coli* cytotoxin is specific for avian cells (44).

Initially, isolates of *E. coli* from litter and lesions could not be differentiated based on biotyping, suggesting that the litter was the source of *E. coli* implicated in cellulitis lesions (10). But genotyping has shown that the prevalence of pathogenic *E. coli* in a broiler house is independent of the prevalence of other *E. coli* in the environment (20). DNA fingerprinting identified the presence of endemic populations of specific cellulitis-associated *E. coli* that exist in the broiler house environment. These organisms persist for at least 6 months irrespective of partial or complete cleaning and disinfection and cause coliform cellulitis in successive flocks (47, 48).

Epidemiology

Regional differences in the prevalence of coliform cellulitis emphasize the important roles of environmental and management factors in the occurrence of the disease. Increased condemnation rates due to coliform cellulitis during the past 15 years indicate that changes have occurred in either the incidence or characteris-

tics of risk factors associated with this disease over the same period. The most notable change during this time has been in the genotype and phenotype of the bird being raised, so it is not surprising that bird-related factors also contribute significantly to the incidence of scratches and subsequent coliform cellulitis.

Risk Factors
Breed
Fast-growing, heavy broiler strains are more likely to have an increased prevalence and severity of skin scratches, which predispose to coliform cellulitis. Several reasons may explain this association. The strength of the skin in broilers is related to genetics. The lack of association between scratches and abdominal circumference suggests that strain of bird *per se* could be a better predictor than body characteristics (9). Aggressiveness or nervousness of chickens may also be strain dependent. Birds from a more nervous strain could be more active, increasing the chances of being injured or scratched. If aggressiveness is a problem, the source could be farm dependent (e.g., behavioral studies have demonstrated the importance of socialization of the flock by the grower on the birds' behavior) (6). Rapid growth by modern broiler breeds results in higher stocking density sooner in the life of the flock, at a time when feathering is not yet well developed. Poor feathering and crowded conditions could have a significant impact on the incidence of coliform cellulitis. Macklin *et al*. (2002) showed that the major histocompatibility complex affects the likelihood of an individual chicken developing cellulitis, although not the severity of the lesion. Breed differences in immune response, feathering, and body conformation are known to exist, but their possible contribution to the occurrence of coliform cellulitis requires further studies.

Feathering
Feather cover helps protect the skin from damage. A positive association exists between scratches and poor feathering (8). Birds

with poor feathering have more abdominal skin exposed for a longer period of time than birds with good feathering. Although little is known about the nutrition and environmental factors that affect feather growth and development, birds kept in warm temperatures tend to feather less rapidly than birds kept in lower temperatures.

Sex

Coliform cellulitis occurs more frequently in males than females (7, 51). The gene responsible for sexing regulates feather growth. Slower feathering males may be more vulnerable to skin injuries because of greater exposure of the skin to potential physical damage. Sex may also contribute to coliform cellulitis because of its association with weight, aggressiveness, or management practices. Also, production time is longer for roasters than for broilers.

Stocking Density

Stocking density plays a dual role as a risk factor. It leads to an increase in skin scratches (8) and stress, but it also contributes by increasing the level of contact between birds. Cellulitis lesions occurred more readily when birds were palpated daily to simulate close contact among birds (29).

Litter

Flocks grown on straw were 2.8 times more likely to experience coliform cellulitis than flocks grown on shavings (7). Physically, straw consists of sharp, pointed pieces that may inflict minor injuries to the skin and predispose birds to infection. Straw may also provide a good medium for growth and multiplication of *E. coli* because of its ability to hold more moisture than shavings. A positive association also exists between the number of flocks raised on the same litter and cellulitis (46). However, this association could not be explained by an increase in litter bacterial load. Furthermore, litter environmental variables (water activity, pH, moisture content, and ammonia levels), as measured in this study, were also not significant. Nevertheless, litter quality should be considered an important factor by those working on reducing this condition in the field.

Total Down Time

Total down time is negatively associated with coliform cellulitis (i.e., the longer the down time, the lower the incidence of the disease) (2, 46). This supports the hypothesis that the bacterial load of the environment is associated with disease prevalence.

Ambient Air Temperature

In a prospective study, Schrader *et al*. (2004) found a positive association between ambient temperature during early grow-out and cellulitis. Their predictive model, after controlling for other significant variables, indicated a 40 to 60 percent increase in cellulitis as temperatures increased over a range of approximately 60°F (15.5°C) from 29°F (–1.7°C) to 94°F (34.4°C). Hence, low cellulitis prevalence flocks would increase from 0.5 to 0.8 percent, while high prevalence flocks would go from 1.2 to 1.9 percent.

Relative Humidity

Similar to ambient temperature, increased relative humidity at mid–grow-out correlated with increased occurrence of cellulitis. An increase in relative humidity from 36 to 93 percent was predicted to increase cellulitis from 0.3 to 0.9 percent in low-prevalence flocks and from 1.0 to 1.9 percent in high-prevalence flocks (46).

Feed

A positive association was observed between coliform cellulitis and feed company in a prospective study (7). The effect of nutrition on the pathogenic process of the disease is not well known. Amino acid levels in the feed may be important. Feed deficient in cysteine and methionine can cause nervousness and affect feathering (39, 45). A relative deficiency occurs in feeds with high energy to total protein ratios. High-energy feeds may also contribute to coliform cellulitis by increasing fat deposition in the skin, which may result in the skin being more susceptible to scratches and injuries (45).

Occurrence of coliform cellulitis was higher in vegetarian broilers compared to broilers fed feeds containing animal products. Condemnation rates for birds fed a standard diet, which contained growth promotants, antibiotics, and anticoccidials, was substantially lower (0.26 percent) than for birds fed a vegetarian or organic feed without additives (1.18 percent) (17).

Providing vitamin E at 300 mg/kg or vitamin A at 60,000 IU/kg improves the resistance of 6-week-old broilers against *E. coli* infection (50). Supplementation with vitamin E had a variable impact on the development of coliform cellulitis. Intermediate levels were superior to both lower and higher levels of the vitamin (27). Birds fed both vitamin E at 48 IU/kg and a zinc-protein complex at 40 ppm of zinc decreased the occurrence of coliform cellulitis (36). Improved wound healing and immune system potentiation by the supplements were considered responsible for the beneficial effect.

Pathobiology

Natural and Experimental Hosts

Coliform cellulitis affects chickens. Older chickens are more likely to develop lesions of cellulitis following inoculation of scratches or subcutaneous injection than young chickens, which tend to develop systemic disease and experience high mortality (14, 21, 22, 26, 33, 35, 41). Recently, a case in quail was described (2). Cellulitis also has been used to describe a skin disease that has recently emerged in turkeys. In Canada, on average, 0.37 percent of turkeys were condemned for cellulitis in 2005. In February 2006, the condemnation rate rose to almost 0.60 percent in some regions (3). However, the validity of this assessment has not been done, and several cases could be more consistent with gangrenous dermatitis. In late 1999, Gomis *et al*. (2002) identified 0.14 percent of about 27,000 birds examined at a slaughter plant as having cellulitis in legs or caudal thoracic area. These lesions were further categorized as cellulitis with open skin and no open skin lesions. Bacteria could be isolated from only about half the lesions. When present, *E. coli* was only pres-

ent in low numbers, often in association with other bacteria, such as *Proteus mirabilis, Lactobacillus* spp., *Klebsiella* spp., and *Staphylococcus* spp.

Pathology

Cellulitis lesions are primarily unilateral and located on the abdomen or thigh. Skin color varies from normal to yellow or red-brown, and the skin may be swollen at the site of inflammation (Fig. 18.6). The size of the lesion normally varies between 1–10 cm. (11). Scratches and scabs on the skin overlying the lesions often can be identified. Beneath the skin, there is subcutaneous edema, exudate, and muscle hemorrhage. A fibrinous to caseous plaque between the muscle and the subcutis is the characteristic lesion (Figs. 18.2H, 18.7).

Lesions develop rapidly; exudate is visible as early as 6 hours postinfection, and the caseous plaque could be experimentally produced within 18–24 hours postinfection. Rapid lesion development suggests that events occurring late in the life of the flock could be important in the development of lesions found at processing (14, 33). When birds were inoculated experimentally with *E. coli* strains isolated from coliform cellulitis lesions, the highest percentage of birds developing typical lesions had been challenged only 3 days prior to processing (32). Lesions were still present 3 weeks postinoculation (33).

High coliform cellulitis condemnation rates are not of hatchery origin. Scratching the dorsal skin surface of older birds and inoculating them with *E. coli* produces lesions referred to as type I coliform cellulitis, which have been thought to originate from navel infections in the hatchery. Bacteria and inflammatory exudate gravitate from the area where it originates to around the navel, producing the so-called type I lesion (34). In Canada, only 1.7 percent of coliform cellulitis lesions were consistent with a primary navel infection (11).

Experimental exposure of young chickens to cellulitis isolates of *E. coli* results in septicemia, death, or marked stunting, indicating that most birds affected by *E. coli* in the hatchery would either die or be culled before reaching the processing plant (21, 22, 35). No association between cellulitis and the source of eggs, age of parent flocks, total bacterial count, and coliform count in the hatchers was found (10).

Pathogenesis

Skin trauma, especially scratches, provides the main portal of entry into the host for specific cellulitis-type *E. coli* present in the litter. Applying bacteria to feather follicles from which the feather had been pulled did not cause coliform cellulitis. Oral feeding or swabbing the navel of young chickens did not produce cellulitis but did result in mortality, depressed growth, and other types of colibacillosis, which was dose dependent (22). The disease is reproduced readily by swabbing damaged skin with broth cultures or subcutaneous inoculation (14, 21, 22, 26, 33, 35, 41).

A recent study by Olkowski *et al*. (2005) compared a strain of fast-growing broiler chickens to a strain of leghorns. They concluded that the broiler strain was more predisposed to cellulitis because of an inferior first line of defense of their skin. Indeed, compared to leghorns, the wound-healing process was slower;

the lesions were more severe and covered a larger area; and the mobilization and functionality of phagocytic cells were inferior.

Usually, an affected bird has only skin lesions, but concurrent lesions of systemic colibacillosis occasionally can be found, suggesting that cellulitis may result from systemic spread or, conversely, that localized lesions in the skin can be a source for systemic disease. The latter is inversely correlated with age (i.e., the younger the bird, the more likely it is to develop systemic disease) (14, 21). Lesions have been correlated with other categories of condemnation in which *E. coli* would be expected to play a significant role (septicemia, airsacculitis, etc.) (10, 11, 13, 15, 51). Coliform cellulitis has been associated with previous outbreaks of colibacillosis in some flocks (40).

A positive association between cellulitis and ascites has been shown, but in one study, it could only account for 10 percent of coliform cellulitis cases (10, 51). Ascites is a common condition in broiler chickens characterized by an abnormally large abdomen. Because most cellulitis lesions are located in the abdominal area, it may be that ascites is a biological predisposing factor for cellulitis. Also, it is possible that both conditions may share common risk factors such as rapid growth.

Valgus-varus leg deformity, characterized by lateral or medial deviation of the distal tibiotarsus with a corresponding deviation of the tarsometatarsus, occurred more frequently in carcasses condemned for cellulitis, although in one study, the association was weak (10, 51). Valgus-varus deformity is considered to be the most frequent cause of leg weakness and lameness in broiler chickens (43). However, the association between valgus-varus deformity and coliform cellulitis needs to be interpreted with caution because of potential confounding with sex and breed. Most valgus-varus deformity affects male birds, and the incidence of coliform cellulitis can vary with breed. Birds with valgus-varus leg deformity spend more time lying on the floor (23), which results in greater contact exposure between the skin and the *E. coli* present in the litter. Also, prolonged resting by lame birds may result in skin damage as other birds tread on them (10).

Diagnosis

Cellulitis lesions are identified readily at processing, normally making it possible to use condemnation results to assess control strategies. However, an epidemiological study in Ontario has found that 30% of the variation in cellulitis prevalence was dependent on the slaughter plant (49). Therefore, the possibility of misclassification may exist, and should be considered in an investigation. Lesions should be cultured aseptically to determine the presence of *E. coli*. Currently, there is no *in vitro* method to distinguish cellulitis-type isolates from other types of the organism except by inoculation of scratches inflicted in the skin of older chickens (preferably greater than 3 weeks of age).

Prevention, Control, and Treatment

There is no treatment for coliform cellulitis, and eradication of the disease will not be possible because of the ubiquitous occurrence of *E. coli*. Recent advances in the development of immuno-

protective agents or immunomodulators suggest that a molecular approach to cellulitis control is possible, although not currently practical or economical (1). However, by carefully managing the environment and nutrition of the modern, fast-growing, heavy broiler, it is possible to substantially reduce the incidence and impact of the disease. A key aspect of any control strategy is its cost-benefit. Adequate monitoring to ensure implementation and compliance of control strategies will be needed to determine what is feasible. Interventions modifying the risk factors described previously can be envisioned, but the challenge will be to determine whether they are cost-effective. Following are some recommendations.

Time of Occurrence

Very early lesions consist mainly of serosanguineous fluid in contrast to the caseous lesions observed after 24 hours post-infection. When increased coliform cellulitis condemnations occur, it is important to determine the type of lesions (acute or chronic) found in the condemned birds. A high prevalence of acute lesions indicate that events occurring just prior to or during transportation should be investigated, especially if at least 10 hours exists between load-out and processing. In contrast, a majority of chronic lesions would indicate the need to focus on earlier events that occurred during the grow-out period.

Identify Risk Factors

Contrast problem flocks with flocks that did well during the same time period within the same company and determine the risk factors for each type of flock. Any management or environmental factors that affect the bird's resistance or contribute to skin scratches should be identified. Pay special attention to stocking density, feeder and waterer space (effective space—i.e., in some houses, the space is available, but the drinkers or feeders are not all functional), migration fencing, type of litter, quality of litter, and feed restriction and lighting programs. Any intervention must first focus on improving the environment of the birds. This includes good sanitation to reduce the bacterial load of the environment.

Monitor and Review Control Strategies

The best plan will fail if it is not fully implemented. Noncompliance is a key issue in health-related fields. Before judging the efficacy of a prevention measure, it is important to make sure that it was properly implemented.

Chapter 19
Pasteurellosis and Other Respiratory Bacterial Infections

Introduction
John R. Glisson

A number of distinct respiratory diseases are caused by small gram-negative bacteria in commercial poultry. These diseases may have very similar clinical presentations. Many of the etiologic agents of bacterial respiratory diseases are classified as members of the family Pasteurellaceae but have in recent years been designated to new genera. Recent reclassifications included changing the name of *Pasteurella haemolytica* to *Gallibacterium anatis biovar haemolytica, Pasteurella gallinarum* to *Avibacterium gallinarum*, and *Haemophilus paragallinarum* to *Avibacterium paragallinarum*. The current taxonomy reflects advancements in techniques for determining genetic relatedness among bacteria. The new taxonomy is used in this text.

Four distinct diseases are included in this chapter: fowl cholera caused by *Pasteurella multocida*, *Riemerella anatipestifer* infection, *Ornithobacterium rhinotracheale* infection, and bordetellosis. These diseases are grouped together because they are caused by organisms that are genotypically and phenotypically related and because they induce diseases in commercial poultry that may present in a clinically similar way. Other diseases of poultry caused by members of the family Pasteurellaceae, such as

fowl coryza caused by *Avibacterium paragallinarum*, are presented elsewhere in this text because the disease produced by infection with these organisms presents distinctly differently from the diseases included in this chapter.

In diagnostic poultry medicine, definitive diagnosis of fowl cholera, *Riemerella anatipestifer* infection, *Ornithobacterium rhinotracheale* infection, and bordetellosis is dependent upon the isolation and identification of the causative organism. Several organisms, such as *Avibacterium gallinarum,* which are of less importance as disease agents, may be isolated and must be differentiated from the more important disease agents included in this chapter. A clinical diagnostic text will be helpful in this regard (1).

Fowl Cholera
John R. Glisson, Charles L. Hofacre, and Jens P. Christensen

Introduction

Fowl cholera (FC) (avian cholera, avian pasteurellosis, or avian hemorrhagic septicemia) is a contagious disease affecting domesticated and wild birds. It usually appears as a septicemic disease associated with high morbidity and mortality, but chronic or benign conditions often occur. This disease is of historical importance because of its role in the early development of bacteriology and because it was one of four diseases the Veterinary Division

of the United States Department of Agriculture (USDA) was created to investigate.

History

Several epornitics among fowl occurred in Europe during the latter half of the 18th century. The disease was studied in France by Chabert in 1782 and in 1836 by Mailet, who first used the term *fowl cholera*. Huppe in 1886 referred to "hemorrhagic septicemia," and Lignieres in 1900 used the term *avian pasteurellosis*. Benjamin in 1851 gave a good description of the disease and demonstrated that it could be spread by cohabitation. With this knowledge of the disease, he formulated procedures for its

prevention. At about the same time, Renault, Reynal, and Dela-
fond demonstrated its transmissibility to various species by inoc-
ulation. In 1877 and 1878, Perroncito of Italy and Semmer of
Russia observed in tissues of affected birds a bacterium that had
a rounded form and occurred singly or in pairs. In 1879,
Toussaint isolated the bacterium and proved it was the sole cause
of the disease (54).

Pasteur (131) isolated the organism and grew pure cultures in
chicken broth. In further studies, Pasteur (132, 133) used the FC
organism to perform his classic experiments in attenuation of
bacteria for use in producing immunity. Salmon (159) appears to
have been the first to study the disease in the United States. A
good description of disease signs was reported, however, as early
as 1867 in Iowa, where losses of chickens, turkeys, and geese had
occurred (7).

Incidence and Distribution

Normal fowl cholera is more prevalent in late summer, fall, and
winter. This seasonal occurrence is one of circumstance rather
than lowered resistance, except that chickens become more sus-
ceptible as they reach maturity.

Etiology

Classification

Pasteurella multocida is the causative agent of FC. When pro-
nouncing *multocida*, the accent should be on the *ci* (19) rather
than on the *to* as given in the 7th and 8th editions of *Bergey's
Manual*. In the past, the bacterium has been given many names,
including *Micrococcus gallicidus,* 1883; *M. cholerae gallinarum,*
1885; *Octopsis cholerae gallinarum,* 1885; *Bacterium cholerae
gallinarum,* 1886; *Bacillus cholerae gallinarum,* 1886; *P.
cholerae-gallinarum,* 1887; *Coccobacillus avicidus,* 1888; *P. avi-
cida,* 1889; *Bacterium multicidum,* 1899; *P. avium,* 1903; *Bacil-
lus avisepticus,* 1903; *Bacterium avisepticum,* 1903; *Bacterium
avisepticus,* 1912; and *P. aviseptica,* 1920 (19, 22).

For a while, each isolate of *P. multocida* was named according
to the animal from which it was isolated, such as *P. avicida* or *P.
aviseptica, P. muricida* or *P. muriseptica.* In 1929, it was sug-
gested that all isolates be referred to as *P. septica* (175). This
name was used mainly in the United Kingdom and can be found
in recent literature. *Pasteurella multocida,* proposed by
Rosenbusch and Merchant (157), is now accepted as the official
name in *Bergey's Manual* and is used exclusively throughout the
world.

Morphology and Staining

P. multocida is a gram-negative, nonmotile, non-spore-forming
rod occurring singly, in pairs, and occasionally as chains or fila-
ments. It measures $0.2–0.4 \times 0.6–2.5$ mm but tends to become
pleomorphic after repeated subculture. A capsule can be demon-
strated in recently isolated cultures, using indirect methods of
staining (Fig. 19.1). In tissues, blood, and recently isolated cul-
tures, the organism stains bipolar (Fig. 19.2). Pili have been re-
ported (51, 141).
19.1. Electron photomicrograph of *Pasteurella multocida*-
encapsulated cell (C) and nonencapsulated cell (N) suspended in
India ink. ×19,000.

Growth Requirements

P. multocida grows aerobically or anaerobically. The optimal
growth temperature is 37°C. The optimal pH range is 7.2–7.8,
but growth can occur in the range 6.2–9.0, depending upon com-
position of the medium. In liquid media, maximum growth is ob-
tained in 16–24 hours. The broth becomes cloudy, and in a few
days, a sticky sediment collects. With some isolates, a flocculent
precipitate occurs.

The bacterium will grow on meat infusion media; growth is en-
hanced when the medium is enriched with peptone, casein hy-
drolysate, or avian serum. Blood or serum from some animals in-
hibits growth of *P. multocida.* Inhibition is greatest from blood of
horses, cattle, sheep, and goats; blood of chickens, ducks, swine,
and water buffalo has little or no inhibitory action (158). Several se-
lective media for isolation have been described (29, 30, 47, 99, 115,
165). Chemically defined media have been described by Jordan
(91), Watko (172), Wessman and Wessman (174), and Flossmann *et
al.* (45). Berkman (11) found that pantothenic acid and nicotinamide
are essential for growth. Dextrose starch agar with 5% avian serum is
an excellent medium for isolating and growing *P. multocida.*

Colonial Morphology and Related Properties

Colonial morphology observed with obliquely transmitted light
is one of the most useful characteristics in the study of *P. multo-*
19.2. *Pasteurella multocida* in liver imprint from chicken with acute FC (note bipolarity). Wright's stain, ×2500.

cida. On primary isolation from birds with FC, colonies may be iridescent, sectored with various intensities of iridescence, or blue with little or no iridescence (Fig. 19.3). Iridescence is related to the presence of a capsule. The term *fluorescent* used to describe colonies in older literature should be considered synonymous with the term *iridescent*; the latter is the appropriate term.

The composition of the medium determines to a certain extent the degree and type of iridescence. Occasionally, an isolate produces blue colonies; when serum is added to the medium, sectored or iridescent colonies are sometimes produced. Examination of 18- to 24-hour colonies with a stereomicroscope using obliquely transmitted light (Fig. 19.4) is helpful when observing colonial morphology (76). Iridescent colonies on primary isolation from acute cases of FC are circular (2–3 mm), smooth, convex, translucent, glistening, and butyrous and show a tendency to coalesce. As the colony ages, it usually loses these distinguishing properties, becomes larger and viscous, and may adhere to the medium when picked with an inoculating needle. Blue colonies often isolated from birds with the chronic type of cholera or derived by dissociation of iridescent colonies are circular (1–2 mm), smooth, slightly convex or flat, translucent, butyrous, and discrete. The watery mucoid colonies produced by encapsulated strains from the respiratory tract of cattle, swine, sheep, rabbits, and humans are not iridescent but gray (70).

Anderson *et al.* (5) observed that a highly virulent isolate, which produced smooth colonies, later dissociated on subculture and produced rough colonies. Organisms from the smooth colonies were approximately 3–4 million times more virulent for pigeons than those from rough colonies. Hughes (81) studied the colonial morphology of 210 cultures from cases of FC and distinguished three types. The iridescent type was associated with
19.3. *Pasteurella multocida* 20-hour colonies on dextrose starch agar viewed with obliquely transmitted lighting (see Fig. 19.4). I. Iridescent. S. Sectored. B. Blue C. Rough. ×20.

outbreaks of acute FC and was highly virulent. The blue type was of low virulence and occurred in flocks in which cholera was enzootic. The third type was intermediate in its properties of iridescence and virulence.

Heddleston *et al.* (71) reported that a virulent isolate of *P. multocida* of avian origin produced iridescent colonies that dissociated *in vitro* and produced blue colonies. Organisms from blue colonies also mutated and produced gray colonies, which have not been reported in primary cultures from birds. Cells from iridescent colonies occurred singly or in pairs, did not agglutinate in immune serum, were encapsulated, and were virulent for chickens, turkeys, rabbits, and mice when administered on mucous membranes of the upper air passages. Cells from blue colonies occurred singly or in pairs, were agglutinated by immune serum, were unencapsulated, and were avirulent when applied to mucous membranes of chickens and mice but were virulent for rabbits and slightly virulent for turkeys. Cells from gray colonies occurred only as chains and were unencapsulated and avirulent. Killed organisms from all three colonial forms induced immunity in chickens. Antigens extracted with hot saline from highly virulent encapsulated cells of iridescent colonies by Yaw and Kakavas (178) actively immunized chickens and mice, whereas less virulent unencapsulated cells from blue colonies immunized chickens more effectively than mice.

Physiologic Properties

The physiologic properties of *P. multocida* are used for identification. *P. multocida* does not produce gas but produces oxidase, catalase, peroxidase, and a characteristic odor. Unlike most gram-negative bacteria, it is sensitive to penicillin. The results of 29 other physiologic tests with 948 cultures of avian origin are shown in Table 19.1.

Significant differential characteristics are listed in Table 19.2.

Resistance to Chemical and Physical Agents

P. multocida is destroyed easily by ordinary disinfectants, sunlight, drying, or heat, being killed within 15 minutes at 56°C and 10 minutes at 60°C. A 1% solution of formaldehyde, phenol, sodium hydroxide, betapropiolactone, or glutaraldehyde and a 0.1% solution of benzalkonium chloride killed within 5 minutes 4.4×10^8 organisms of *P. multocida*/ml suspended in 0.85% saline solution at 24°C.

Das (29) observed that cotton swabs saturated with blood from infected mice contained viable organisms after 118 hours but not after 166 hours (at which time the swabs were completely dry); films of blood on glass contained viable organisms after 24 but not 30 hours. Das also reported that infected blood sealed in glass tubes and held in a cold room contained viable organisms after 221 days. Skidmore (164) observed that the organism survived in dried turkey blood on glass for 8 but not 30 days at room temperature. In studies of environmental influence on the incidence of FC, Van Es and Olney (169) found the infection hazard had apparently disappeared from a poultry yard 2 weeks after occurrence of the last death and removal of birds.

Influence of temperature on viability and virulence of *P. multocida* was studied by Nobrega and Bueno (124), who observed that broth cultures stored in sealed tubes at an average room temperature of 17.6°C were still virulent after 2 years; at 2–4°C, they were nonviable after 1 year. With controlled experiments, Dimov (35) observed that *P. multocida* died rapidly in soils with moisture content of less than 40%. At a moisture content of 50% and temperature of 20°C, it survived for 5–6 days at pH 5.0, 15–100 days at pH 7.0, and 24–85 days at pH 8.0. A culture survived without loss of virulence for 113 days in soil with 50% moisture at 3°C and pH 7.15.

Cultures may be maintained without dissociation or loss of virulence in the lyophilized state or sealed in glass tubes and stored at 4°C or colder (173). Lyophilized cultures tested after 26 years were still virulent for chickens, and a culture sealed in a rubber-stoppered bottle containing beef infusion broth with 50% horse serum and held at room temperature was virulent after 26 years (63).

Subgrouping of P. multocida

Based upon DNA homology studies *P. multocida* has been divided into three subspecies namely *P. multocida* subspecies *multocida*, *P. multocida* subspecies *septica* and *P. multocida* subspecies *gallicida* (119). The subspecies can be differentiated by their physiologic properties (119). Important differential characteristics are listed in Table 19.3. By the use of full phenotypic characterization, Fegan *et al.* (43) were able to identify 10 biotypes among a strain collection including all three subspecies of *P. multocida* (43). All three subspecies of *P. multocida* have been isolated from outbreaks of fowl cholera (166, 77, 43). However, it appears that subspecies *multocida* is the most common subspecies isolated from chickens and turkeys and that only a minor percentage of isolations is made up by strains of subspecies *septica* (166, 43, 117). *P. multocida* subspecies *multocida* also seems to represent the predominant type of raptors and psittacines (113, 114) Subspecies *gallicida* is mainly associated with web-footed

birds (77, 116, 52). The most recent taxonomic investigations of *P. multocida* include sequencing of 16S rRNA and housekeeping genes and indicate that subspecies *multocida* and *gallicida* belong to the same phylogenetic lineage and that subspecies *septica* makes up a separate lineage. Phenotypic criteria for separation of these two lineages, however, remain to be identified (15).

Conventional subgrouping of *P. multocida* entails serological determination of capsular and somatic antigens. Specific capsule serogroup antigens are recognized using passive hemagglutination tests (24). Five capsular types (A, B, D, E, and F) are currently recognized (153). Carter (24) studied numerous isolates from various animals and found capsular types A and D were isolated from fowl and other animals. In a study of isolates representing a variety of avian hosts, Rhoades and Rimler (144) found organisms belonging to A, B, D, and F. Presumptive identification of capsular types A, D, and F can be determined by capsule depolymerization with specific mucopolysaccharidases (151). However, a highly specific multiplex capsular PCR assay has been developed which enables less laborious and more specific capsular typing than conventional tests. (168)

Somatic serotyping has been done by tube agglutination test (120) and gel diffusion precipitin methods (73). Comparative studies by Brogden and Packer (20) indicated that a serotype determination by one method did not correlate with a serotype determination by the other method. Often, cultures that represented a single somatic serotype in a particular test represented more than one serotype in the other test. Because of its simplicity, the gel diffusion precipitin test is used routinely in the United States, and its popularity is increasing throughout the world. The test uses antisera prepared in chickens and heat-stable antigens extracted from formalinized saline suspensions of the bacteria. The heat-stable antigens form lines of identity with lipopolysaccharide-protein complexes from culture supernatants (73). Somatic serotype specificity seems to be determined by the lipopolysaccharide component of a complex (149). Heddleston *et al.* (73) found there was good, though not absolute, correlation between

the gel precipitin test and the immune response in chickens and turkeys. Rimler and Phillips (152) showed that lipopolysaccharide combined with carrier protein protected chickens against FC. To date, 16 somatic serotypes have been described (21). All of these somatic serotypes have been isolated from avian hosts. Correlation between subspecies and serovars of *P. multocida* obtained by traditional serotyping systems has not been demonstrated (16). During the years, somatic serotyping has provided useful information regarding the diversity of avian *P. multocida* strains, however, some particular serovars predominate in certain geographical regions making detailed conclusions concerning the epizootiology of *P. multocida* difficult. Thus, Snipes *et al.* (166) found that more than 60% of clinical *P. multocida* isolates from turkeys in California belonged to serovar 3,4 (161) and according to Gunawardana *et al.* serovar 1 dominates in Vietnam (56). In Australia, serovar 3 appears to dominate (16). In addition, phenotypic and genotypic variation within a given serovar has been demonstrated several times and underlines the limitations of serotyping as a method for strain differentiation (16, 23, 96, 176).

Other phenotypic methods of grouping strains of *P. multocida* have included phagetyping and Multi-Locus Enzyme Electrophoresis (MLEE). Phage sensitivity as a basis for grouping *P. multocida* has been investigated. Rifkind and Pickett (148) found that 84 of 118 isolates from various hosts were sensitive to one or more of 16 bacteriophages. Kirchner and Eisenstarck (97) examined 25 cultures of avian origin and found that 11 were lysogenic. They divided the 11 bacteriophages into five groups based on their host range, and into three groups based on plaque morphology. Karaivanov and Mraz (94) identified 87% of 77 cultures of *P. multocida* using one strain of bacteriophage. Saxena and Hoerlein (160) demonstrated lysogeny in 63 of 112 cultures from various hosts. One phage caused lysis of 8 different cultures; many were lysogenic for only 1 or 2 cultures. Gadberry and Miller (46) showed that 32 of 61 isolates were sensitive to 1 or more of 3 phages. Isolates of *Gallibacterium anatis, Avibacterium gallinarum, Actinobacillus ureae, [P.] pneumotropica*, and three species of the genus *Yersinia* were resistent to lysis. Results of these investigations demonstrated the possibility of a phage grouping system for *P. multocida*.

The analysis of isoenzymes, i.e. enzymes with the same functional activity but encoded by different alleles, has been used for many years in the study of eukaryotic population genetics (101), and has more recently been applied to prokaryotic organisms (161). Recently, Blackall *et al.* used MLEE to investigate the population stucture of Australian *P. multocida* isolates obtained from poultry (17). Although the 81 field isolates of *P. multocida* investigated were diverse, being divided into 56 electrophoretic types (ETs) the overall population structure was shown to form a clonal population in which little horizontal gene flow apparently had been occurring. No obvious correlation between serotype or subspecies and particular ETs was found.

Among phenotypically based methods used for grouping strains of *P. multocida* MLEE has provided the highest discriminatory power and has been suggested as a tool for elucidating the complex epizootiology of *P. multocida* infections (17). Data pub-

lished on antibiotic resistance profiling do not seem to provide enough discriminatory power to allow its use for epidemiological investigations (126).

A number of nucleic acid based typing methods have been introduced for differentiation of avian strains of *P. multocida*. In favor of these methods, they do not depend on expression of phenotypic properties, all strains are typeable and the discriminatory power generally high (126). Bacterial genomes can be compared by electrophoretic separation of DNA fragments generated *in vitro* by digestion with restriction enzymes. To simplify the reading of results, the DNA fragments may be transferred to hybridization membranes and hybridized with a labelled hybridization probe (RFLP: Restriction Fragment Length Polymorphism), in which case the strain comparison is only based on restriction fragments that show homology to the probe. Strains that are of the same origin are anticipated to have the same genome and therefore both the same number and the same position of recognition sites for a restriction enzyme. Restriction enzyme analysis (REA) and RFLP of *P. multocida* have been used extensively to obtain knowledge about routes of transmission and about strain diversity in outbreak situations (23, 25, 113, 114, 166, 177). The restriction enzymes *Hpa*II and *Hha*I are most frequently used (26). Recently, also amplified fragment length polymorphism (AFLP) has proved useful for epidemiological purposes (41). This method is based on amplification of genomic fragments by the use of nonspecific primers following restriction endonuclease digestion and ligation of appropriate adaptors.In addition, RFLP analysis results have supported the population structure data on *P. multocida* obtained by MLEE (16). Pulsed Field Gel Electrophoresis (PFGE), using rare cutting restriction enzymes, allows the resolution of large DNA fragments reflecting restriction fragment length polymorphism throughout the entire genome. Gunawardana *et al.* (56) demonstrated a very high discriminatory power of PFGE using the technique on avian isolates of *P. multocida* originating from Australia and Vietnam.

In recent years, polymerase chain reaction (PCR) based methods have been used for differentiation of avian *P. multocida* isolates. Hopkins *et al.* succesfully used arbitrary primed PCR (AP-PCR) to distinguish the CU vaccine strain from fowl cholera outbreak strains (79). Repetitive extragenic palindromic sequence PCR (REP-PCR) has also been shown to be of value in identifying epidemiologically related and unrelated strains from Australia and Vietnam (56).

The use of plasmid profiling in subtyping of *P. multocida* has been of limited use due to a low number of plasmid carrying strains. Most investigations using this technique have shown that only approximately 20% of the isolates carry plasmids (25, 166).

Pathogenicity

Pathogenicity or virulence of *P. multocida* in relation to FC is complex and variable, depending on the strain, host species, and variations within the strain or host and conditions of contact between the two. The ability of *P. multocida* to invade and reproduce in the host is enhanced by the presence of a capsule (see Fig. 19.1) that surrounds the organism (104). Loss of ability of a virulent strain to produce the capsule results in loss of virulence

(71). Many isolates from cases of fowl cholera have large capsules but are of low virulence. Therefore, virulence is apparently related to some chemical substance associated with the capsule, rather than with its physical presence.

P. multocida usually enters tissues of birds through mucous membranes of the pharynx or upper air passages, but it may also enter through the conjunctiva or cutaneous wounds. Hughes and Pritchett (82) were unable to infect chickens by placing a culture in a gelatin capsule and inserting it into the esophagus, but chickens were infected when the culture was dropped on the roof of the nasal cleft. Arsov (8) infected birds by mouth, using ^{35}P-labeled culture, and observed that the portal of infection was the mucous membrane of the mouth and pharynx but not the esophagus, crop, or proventriculus. The eustachian tube was suggested by Olson and McCune (127) as the most likely route of infection, because the infection localizes in air spaces of the cranial bone, middle ear, and meninges.

Turkeys are much more susceptible than chickens to infection with *P. multocida,* and mature chickens are more susceptible than young ones (62). Hungerford (83) observed heavy losses in mature chickens, but no losses in birds up to 16 weeks of age in a case involving 90,000 birds. When testing infectivity of an isolate or susceptibility of a host, cohabitation is the most natural method of exposure. Unless the host is highly susceptible and the isolate highly invasive, however, results may be slow. Therefore, it is often advantageous to swab the nasal cleft with cotton saturated with the culture; if a more severe exposure is required, the culture can be injected parenterally.

Toxicity

A dried culture filtrate of *P. multocida* was first demonstrated to produce signs of toxicity in chickens by Pasteur (131). Salmon (159) repeated this work and described signs resulting from toxicity similar to those observed in cases of acute FC. Kyaw (100), using the developing chick embryo in the study of pathogenesis, suggested that a toxin was produced *in vivo* by *P. multocida.* Rhoades (143) observed severe general passive hyperemia in chickens that died from acute FC. This lesion was considered to be indicative of shock and was attributed to the action of endotoxin.

Endotoxins

Endotoxins are produced by all *P. multocida,* both virulent and nonvirulent. They may contribute to virulence; however invasion and multiplication of a strain are necessary for the production of sufficient quantities of endotoxin *in vivo* to contribute to pathologic processes.

Pirosky (137) obtained an endotoxin from *P. multocida* of avian origin by the trichloroacetic acid extraction procedure of Boivin. Heddleston and Rebers (67) demonstrated that a loosely bound endotoxin could be washed from *P. multocida* with cold formalinized saline solution. This endotoxin was a nitrogen-containing phosphorylated lipopolysaccharide, readily inactivated under mild acid conditions. Signs of acute FC were induced in chickens by injection of fractional amounts of endotoxin. The LD_{50} for chicken embryos was 5.2 mg via the

chorioallantoic membrane; the LD_{50} for mice was 194 mg via the peritoneal cavity. One dose of 1.9 mg injected intravenously killed five of six 19-day-old turkeys; the median death time was only 3 hours. The endotoxin was present in the vascular system of turkeys with FC and could be detected with the Limulus lysate test and antiserum in the gel diffusion precipitin test. The serologic specificity of the endotoxin was associated with the lipopolysaccharide. Free endotoxin induced active immunity.

Purified lipopolysaccharides of each of the Heddleston serotypes were prepared by Rimler *et al.* (154). The lipopolysaccharides were similar to those of other gram-negative bacteria. Week-old poults were relatively resistant to the lethal effects of purified lipopolysaccharides from two highly pathogenic FC strains of *P. multocida* (145). In poults, the lipopolysaccharides did not provoke a dermal Shwartzman reaction, and lethality was not enhanced by a liver-damaging substance, a histamine-releasing substance, or a surgical bursectomy.

Protein Toxins

Heat-labile protein toxins have been found in serogroup A and D strains isolated from different animal species. Nielsen *et al.* (123) found 6 of 10 turkey strains produced heat-labile protein toxins; the strains were not serotyped. Four serogroup D strains isolated from turkeys were found to contain a heat-labile toxin (146). Sonicated suspensions of these strains produced necrotic lesions in turkey skin and were lethal to poults. Antiserum prepared against the heat-labile toxin from a swine strain neutralized the ability of the avian strain sonicated material to produce skin necrosis (147). Baba and Bito (9) chemically purified a protein toxin from an avian strain.

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Most reported outbreaks of FC affected chickens, turkeys, ducks, or geese. However, this disease also affects other types of poultry, game birds raised in captivity, companion birds, birds in zoos, and wild birds. The wide range of avian hosts in which FC has been reported suggests that all types of birds are susceptible.

Among types of poultry, turkeys are most affected. Most or all in an infected flock may die within a few days. The disease usually occurs in young mature turkeys, but all ages are highly susceptible. Under experimental conditions, 90–100% of mature turkeys may die within 48 hours when exposed to a highly virulent strain of *P. multocida* by swabbing the palatine cleft or by contact with infected birds.

The disease in turkeys was first reported in detail by DeVolt and Davis (34), who described an outbreak in a flock of 175 turkeys in Maryland, where the mortality was 17%. Alberts and Graham (2) described outbreaks in four flocks of turkeys in which mortality was 17–68%. They emphasized that environmental stressors such as changes in climate, nutrition, injury, and excitement may have influenced the incidence and course of the disease.

Death losses from FC in chickens usually occur in laying flocks, because birds of this age are more susceptible than younger chick-

ens. Chickens less than 16 weeks of age generally are quite resistant. Fowl cholera in young chickens usually is caused by serotype 1 and often occurs in conjunction with some other malady. Recent outbreaks of FC in six flocks of 20–46-day-old broilers, however, resulted from infections with serotypes 3; 1,3; and 3,4. Experimental challenge of 5-week-old broilers with two representative strains (serotypes 3 and 1,3) resulted in mortality and lameness. In naturally infected chickens, mortality usually ranges from 0–20%, but greater losses have been reported. Reduced egg production and persistent localized infection often occur. Chickens are more susceptible to FC after withdrawal of feed and water or after an abrupt change of diet (18). Heat or rough treatment on a shaking machine increased the incidence in chickens exposed experimentally (92, 93).

Under experimental conditions, 90–100% of mature chickens exposed by swabbing the palatine cleft may die within 24–48 hours, depending on the strain of *P. multocida* used, but only 10–20% usually die within a 2-week period when exposed by contact with infected birds. Pritchett *et al.* (139) observed mortality of 35–45% in three houses of pullets. In one house, 45% of the birds died within 4 weeks. In a flock of 45 birds that had survived an acute outbreak the previous year, no losses were observed, but the number of birds with localized lesions increased during winter. In South Carolina and adjoining areas, FC existed mainly as a persistent, subacute chronic disease that clinically resembles avian monocytosis (13).

Domestic geese and ducks are also highly susceptible to FC. Curtice (28) reported the disease in geese in Rhode Island, where about 3200 of a flock of 4000 died in a short period. Van Es and Olney (169) recognized the marked susceptibility of geese to FC, in using them to test for persistence of viable organisms in lots after removal of infected chickens. Fowl cholera in ducks has been a serious problem on Long Island, where it was diagnosed on 32 of 68 commercial duck farms. Losses usually occur in ducks greater than 4 weeks of age, and mortality may reach 50% (40).

Birds of prey, waterfowl, and other birds kept in zoologic gardens occasionally succumb to infection; *P. multocida* has been isolated from more than 50 species of feral birds. During a $2\frac{1}{2}$-year survey, Faddoul *et al.* (42) isolated *P. multocida* from 13 (seven species) of 248 feral birds submitted to the diagnostic laboratory. Jaksic *et al.* (89) described an acute epornitic among pheasants, in which 1700 died. An outbreak in the San Francisco Bay area was reported to have been responsible for an estimated loss of 40,000 waterfowl (156). Gershman *et al.* (48) observed a serious outbreak among eider ducks (*Somateria mollissima*) in their nesting area 6 miles off the coast of Maine, where more than 200 birds died and more than 100 nests were lost. More than 60,000 waterfowl died of FC during the winter of 1956–1957 at the Muleshoe National Wildlife Refuge in Texas (90). Rosen (155) reported that there are two areas in the United States where fowl cholera is enzootic in waterfowl: the Muleshoe National Wildlife Refuge and the north central area of California. Both locations have had periodic outbreaks since 1944.

P. multocida from birds with FC usually will kill rabbits and mice, but other mammals are resistant to infection. According to

Heddleston and Watko (69), rabbits, mice, pigeons, and sparrows died of acute septicemia when exposed intranasally to an isolate of *P. multocida* from an acute case of FC; rats, ferrets, guinea pigs, a sheep, a pig, and a calf did not show any clinical response to the same organism. One of 5 rats, 1 of 2 mink, and 11 of 19 mice fed viscera of infected chickens developed nasal infection, pneumonia, and fatal septicemia, respectively. A calf died of acute septicemia less than 18 hours after intramuscular (IM) exposure. Guinea pigs exposed by IM inoculation developed necrosis at the inoculation site; those exposed intraperitoneally usually died.

Horses, cattle, sheep, pigs, dogs, and cats are refractory to oral inoculation, and subcutaneous (SC) inoculation results in localized abscesses. All of these animals, however, may succumb to intravenous inoculation.

Transmission, Carriers, and Vectors

How FC is introduced into a flock is often impossible to determine. Chronically infected birds are considered to be a major source of infection. The only limit to the duration of the chronic carrier state is the lifespan of the infected bird. Free-flying birds having contact with poultry may be a source of FC organisms. Transmission of the organism through the egg seldom, if ever, occurs. A study of more than 2000 fresh and embryonated eggs from chickens infected with chronic FC yielded no evidence that *P. multocida* was transmitted through the egg (163).

Pritchett *et al.* (139, 140) and Pritchett and Hughes (138) examined three infected commercial flocks of white leghorns for *P. multocida* and found that many birds harbored the organism in nasal clefts. Presence of the bacterium was related to severity of upper respiratory infection in the flocks. They concluded that the enzootic focus of infection was healthy nasal carriers. These studies, as well as those of Van Es and Olney (169) and Hall *et al.* (58), proved that survivors of an epornitic of FC may be reservoirs of infection. Dorsey and Harshfield (39) reported a higher incidence of FC during late summer and fall in South Dakota. Carrier birds among the older flock, held over for a second year, provided a reservoir of infection for young susceptible pullets housed with them.

Most species of farm animals may be carriers of *P. multocida*. Generally, these organisms, except for those from swine and possibly those from cats, are avirulent for fowl. Iliev *et al.* (85) isolated *P. multocida* from tonsils of 34 of 75 slaughtered cattle, 14 of 27 sheep, and 102 of 162 pigs. Isolates from cattle and sheep were not pathogenic for fowl, but all 18 isolates from pigs in areas where FC was common were highly pathogenic for fowl. Only 2 of 47 isolates from pigs in areas having low incidence of FC were pathogenic. Iliev *et al.* (86) also reported that healthy pigs that were carriers of *P. multocida* transmitted infection to fowl in the same enclosure. Two isolates, serotypes 1:A and 5:A, from lungs of pigs with pneumonia, were studied by Murata *et al.* (118). Serotype 5:A was highly virulent for chickens, and serotype 1:A was avirulent. They found no cross-immunity in chickens between the two serotypes.

Gregg *et al.* (55) isolated two cultures from raccoons that were pathogenic for turkeys. They suggested that raccoons are a reser-

voir of *P. multocida*, and the organisms may be transmitted to turkeys via the raccoon bite. Contaminated crates, feed bags, or any equipment used previously for poultry may serve in introducing FC into a flock. Organisms are disseminated throughout the carcasses of birds that die of acute FC and may serve as an infection source, especially because fowl tend to consume such carcasses. Hendrickson and Hilbert (75) were able to isolate *P. multocida* from the blood of a naturally infected chicken for 49 days preceding death. They noticed a rapid increase in the number of organisms immediately preceding and following death and that the organisms remained viable 2 months at 5–10°C. Serdyuk and Tsimokh (162) demonstrated experimentally that sparrows, pigeons, and rats could become infected with *P. multocida* when exposed to chickens with FC and that they in turn could infect susceptible chickens. Sparrows and pigeons carried organisms without showing clinical signs, but 10% of infected rats developed acute pasteurellosis.

The possibility that insects may serve as vectors of FC has been investigated. Skidmore (164) experimentally transmitted FC to turkeys by feeding them flies that had previously fed on infected blood. He pointed out that under natural conditions, ingestion of flies might be a means of introducing the disease into a flock. Transmission by flies, however, is probably not common, as indicated by studies of Van Es and Olney (169). Although FC was maintained in two lots of chickens during the height of the fly season, no spread of the disease occurred to adjoining lots separated only by poultry netting. Iovcev (88) observed that larvae, nymphs, and adult ticks (*Argas persicus*) contained *P. multocida* after feeding on infected hens. Petrov (135) demonstrated that the red mite (*Dermanyssus gallinae*) became infected with *P. multocida* after feeding on infected birds, but the mite did not transmit the organism.

Heddleston and Wessman (70) showed that 27 cultures of *P. multocida* from the upper respiratory tract of humans were not pathogenic for turkeys. Humans can become infected, however, and may infect poultry via excretion from the nose or mouth.

Dissemination of *P. multocida* within a flock is primarily by excretions from the mouth (Fig. 19.5), nose, and conjunctiva of diseased birds that contaminate their environment, particularly feed and water. Feces very seldom contain viable *P. multocida*; however, Reis (142) found the organism in feces from 1 of 9 birds just before death. In the remaining 8 birds, the organisms were isolated only in feces collected from the cloacae of dead birds. Iliev *et al.* (87) demonstrated that *P. multocida* labeled with ^{32}P was inactivated in the proventriculus, and feces contained no viable *P. multocida*. Turkeys drinking from the same water trough with those experimentally infected with *P. multocida* developed FC (129).

Signs of Infection
Acute
Signs of infection in acute FC are often present for only a few hours before death (see Fig. 19.5). Unless infected birds are observed during this period, death may be the first indication of disease. Signs that often occur are fever, anorexia, ruffled feathers, mucous discharge from the mouth, diarrhea, and increased respi-

19.5. Acute FC; mucous excretion from the mouth contains large numbers of *Pasteurella multocida* that can contaminate feed and water.

ratory rate. Cyanosis often occurs immediately prior to death and is most evident in unfeathered areas of the head, such as comb and wattles. Fecal material associated with the diarrhea is initially watery and whitish in color but later becomes greenish and contains mucus. Birds that survive the initial acute septicemic stage may later succumb to the debilitating effects of emaciation and dehydration, may become chronically infected, or may recover.

Chronic
Chronic FC may follow an acute stage of the disease or result from infection with organisms of low virulence. Signs generally are related to localized infections. Wattles (Fig. 19.6), sinuses, leg or wing joints, foot pads, and sternal bursae often become swollen. Exudative conjunctival (Fig. 19.7) and pharyngeal lesions may be observed, and torticollis (Fig. 19.8) sometimes occurs. Tracheal rales and dyspnea may result from respiratory tract infections. In the past, the term *roup* was used to indicate a condition in which signs were associated with chronic infections of cephalic mucous membranes. The term was not limited to FC, but included other diseases as well. Chronically infected birds may succumb, remain infected for long periods, or recover.

Gross and Microscopic Lesions
Lesions of FC are not constant but vary in type and severity. The greatest variation is related to the course of the disease, whether

19.6. Chronic FC; swollen wattle resulting from localized infection.

19.7. Chronic FC; serous inflammation of conjunctiva.

19.8. Chronic FC; torticollis resulting from meningeal infection.

acute or chronic. Although it is convenient for descriptive purposes to refer to either acute or chronic FC, it is sometimes difficult to categorize the disease in this manner. Signs of infection and lesions that occur may be intermediate to those described for acute and chronic forms.

Acute

When the course of the disease is acute, most of the postmortem lesions are associated with vascular disturbances. General hyperemia usually occurs, is most evident in veins of the abdominal viscera, and may be quite pronounced in small vessels of the duodenal mucosa (Fig. 19.9). Large numbers of bacteria usually can be observed microscopically in the hyperemic vessels. Petechial and ecchymotic hemorrhages are frequently found and may be widely distributed. Subepicardial (Fig. 19.10A) and subserosal hemorrhages are common, as are hemorrhages in the lung, ab-

dominal fat, and intestinal mucosa. Increased amounts of pericardial and peritoneal fluid frequently occur. Disseminated intravascular clotting or fibrinous thrombosis has been observed in chickens and ducks that died from acute experimentally induced FC (84, 130).

Livers of acutely affected birds may be swollen and usually

19.9.   Acute FC; hyperemia of chicken duodenum.

contain multiple small focal areas of coagulative necrosis (Fig. 19.10B) and heterophilic infiltration (Fig. 19.11). Some of the less virulent *P. multocida* do not produce necrotic foci in the liver. Heterophilic infiltration also occurs in lungs and certain other parenchymatous organs (143). Lungs of turkeys are affected more severely than those of chickens, with pneumonia being a common sequela. Large amounts of viscid mucus may be observed in the digestive tract, particularly in the pharynx, crop, and intestine.

Ovaries of laying hens are commonly affected. Mature follicles often appear flaccid; thecal blood vessels, which are usually easily observed, are less evident (Fig. 19.10E). Yolk material from ruptured follicles may be found in the peritoneal cavity. Immature follicles and ovarian stroma are often hyperemic.

Chronic

Chronic FC is characterized by localized infections, in contrast to the septicemic nature of the acute disease. These generally become suppurative and may be widely distributed anatomically. They often occur in the respiratory tract and may involve any part, including sinuses and pneumatic bones (Fig. 19.12). Pneumonia (Fig. 19.10C, D) is an especially common lesion in turkeys. Infections of the conjunctiva and adjacent tissues occur (see Fig. 19.7), and facial edema may be observed. Localized infections may also involve the hock joints (Fig. 19.10F), foot pads, peritoneal cavity, and oviduct.

Chronic localized infections can involve the middle ear and

cranial bones and have been reported to result in torticollis. In turkeys, torticollis and eventual death can be associated with infections of the cranial bones, middle ear, and meninges. In a study of naturally infected turkeys exhibiting torticollis, Olson (125) described lesions at these sites. The outstanding gross lesion was yellowish caseous exudate in air spaces of the calvarial bones. Heterophilic infiltration and fibrin were consistently observed in the air spaces, middle ear, and meninges. Multinuclear giant cells were often associated with necrotic masses of heterophils in air spaces. Similar lesions were found in experimentally exposed turkeys (127). Localized meningeal infections (Fig. 19.13), without involvement of cranial bones or the middle ear, have been observed in turkeys exhibiting torticollis, as have cerebellar infections (44).

Immunity

Pasteur (133) used an avirulent culture attenuated by prolonged growth on artificial medium and produced immunity that protected fowl against subsequent exposure. In field use, his method did not prove practical because uniform attenuation could not be obtained, and heavy losses sometimes occurred in vaccinated flocks.

Since Pasteur's classic work, numerous attempts have been made to produce efficient vaccines against FC, but results have not been consistent. There can be little doubt, however, that a substantial, but not absolute, immunity can be induced in fowl by using killed *P. multocida* vaccines under controlled conditions (10, 64). Killed *P. multocida* vaccines usually are prepared by growing selected immunogenic strains on a suitable medium and suspending them in formalinized saline solution. The killed organisms usually are incorporated with an adjuvant and injected subcutaneously.

Under field conditions, losses from FC sometimes occur in vaccinated flocks. This failure may be due to improperly prepared or administered vaccine or immune impaired birds. Heddleston and Reisinger (68) demonstrated that stress caused by changing the social or peck order of vaccinated males, as well as fowlpox infection in chickens at time of vaccination and exposure, significantly reduced the efficacy of vaccination. In experimental studies (136), the manifestation of acquired resistance was impaired in turkeys vaccinated against *P. multocida* while receiving aflatoxin in their feed. It was also observed that an isolate of *P. multocida* recovered from an FC outbreak in previously vaccinated turkeys differed serologically from the culture used in preparing vaccine (72).

In experimental studies, Heddleston and Rebers (66) showed that bacterins prepared with tissues from infected turkeys or live *P. multocida* administered in drinking water will induce immunity in turkeys against a different immunogenic type. A bacterin prepared with bacteria grown on conventional agar media did not induce cross-immunity. These studies indicate that *P. multocida* produces a wider spectrum of immunogens *in vivo* than *in vitro*. Rimler (150) showed that turkeys vaccinated with *in vivo*-grown *P. multocida* and challenged with the homologous strain produced serum that passively immunized poults against five different serotypes. Bierer and others at Clemson University stimu-
19.11.   Acute FC; coagulative necrosis and heterophilic infiltration in turkey liver. H & E, ×600.

lated renewed interest in live FC vaccine administered in drinking water. Bierer and Derieux (14) demonstrated good immunity in 14-week-old turkeys that were given a live culture of *P. multocida* (CU strain, previously CS-148) in drinking water 2 weeks before challenge exposure. The vaccine, however, killed 4.2% of 120 turkeys. Best results were obtained by inoculating 8-week-old turkeys with a killed bacterin and then administering the live vaccine 2 weeks later; the live vaccine killed only 2.5% of 120 turkeys. Derieux and Bierer (33) stated that good immunity may be obtained in 6-week-old turkeys by administering 2 doses of vaccine in drinking water on the same day and repeating the vaccination 4 weeks later. No data were given, however, as to duration of immunity or number of turkeys killed by vaccination. The CU strain administered in drinking water was immunologically

less effective in chickens than in turkeys. It was more effective in chickens by wing-web or SC inoculation than in drinking water (32). Live vaccines are commercially available for oral administration to turkeys and parenteral administration to chickens.

Maheswaran *et al.* (103) also induced immunity in turkeys with live vaccines via drinking water; they suggested that the vaccine induced localized, but not systemic, protection. In other studies, Heddleston *et al.* (74) showed that serum from birds vaccinated via drinking water would induce passive immunity in chicks and turkeys.

Passive immunity for prevention of FC was studied in 1892 by Kitt, who used immune horse serum. This method was used frequently, but because of the short duration of passive immunity, it is presently used little if at all. Bolin and Eveleth (18) reported

19.13.   Chronic FC; fibrinoheterophilic meningitis in turkey. H & E, ×400.

19.12.   Chronic FC; caseous exudate (arrows) in turkey humerus.

that *P. multocida* antiserum prepared in chickens gave maximum protection 16–24 hours after injection; protection began to decline after 48 hours and had disappeared after 192 hours.

Diagnosis

A presumptive diagnosis of FC may be made from clinical observations, necropsy findings, or isolation of *P. multocida*; a conclusive diagnosis should be based on all three. Signs and lesions of the disease were described previously.

Isolation and Identification

P. multocida can be isolated readily from viscera of birds that die of acute FC and usually from lesions of chronic cases; it is less likely to be isolated from dehydrated, emaciated survivors of an acute outbreak. A tentative diagnosis of acute FC can be made by demonstrating bipolar organisms in liver imprints (see Fig. 19.2) using Wright's stain. Immunofluorescent microscopy can be used to identify *P. multocida* in tissue or exudate (105).

Bone marrow, heart blood, liver, meninges, or localized lesions are preferred for culturing. To isolate *P. multocida,* sear the tissue or exudate with a spatula and obtain a specimen by inserting a sterile cotton swab or wire loop through the seared surface. If birds are living, squeeze mucus from the nostril or insert a cotton swab into the nasal cleft. Transfer the specimen to peptone broth and streak on dextrose starch agar containing 5% chicken serum or other suitable media. Specimens may also be streaked on MacConkey and blood agar media to aid in identification.

Colonies characteristic of *P. multocida* (described under Etiology) are transferred to dextrose starch agar slants incubated 18–24 hours. Tubes of phenol red broth base containing 1% glucose, lactose, sucrose, mannitol, and maltose, respectively, are then inoculated with growth from the slant. Fermentation of glucose, sucrose, and mannitol without gas is characteristic of *P. multocida.* Lactose is usually not fermented, but some avian isolates will ferment it. Inoculate 2% tryptose in 0.85% saline solution, incubate 24 hours at 37°C, and test for indole (Kovac's test). Indole is almost always produced by *P. multocida.* There should be no hemolysis of blood and no growth on MacConkey agar (Table 19.2).

Inoculation of animals may be used as an aid in isolating *P. multocida* from contaminated materials. Rabbits, hamsters, or mice are inoculated subcutaneously or intraperitoneally with 0.2 ml exudate or minced tissue. If *P. multocida* is present, the animal usually dies within 24–48 hours, and the organism can be isolated in pure culture from heart, blood, or liver.

Serologic diagnosis of FC by rapid whole-blood agglutination, serum plate agglutination, agar diffusion tests, or ELISA has limited value in chronic cholera and no value with the acute form of the disease.

Differential Diagnosis

Avibacterium gallinarum and *Gallibacterium anatis biovar haemolytica* are two closely related bacteria that may be isolated

from diseased poultry and incorrectly identified as *P. multocida* (65). *Avibacterium gallinarum* was first described by Hall *et al.* (58), who isolated it along with *P. multocida* from chickens with other maladies characterized by inflammation of the upper respiratory tract. The gel diffusion precipitin test shows a common antigen between *Avibacterium gallinarum* and *P. multocida.* Clark and Godfrey (27) found *Avibacterium gallinarum* associated with a respiratory disease complex of chickens in southern California. Gilchrist (49), in a survey of avian respiratory diseases in New South Wales, reported finding *Avibacterium gallinarum, Gallibacterium anatis biovar haemolytica,* and *P. multocida.* Harbourne (60) isolated *Gallibacterium anatis biovar haemolytica* on four occasions from livers of young chickens and turkeys. *Gallibacterium anatis biovar haemolytica* was isolated from young chickens with salpingitis, which was often accompanied by nasal catarrh, helminth infection, or leukosis; the organism was also isolated from the lungs of fowl with chronic respiratory disease and infectious bronchitis (122). Matthes *et al.* (106) isolated *Gallibacterium anatis biovar haemolytica* from chickens with a septicemia. Chloramphenicol was effective in treatment. Hacking and Pettit (57) reported on 8 cases of *Gallibacterium anatis biovar haemolytica* in pullets and laying hens: 5 cases involved egg production, with some birds showing peritonitis or salpingitis; 3 cases involved mortality; some birds had enteritis, enteritis, and hepatitis, or respiratory infection. In most cases, *Gallibacterium anatis biovar haemolytica* was thought to be a secondary pathogen.

Differential characteristics of *P. multocida, Avibacterium gallinarum,* and *Gallibacterium anatis biovar haemolytica* that may be isolated from poultry are listed in Table 19.2.

Treatment

Antibacterial chemotherapy has been used extensively in the treatment of FC with varying success, depending to a large extent on the promptness of treatment and drug used. Sensitivity testing is often advantageous, because strains of *P. multocida* vary in susceptibility to chemotherapeutic agents (37, 171), and resistance to treatment may develop, especially during prolonged use of these agents.

Sulfonamides

Several of the sulfonamides have been employed both experimentally and in naturally occurring outbreaks. The main disadvantages of the sulfonamides are their bacteriostatic instead of bactericidal action, inability to cure localized abscesses, and their toxic effect on birds. Kiser *et al.* (98) reported 63–85% reduction in mortality from experimentally produced FC compared with untreated controls when using sulfamethazine and sodium sulfamethazine. In naturally occurring outbreaks, mortality was reduced 45–75%. Favorable results were obtained with 0.5–1% of the drug in food, or 0.1% in drinking water.

Alberts and Graham (3) employed 0.5% sulfamerazine in mash feed for 5 days in a field outbreak of FC in turkeys. Mortality was 1.9% in the treated group compared with 50% in untreated birds. Fowl cholera recurred four times after cessation

of treatment, and each time losses were arrested after turkeys were again given the sulfamerazine-mash mixture. In experimental infection in turkeys, sodium sulfamerazine at oral dosage rates of 143 and 107.25 mg/kg body weight effectively reduced mortality. In chickens, 0.2% sodium sulfamerazine in drinking water or 0.4% sulfamerazine in mash checked mortality in an established outbreak 2 days after treatment was started (1). Sulfaquinoxaline in amounts of 0.01–0.05% in drinking water was completely prophylactic in experimental FC when treatment was started 24 hours before birds were inoculated. Peterson (134) treated two naturally occurring outbreaks in turkey flocks successfully with 1:2000–1:4000 dilution of the drug in drinking water. He found sulfamethazine and sodium sulfamerazine also were markedly effective in reducing experimental FC; sulfadiazine, sulfathiazole, and sulfanilamide were much less so. Sulfaquinoxaline was used by Delaplane (31) at the rate of 0.1% or 0.05% in mash in prophylaxis of FC in chickens. Nelson (121) reported favorable results in controlling mortality in turkeys with a concentration of 0.025% sulfaquinoxaline in drinking water for 5–7 days; he stated also that its administration 1 day out of 4 usually controls later mortality and permits the grower to finish birds for market. Dorsey and Harshfield (39) confirmed the usefulness of several sulfonamide drugs in checking losses from FC if treatment is carried out in early stages of an outbreak. They also noted frequent recurrence of mortality after treatment was discontinued and unsatisfactory results of treatment after the disease had become chronic.

Sulfaethoxypyridazine was reported by Stuart *et al.* (167) to be effective in controlling FC in chickens and turkeys. Effectiveness of the drug was dependent in part on size of dose and on the duration and promptness of treatment. Sulfadimethoxine, used alone or potentiated with ormetoprim, was found to be safe, palatable, and effective against experimentally induced FC in chickens and turkeys (109, 110, 111, 112, 167). Anderson *et al.* (6) reported that sulfachloropyrazine administered in drinking water was effective in preventing mortality in experimentally exposed chickens.

Antibiotics

Streptomycin given IM in a dose of 150,000 mg prevented deaths in adult turkeys when administered before or at the time of inoculation of *P. multocida.* When treatment was delayed for 6–24 hours or dosage was reduced, chronic infection resulted (108). Penicillin, streptomycin, penicillin and streptomycin, and oxytetracycline (administered IM at the time of experimental exposure of chickens) all possessed activity as therapeutic agents (13). Chlortetracycline reduced losses in chicks about 80% when given at the rate of 40 mg/kg body weight IM 30 minutes after parenteral inoculation of the organism (102). Chicks that received mash containing 1 mg/g had 50% fewer losses than untreated controls. In an outbreak of FC in pheasants, however, Alberts and Graham (4) did not observe any beneficial results when 1 mg/g mash was fed. When chlortetracycline was given IM, a slight reduction in mortality was recorded. Novobiocin administered in feed or water reduced death losses in experimentally exposed turkeys (59). Chloramphenicol (20 mg/kg body

weight) in a single IM injection was effective in treating FC, but in flocks in which FC and fowl typhoid or fowlpox were concurrently present, chloramphenicol treatment was not successful (80). A chloramphenicol-dexamethasone-pyribenzamine combination was used successfully with vaccination in treatment of FC in breeding turkeys. Respiratory problems, which occurred 1 week after the initial outbreak, responded readily to IM administration of this drug combination (53). Water-soluble erythromycin at the rate of 1 lb/50 gal drinking water halted mortality in two flocks of Muscovy ducklings infected with *P. multocida* (61). Fluoroquinolones are used successfully to treat fowl cholera. *Pasteurella multocida* isolates from poultry are typically highly susceptible to fluoroquinolones (50).

Antibiotics used in rations at very low levels for promotion of growth, according to the experiments of Dorsey and Harshfield (39), did not significantly influence the course of FC infection in inoculated birds. At therapeutic levels, birds that received penicillin and streptomycin in feed died at about the same rate as controls. No deaths occurred in groups that received sulfaquinoxaline or sulfamerazine. These workers found oxytetracycline and chlortetracycline effective also in preventing mortality in experimental FC in a small flock of laying birds; mortality was 80% in an untreated group compared with 12% in a group receiving mash containing oxytetracycline at the level of 500 g/ton. In six naturally occurring outbreaks, oxytetracycline at this level in feed checked mortality, but losses returned in three flocks after withdrawal of the antibiotic.

Prevention and Control

Management Procedures

Prevention of FC can be effected by eliminating reservoirs of *P. multocida* or by preventing their access to poultry flocks. Good management practices, with emphasis on sanitation as prescribed by Zander, Bermudez, and Mallinson (see Chapter 1), are the best means of preventing FC. Unlike many bacterial diseases, FC is not a disease of the hatchery. Infection, therefore, occurs after birds are in the hands of the producer, and consideration must be given to the many ways that infection might be introduced into a flock.

The primary source of infection is usually sick birds or those that have recovered and still carry the causative organism. Only young birds should be introduced as new stock; they should be raised in a clean environment completely isolated from other birds. Isolation should be extended to housing. Unless separate houses can be provided for first- and second-year layer flocks, the older flock should be marketed in its entirety. Different species of birds should not be raised on the same premises. The danger of mixing birds from different flocks cannot be overemphasized. Farm animals (particularly pigs, dogs, and cats) should not have access to the poultry area. Water fountains should be self-cleaning, and feeders should be covered to prevent contamination as much as possible.

That *P. multocida* has been recovered from many species of free-flying birds warrants consideration of this source of infection to poultry, with measures taken to prevent their association with the flock. Raising turkeys in areas where FC is a serious problem may warrant their confinement in houses from which free-flying birds, rodents, and other animals can be excluded. If an outbreak of FC occurs, the flock should be quarantined and disposed of as soon as economically feasible. All housing and equipment should be cleaned and disinfected before repopulation.

Immunization

Vaccination should be considered in areas where FC is prevalent, but it should not be substituted for good sanitary practice. Commercially produced bacterins and live vaccines are available. Bacterins usually contain whole cells of serotypes 1, 3, and 4 emulsified in an oil adjuvant. Because a bacterin will not provide protection against a FC challenge from a serotype not contained in that bacterin, an autogenous whole-cell bacterin containing a locally isolated strain other than serotypes 1, 3, or 4 may be used (62). The choice of adjuvant for an autogenous vaccine can be water-in-oil emulsion or aluminum hydroxide (12). Autogenous bacterins using aluminum hydroxide as the adjuvant are useful for the vaccination of turkey breeder or broiler breeder flocks that are in lay because the water-in-oil emulsion, in combination with the whole bacterial cell, results in a significant tissue response by the bird. This response can result in significant declines in egg production. The negative effect on egg production is less with aluminum hydroxide adjuvant whole-cell FC bacterins. It has been well documented that aluminum hydroxide bacterins do not stimulate the immune response as well as water-in-oil bacterins (68, 107). Therefore, if an aluminum hydroxide bacterin is used, revaccination may be required to afford immunity to a flock for an entire laying cycle.

Three live vaccines available for use in the United States are CU (Clemson University), a strain of low virulence; M-9, a mutant of CU with very low virulence; and PM-1, a mutant of CU intermediate in virulence between CU and M-9. Vaccination of chickens and turkeys with these live *P. multocida* vaccines induces protection against heterologous serotype challenge. The use of live FC vaccines stimulates an effective immune response but has the disadvantage of potentially resulting in mortality in the vaccinated birds (14). If the mortality post-vaccination becomes excessive, it can be reduced by the administration of an antibiotic. This should be avoided, if possible, until at least 4 days post-vaccination when there will be at least partial immunity induced by the vaccine (128).

When considering the most appropriate vaccination program for FC, the following should be taken into consideration: prevalence of FC in the area, most prevalent serotypes of *P. multocida* in area, age of birds to be vaccinated, and the value of the birds to be vaccinated (i.e., breeder turkeys versus commercial turkeys or parent chicken breeders versus grandparent chicken breeders). There have been many successful vaccination protocols for chicken breeders against FC. Bacterins, live vaccines, or both are used, and usually two doses are given: the first at 8–10 weeks of age and the second at 18–20 weeks of age. Protection occurs only against serotypes contained in the bacterin and does not give solid immunity for an entire laying cycle. Some of the more commonly used vaccination programs consist of administering a live vaccine

in the wingweb at 10–12 weeks of age followed by either another live vaccine in the wingweb or a bacterin at 18–20 weeks. Vaccination with live vaccine provides protection against multiple serotypes, but the vaccine can cause chronic FC. The use of a bacterin at 10–12 weeks and a live vaccine at 18–20 weeks, just prior to movement to the laying house, gives protection against multiple serotypes and minimizes live vaccine induced chronic FC (78).

One of the most successful programs for vaccination of both breeder turkeys and commercial/or meat turkeys is the use of a live vaccine in the drinking water every 4 weeks beginning at 6–8 weeks of age and continuing for the life of the flock. Bacterins can also be used in breeder turkeys. They are vaccinated 2–5 times before the onset of egg production, with the first vaccination beginning at 6–8 weeks.

Riemerella anatipestifer Infection

Tirath S. Sandhu

Introduction

Definition and Synonyms

Riemerella anatipestifer (RA) infection is a contagious disease of domestic ducks, geese, turkeys, and various other domestic and wild birds. It is also known as new duck disease, duck septicemia, anatipestifer syndrome, anatipestifer septicemia, and infectious serositis. In geese, RA infection has been called goose influenza or septicemia anserum exsudativa (40). It occurs as an acute or chronic septicemia characterized by fibrinous pericarditis, perihepatitis, airsacculitis, caseous salpingitis, and meningitis.

Economic Significance

R. anatipestifer infection is a major disease confronting the duck industry throughout the world. It accounts for significant economic losses due to high mortality, weight loss, condemnations, downgrading, and salvage. Prevention and control programs consisting of vaccination and treatment add to the cost.

Public Health Significance

The disease is of no public health significance.

History

R. anatipestifer infection was first described in 1932 in Pekin ducks from three farms on Long Island, New York (28). The report referred to a new disease, which became known in the area as "new duck disease." The disease started in 7- to 10-week-old ducks with about 10% mortality and later spread to younger ducklings of about 3 weeks of age. Six years later, the disease was observed in ducks from a commercial farm in Illinois and was reported as "duck septicemia" (20). The designation "infectious serositis" was given by Dougherty and coworkers (16) after a comprehensive pathologic study. The term *R. anatipestifer infection* was recommended by Leibovitz (39) to identify the disease specifically caused by *R. anatipestifer* and to differentiate it from other infections with similar pathology. A similar disease, septicemia anserum exsudativa, was described in geese by Riemer (55). The causative agent, *Pasteurella septicaemiae*, is identical to RA on the basis of reported characteristics (30, 69).

Etiology

Classification

The causative bacterium was isolated and characterized by Hendrickson and Hilbert (28), who called it *Pfeifferella anatipestifer*. Bruner and Fabricant (10) studied and compared its characteristics with those of *Brucella, Pasteurella, Moraxella, Actinobacillus,* and *Haemophilus*. They concluded that the organism had more in common with *Moraxella* sp. and suggested the name *Moraxella anatipestifer*. It was listed in the seventh edition of *Bergey's Manual of Determinative Bacteriology* as *Pasteurella anatipestifer* (8). Because of its uncertain taxonomic status, it was placed as species *incertae sedis* in the eighth (69) and ninth (43) editions of *Bergey's Manual of Systematic Bacteriology*. Comparison of its DNA base composition, DNA-DNA homology, and cellular fatty-acid profile indicated its exclusion from the genus *Moraxella* as well as *Pasteurella* (5, 43). Piechulla *et al.* (53) suggested the transfer of RA to the *Flavobacterium/Cytophaga* group on the basis of low but significant DNA binding and production of menaquinones and branched-chain fatty acids. Segers *et al.* (68) reported significant differences between RA and its close genotypic relatives *Flavobacterium* and *Weeksella*. They suggested placing this organism in a separate genus *Riemerella*, in honor of Riemer (55), who first described the disease "septicemia anserum exsudativa" in geese in 1904, and named it *Riemerella anatipestifer* on the basis of a DNA-ribosomal RNA hybridization analysis, its protein and fatty acid methylester (FAME) profiles, and its phenotypic characteristics such as lack of pigment production and presence of respiratory quinone "menaquinone 7."

R. anatipestifer-like organisms of taxon 1502 (32) isolated from ducks and geese were assigned to the genus *Coenonia* and named *Coenonia anatina* gen. nov., sp. nov. on the basis of phenotypic and genotypic characteristics and FAME profiles (74). *C. anatina* differed from RA by the absence of arginine dihydrolase and gelatinase and by the presence of hyaluronidase, chondroitin sulfatase activity, aesculin hydrolysis, and β-glucosaminidase activity.

Morphology and Staining

R. anatipestifer is a gram-negative, nonmotile, nonspore-forming rod occurring singly, in pairs, and occasionally in chains. The cells vary from 0.2–0.4 mm in width and 1 to 5 mm in length. Many cells stain bipolar with Wright's stain, and a capsule can be demonstrated in preparations with India ink.

Growth Requirements

The organism grows well on chocolate agar, blood agar, or trypticase soy agar. Growth of fastidious strains can be enhanced by the addition of 0.05% yeast extract and 5% newborn calf serum. Growth is more abundant with increased carbon dioxide (20). Hendrickson and Hilbert (28) described the organism as a strict aerobe on the basis of results obtained with the pyrogallic acid and sodium hydroxide procedure for removing oxygen. However, because carbon dioxide would also be depleted by reacting with the sodium hydroxide, neither oxygen nor carbon dioxide was available to the organism. Although some strains of RA grow at an incubation temperature of 45°C, no growth is observed at 4°C or 55°C (4); maximum growth usually occurs in 48–72 hours when incubated at 37°C in a candle jar that provides increased carbon dioxide and moisture, both of which favor growth.

Colony Morphology

Colonies on blood agar, when grown 24–48 hours at 37°C in a candle jar, are 1–2 mm in diameter, convex, entire, transparent, glistening, and butyrous. Some strains produce slimy growth. Colonies on clear media are iridescent when observed with obliquely transmitted light.

Biochemical Properties

Carbohydrates are not fermented by routine sugar fermentation tests. However, acid production has been detected in dextrin, glucose, maltose, inositol, trehalose, mannose, and fructose by growing in buffered single substrate medium (2, 4, 31). Gelatin is usually liquified, and litmus milk may slowly turn alkaline. Usually, indol and hydrogen sulfide are not produced; however, some strains are indol positive (32). Nitrate is not reduced to nitrite, and starch is not hydrolyzed. There is no growth on MacConkey agar and no hemolysis on blood agar. *R. anatipestifer* is oxidase- and catalase-positive; phosphatase is produced (22). It is negative for aesculin hydrolysis, hyaluronidase, and chondroitin sulfatase (32). Some strains produce urease and arginine dihydrolase.

R. anatipestifer is positive for acid and alkaline phosphatase; ester lipase C8 (APIZYME system); leucine-, valine-, and cystine-

arylamidases; phosphoamidase; α-glucosidase; and esterase C4 and while negative for the following enzyme activities: α- and ß-galactosidases, ß-glucuronidase, ß-glucosidase, α-mannosidase, ß-glucosaminidase, lipase C14, fucosidase, and ornithine and lysine decarboxylases (53, 68).

Susceptibility to Chemical and Physical Agents

Most RA strains do not survive on solid media for more than 3–4 days at 37°C or room temperature; cultures in broth may be viable for 2–3 weeks when stored at 4°C. Incubation at 55°C for 12–16 hours resulted in nonviability of the organism (4). *R. anatipestifer* has been reported to survive in tap water and turkey litter for 13 and 27 days, respectively (6). It is sensitive to penicillin, novobiocin, chloramphenicol, lincomycin, enrofloxacin, ceftiofur, streptomycin, erythromycin, ampicillin, bacitracin, neomycin, and tetracycline but is resistant to kanamycin and polymyxin B (4,13). *R. anatipestifer* is relatively resistant to gentamicin.

Strain Classification

R. anatipestifer isolates have been serotyped using agglutination and agar-gel precipitin (AGP) reactions. Both of these tests involve surface antigens that are presumed to be polysaccharides (9). Plate agglutination is rapid and convenient; tube agglutination is favored over AGP as it is quantitative in terms of antibody titers.

To date, 21 serotypes have been reported. Based on agglutination reactions, Harry identified 16 serotypes (A through P), 4 of which (E, F, J, and K) were lost during storage, and he found serotypes G and N to be identical to serotypes I and O, respectively (7, 21). Seven serotypes (1 through 7) were differentiated using AGP reaction (9). Subsequently, Bisgaard (7) reported serotypes 1, 2, 3, 4, 5, and 6 to be serologically identical to Harry's types A, I/G, L, H, M, and B, respectively. He also suggested numerical designation of serotypes to avoid confusion and to standardize serotype nomenclature for recognition of new serotypes. He identified 2 new serotypes (12 and 13). Serotype 7 was reported to be identical to serotype O/N, and a new serotype (8) was isolated (65). Sandhu and Leister (66) revised the typing scheme proposed by Bisgaard. They redesignated Harry's serotypes C and D as types 9 and 10, excluded serotype 4, which was not RA, and reported 5 new serotypes (11, 14, 15, 16, 17). Loh *et al.* (42) reported serotypes 13 and 17 to be identical. They redesignated Harry's type P as serotype 4 and added 3 new serotypes (17, 18, and 19), which were isolated from ducks in Singapore. Two new serotypes (20, 21) were isolated from ducks in Thailand (51); one of these (serotype 20) was later excluded as it was not RA (59). A new serotype isolated from ducks in Thailand replaced serotype 20 (49). All serotypes reacted specifically with homologous-type antisera with the exception of serotype 5, which gave minor cross-reactions with serotypes 2 and 9 (42, 65).

Cell lysates of various serotypes showed many bands when subjected to polyacrylamide gel electrophoresis (29). Most of the bands were common to all serotypes, but some were specific to

individual serotypes. Subramaniam and his associates (71) cloned an outer membrane protein gene (*OmpA*) from RA that encoded for a 42-kDa major antigenic outer membrane protein (OmpA). All reference strains of RA had the *OmpA* gene, although some minor genetic differences were observed in different strains. Tsai *et al.* (72) reported that all of the RA strains fall into a single cluster based on the phylogenetic analysis of 16S rRNA gene and that the 16S rRNA gene-based polymerase PCR may be a suitable test for screening RA infections.

Recently, most of the RA strains were shown to contain plasmids (12). A 3.9b plasmid carried protein genes similar to the virulence-associated genes of other bacteria. An insertion sequence element found on a second plasmid may be of importance in epidemiological studies (75).

Pathobiology and Epidemiology

Incidence and Distribution

The disease occurs worldwide and has been recognized in countries that have intensive duck production (61). There is a wide variation in the severity of the disease depending on the strain of the organism, the age of the host, and the route of exposure (26, 67). Often, more than one serotype is responsible for the disease at a single farm or in the same hatch of birds.

Natural and Experimental Hosts

R. anatipestifer infection is primarily a disease of domestic ducks and geese. Naturally occurring outbreaks have been reported in turkeys (27, 78). Serious outbreaks in turkeys in the United States and other countries showed that RA is a potential pathogen of domestic turkeys (19, 47, 48, 70). *R. anatipestifer* has also been isolated from pheasants (11), chickens (57), guinea fowl and quail (48), partridge (77), and other waterfowl (17, 37, 46, 54, 76). Recently, it has also been isolated from gulls, budgerigars, guillemots, and pigs (32).

Chickens, geese, pigeons, rabbits, and mice were reported to be refractory to infection with RA; guinea pigs succumbed to inoculation of large doses intraperitoneally (20, 28). However, Heddleston (26) observed that 8×10^6 organisms inoculated into the foot pad killed 5 of 7 one-day-old chicks; 4×10^6 organisms in 2-week-old white Chinese goslings produced signs and lesions similar to those seen in Pekin ducklings.

Ducklings, 1–8 weeks of age are highly susceptible. Ducklings under 5 weeks of age usually die within 1–2 days after clinical signs appear; older birds may survive longer. The disease is rare in breeder ducks.

Transmission, Carriers, and Vectors

Infection takes place via the respiratory tract (38) or through wounds of the skin, particularly of the feet (2). RA and RA-like bacteria have been isolated from pharyngeal mucosa of clinically normal ducklings (58). Cooper (14) suggested that the disease in turkeys may be transmitted by arthropod vectors based on its seasonal occurrence and the apparent affinity of RA for host erythrocytes. The disease can be reproduced most consistently by injection of the organism intravenously, subcutaneously, intraperi-

toneally, intramuscularly, into the foot pad, or into the infraorbital sinus. Experimental infection by subcutaneous and intravenous routes caused high mortality; while no or low mortality was observed in ducklings infected by the oral or nasal route (3, 24, 67).

Incubation Period

The incubation period is usually 2–5 days. Artificial infection of ducklings by the subcutaneous, intravenous or infraorbital sinus routes results in clinical signs and deaths as early as 24 hours postinfection.

Clinical Signs

Signs most often observed are listlessness, ocular and nasal discharge, mild coughing and sneezing, greenish diarrhea, ataxia, tremor of head and neck, and coma. Affected ducklings lie on backs paddling their legs and are unable to move with the brood. Surviving ducks may be stunted (52). Adverse environmental conditions or concomitant disease often predispose birds to outbreaks of RA infection. Mortality may vary from 5 to 75%; morbidity is usually higher.

Pathology

Gross

The most obvious gross lesion in ducks is fibrinous exudate, which involves serosal surfaces in general, but is most evident in the pericardial cavity, over the surface of the liver (Fig. 19.14), and in air sacs; similar lesions have been reported in turkeys and other birds. Fibrinous airsacculitis is common; both abdominal and thoracic air sacs may be involved. Spleen may be enlarged and mottled. Mucopurulent exudate in nasal sinuses and caseous exudate in oviducts have been observed (16).

Chronic localized infections may occur under the skin and occasionally in joints. Skin lesions are in the form of necrotic dermatitis on the lower back or around the vent. Yellowish exudate is observed between skin and fat layers.

Microscopic

Fibrinous exudate on the heart contains a few inflammatory cells, primarily mononuclear cells, and heterophils (Fig. 19.15). Liver lesions observed in the acute stage of the disease are mild periportal mononuclear leukocytic infiltration, cloudy swelling, and hydropic degeneration of parenchymal cells (Fig. 19.16). In less acute cases, moderate periportal lymphocytic infiltration may be observed (52). In air sacs, mononuclear cells are the predominant cell type in the exudate. Multinuclear giant cells and fibroblasts may be observed in chronic cases (16). The respiratory tract may also be infected without showing clinical signs. Lungs of infected ducks may be unaffected; there is interstitial cellular infiltration and proliferation of lymphoid nodules adjacent to parabronchi (52); or there may be an acute fibrinopurulent pneumonia (20). Infections of the central nervous system can produce fibrinous meningitis. Jortner and his associates (36) studied lesions in the central nervous system of naturally infected ducklings and described diffuse fibrinous meningitis with leukocytic infiltration in and around the walls of meningeal blood vessels. Extensive exudate was observed in the ventricular system. Slight to moder-

ate leukocytic and microglial infiltrates were observed in subpial and periventricular brain tissue. Lymphoid necrosis and depletion of lymphocytes have been observed in spleen and bursa of Fabricius (67).

Immunity

Ducklings that recover from the disease are resistant to subsequent infection (2, 20, 28). Inactivated bacterins have been used in ducks to prevent RA infection. Ducks vaccinated with formalin-inactivated bacterins and subsequently challenged with strains representing serotypes 1, 2, and 5 developed homologous, but not heterologous, protection. A trivalent bacterin containing these strains provided protection against challenge with each serotype, but the protection lasted only a short time (60). Harry and Deb (23) evaluated the effectiveness of several types of bacterins and conducted a field trial with a formalin-inactivated bacterin. A single dose of oil-emulsion bacterin provided longer lasting immunity in ducklings (18, 60). Cell-free culture filtrate has also been reported to provide significant protection against homologous challenge (50). Outer membrane proteins OmpA and P45 failed to provide protection against a virulent challenge but did result in production of RA-specific antibodies (34). One-day-old ducklings exposed to live avirulent strains by aerosol or through the drinking water were resistant when challenged at 3–6 weeks of age with virulent homologous strains (62). Passive protection of progeny may be obtained by immunization of the female breeder ducks; maternal immunity lasts for about 2–3 weeks (63). RA specific antibodies were detected in the egg yolk and sera of vaccinated breeder ducks (41); maternal antibodies in the progeny lasted up to 10 days of age. Cell-mediated immunity to RA antigens was transient (similar to vaccination with the bacterin), and live vaccine induced longer lasting protection (29, 62).

Diagnosis

Isolation and Identification of Causative Agent

Although a presumptive diagnosis may be made from clinical signs and necropsy findings, a definite diagnosis should be based on isolation and identification of RA. The bacterium can be isolated most readily when birds are in the acute stage of the disease. Suitable tissues for culture are brain, heart blood, air sacs, bone marrow, lung, liver, and exudates from the lesions. Samples should be taken aseptically, streaked on blood agar or trypticase soy agar containing 0.05% yeast extract, and incubated in a candle jar at 37°C for 24–72 hours. Addition of newborn calf serum (5%) and gentamicin (5 mg/1000 ml) to plate media is helpful for the isolation of RA from contaminated specimens. Isolated colonies should be selected for inoculation of the differential media and identified on the basis of characteristics described under "Etiology." Serotype identification can be established by agglutination and/or AGP reactions with specific antisera. Molecular fingerprinting by restriction endonuclease analysis and repetitive sequence PCR are useful to differentiate RA strains and may be helpful in epidemiological studies (35, 56).

Serology

Immunofluorescent procedures can be used to identify RA in tissue or exudate from infected birds (44). Agglutination test and enzyme-linked immunosorbent assay (ELISA) can be used to detect serum antibodies. ELISA is more sensitive than agglutination test but is not serotype-specific (25, 33, 41).

Differential Diagnosis

R. anatipestifer infection should be differentiated from other septicemic diseases caused by *Pasteurella multocida*, *Coenonia anatina*, *Escherichia coli*, *Streptococcus faecium*, and salmonellae. Because these diseases produce gross lesions indistinguishable from those caused by RA, diagnosis must include isolation and identification of the causal organism. Differential diagnosis should also include chlamydiosis, especially in turkeys and in areas where the latter is a serious problem.

Intervention Strategies

Management Procedures

The most important aspects of prevention are good biosecurity, management, and sanitation practices. This includes proper ventilation, especially in houses where ducks are raised in total confinement. Predisposing factors such as stress due to overcrowding or exposure to hot or cold weather should be avoided. Strict measures should be taken to prevent the spread of infection from diseased to healthy flocks. If ducks are raised on wire, the floors should be periodically washed and sanitized to avoid accumulation of manure and to reduce the exposure to infection.

Vaccination

Inactivated bacterins have been reported to prevent or reduce mortality due to RA (23, 38, 60). Because immunity induced by bacterins is serotype-specific, an ideal bacterin should contain cells of the predominant serotypes to provide an effective protection. A bacterin containing serotypes 1, 2, and 5 has been used in the United States and Canada. Ducklings are vaccinated at 2 and 3 weeks of age to provide adequate protection up to market age (38). A single inoculation of oil-emulsified bacterin has been reported to produce longer-lasting protection, but it may cause unfavorable lesions at the site of inoculation (18, 60).

A live RA vaccine, developed against serotypes 1, 2, and 5, provided significant protection against experimental or field infections with virulent organisms when administered to 1-day-old ducklings by aerosol or in drinking water (62). A single vaccination protected ducklings up to at least 42 days of age. The vaccine strains grew in the upper respiratory tract and produced a humoral antibody response. The vaccine was demonstrated to be avirulent to 1-day-old ducklings when administered by aerosol or injection into the infraorbital sinus. The vaccine strains were safe in ducks up to 10 back-passages using the contact-exposure method. Breeder ducks can be vaccinated with the bacterin or live vaccine to provide protection in progeny through maternal immunity that may last up to 2–3 weeks of age. Maternally immune ducklings respond successfully to active immunization with a live or inactivated vaccine (63).

Treatment

Antibiotics and sulfa drugs have been tested for treatment of RA with varying degrees of success. Sulfamethazine, 0.2–0.25%, in drinking water or feed, was reported to prevent the onset of clinical signs in ducks exposed experimentally to RA (2). Sulfaquinoxaline at levels of 0.025 or 0.05% in feed was effective in reducing mortality in field and experimental infections (15, 64). Medicated feeds containing novobiocin (0.0303–0.0368%) or lincomycin (0.011–0.022%) were reported to be highly effective in reducing mortality when started 3 days prior to experimental infection. A combination of sulfadimethoxine and ormetoprim, when administered at 0.02–0.12% levels in feed, prevented or reduced mortality and gross lesions in experimentally exposed ducks (45, 64). Tetracyclines were of little value for treatment of RA infection (1, 64). Subcutaneous injection of lincomycin-spectinomycin, penicillin, or a combination of penicillin and dihydrostreptomycin were reported to be effective in reducing mortality in artificially infected ducklings (64). Enrofloxacin has been shown to be highly effective in preventing mortality in ducklings when given in drinking water at levels of 50 ppm for the first day followed by 25 ppm for the next 4 days (73). Ceftiofur, a broad-spectrum cephalosporin, reduced mortality in experimentally infected ducklings given a single dose of 2 mg/kg bodyweight subcutaneously 5 hours after infection (13).

Ornithobacterium rhinotracheale Infection
R. P. Chin, Paul C. M. van Empel, and H. M. Hafez

Introduction

Definition and Synonyms

Ornithobacterium rhinotracheale infection is a contagious disease of birds that causes respiratory distress, mortality, and decreased growth. The severity of clinical signs, duration of the disease, and mortality are extremely variable and are influenced by environmental factors such as poor management, inadequate ventilation, high stocking density, poor litter conditions, and poor hygiene.

Economic Significance

O. rhinotracheale can be associated with high economic losses in poultry due to increased mortality and condemnation rates, decreased egg production, or decreased growth.

Public Health Significance

Currently, *O. rhinotracheale* has not been found to be of any public health significance.

History

O. rhinotracheale was first characterized in 1993 by Charlton *et al.* (17). The following year, Vandamme *et al.* (104) reported the phylogenetic position and various genotypic, chemotaxonomic, and classical phenotypic characteristics of 21 isolates, and proposed the name *O. rhinotracheale*. However, it appears that this bacterium was isolated and studied prior to 1993 (44).

In 1981, the first known isolation of *O. rhinotracheale* was made in northern Germany from 5-week-old turkeys with nasal discharge, facial edema and fibrinopurulent airsacculitis. In 1983, it was cultured from the tracheas of young rooks. In 1986, *O. rhinotracheale* was isolated from turkeys in Israel of various ages with acute exudative pneumonia and airsacculitis (12). In 1987, *O. rhinotracheale* was isolated from 10-week-old Pekin ducks in Hungary with a fowl cholera-like disease (89). Between 1986 and 1988, *O. rhinotracheale*, at that time identified as *Pasteurella*-like bacterium, was isolated from turkey breeding flocks in England which showed general depression, decreased egg production, coughing, low mortality, and fibrinous airsacculitis and pneumonia (107).

Isolations of *O. rhinotracheale* in California began in 1986, and Charlton characterized 14 isolates collected from 1990 to 1991 from turkeys and chickens with respiratory disease (17). In 1991, Du Preez observed a respiratory disease in broilers in South Africa from which *O. rhinotracheale* was isolated (87). *O. rhinotracheale* was reported to cause fowl cholera-like lesions in turkeys in Germany in 1993 and 1994 (37, 43) and 32-week-old breeder turkeys in the United States in 1996 (20).

Since its identification by Vandamme, *et al.*, in 1994, *O. rhinotracheale* has been isolated from birds in various countries throughout the world.
19.17.   *Ornithobacterium rhinotracheale* showing highly pleomorphic nature. Gram stain of bacteria from a 48-hour culture. Gram stain, ×375. (Charlton)

Etiology

Classification

Name and Synonyms

O. rhinotracheale belongs to the rRNA superfamily V within the Cythophaga-Flavobacterium-Bacteroides phylum, and is closely related to two other poultry bacteria, *Riemerella anatipestifer* and *Coenonia anatina* (104, 105). Previously, the bacterium was designated as *Pasteurella*-like, *Kingella*-like, Taxon 28, or pleomorphic gram-negative rod before the name *Ornithobacterium rhinotracheale* gen. nov. sp. nov. was suggested (9, 57, 104).

Morphology and Staining

O. rhinotracheale is a gram-negative, nonmotile, highly pleomorphic, rod-shaped, nonsporulating bacterium. From agars, it appears as short, plump rods measuring 0.2–0.9 μm in width and 0.6–5 μm in length (Fig. 19.17). But from fluid media, very long rods measuring up to 15 μm can be observed.

Growth Requirements

O. rhinotracheale grows aerobically, microaerobically, and anaerobically. The optimal growth temperature is 37°C; however growth can occur at 30–42°C. The bacteria will grow best on 5–10% sheep blood agar, but readily grows on tryptose soy agar and chocolate agar. No growth occurs on MacConkey agar, Endo

agar, Gassner agar, Drigalski agar, or Simmons citrate media. The growth in fluid media can be strain-dependent, and media such as brain heart infusion broth, Pasteurella broth or, Todd Hewitt broth are needed.

Colony Morphology

O. rhinotracheale develop very small, nonhemolytic colonies that are circular, gray to gray-white, sometimes with a reddish glow, and convex with an entire edge. On primary isolation, the colonies of most *O. rhinotracheale* cultures show great differences in size (1–3 mm after 48 hour incubation) but when subcultured, the colony size will become more uniform.

Biochemical Properties

Conventional biochemical tests can be inconsistent. Phenotypic characteristics include the production of oxidase, lack of catalase production, lack of motility, no reaction on triple sugar iron agar, production of beta-galactosidase, the inability to reduce nitrate to nitrite, and the inability to grow on MacConkey agar. There is one report of a cytochrome oxidase-negative strain of *O. rhinotracheale* isolated from turkeys in Germany (67). Predominant fatty acids detected are 15:0 iso, 16:0, 15:0 iso 3OH, 17:0 iso, 16:0 3OH, 17:0 iso 3OH, and unknown peaks with equivalent chain lengths of 13.566 and 16.580. Enzymatic reactions are listed in Table 19.4.

Susceptibility to Chemical and Physical Agents

O. rhinotracheale strains were completely inactivated by a 0.5% solution containing formic and glyoxyl acid, and a 0.5% solution of an aldehyde-based (20% glutaraldehyde) product after 15 minutes exposure time (40). These preparations were able to inactivate *O. rhinotracheale in vitro* at concentrations of 0.5% within 15 minutes.

Antigenic Structure and Toxins

Currently, no special structures or properties such as pili, fimbriae, plasmids (49), or specific toxic activities have been reported.

Strain Classification

Antigenicity

Using boiled extract antigens (BEAs) and monovalent antisera in the agar gel precipitation (AGP) and enzyme-linked immunosorbent assay (ELISA) tests, 18 serotypes (A through R) of *O. rhinotracheale* have been determined (92, 95). Serotype A was the most prevalent serotype among chicken isolates (97%) and turkey isolates (61%) (95). There appears to be a correlation between the geographic origin of the *O. rhinotracheale* isolates and their serotype. Serotype C could be isolated only from chickens and turkeys in South Africa and United States (33, 90, 95). There is no indication of host specificity of the serotypes.

Hafez and Sting (41) compared the efficacy of using different antigen extractions (heat-stable, proteinase K-stable and sodium dodecyl sulfate) for serotyping *O. rhinotracheale* in the AGP and ELISA tests. Results indicate that the AGP test with heat-stable

Table 19.4. Enzyme production of *O. rhinotracheale*.

α-Fucosidase	−

or proteinase K-stable antigen extractions is a suitable method for serotyping. Numerous cross-reactions were seen with the ELISA making it unreliable for serotyping.

Immunogenicity or Protective Characteristics

Using a novel experimental method of combining immune depletion and passive transfer of immunity within the same host, Schuijffel, *et al.*, found that the antibody-mediated immunity in chickens was a key component in the protection against *O. rhinotracheale* infection (72).

Molecular

Amonsin *et al.* (3) using multilocus enzyme electrophoresis, repetitive sequence based-PCR, and 16S rRNA gene sequencing demonstrated that the majority of 55 *O. rhinotracheale* isolates recovered from domesticated poultry throughout the world had limited heterogeneity and were represented by a small group of closely related clones. They propose that the bacterium was recently introduced to domesticated poultry from wild bird populations.

Twenty-three isolates of *O. rhinotracheale* from France were tested using the random amplified polymorphic DNA (RAPD) analysis (49). Results showed that this method gave reproducible DNA fingerprints and a good level of discrimination, thus appearing to be another method for typing.

Van Empel *et al.* (89) used amplified fragment length polymorphism (AFLP) to characterize 56 isolates belonging to different serotypes which were isolated from different bird species from various countries. These isolates could be grouped in 3 major clusters with significantly different DNA fingerprints.

Popp and Hafez (62) investigated several *O. rhinotracheale* isolates from turkeys and chickens originated from Germany,

Hungary, and Spain by pulsed-field gel electrophoresis (PFGE) of genomic macro-restriction fragments using the enzyme *Sal*I. In general, most isolates showed differences in DNA fingerprints although the overall profiles were very similar and a correlation between geographic origin, serotype and DNA fingerprint pattern was observed. In contrast, Koga and Zavaleta (48) recently investigated 25 *O. rhinotracheale* isolates from broilers, breeders, and layers from several geographic zones of Peru using PCR and repetitive extragenic palindromic PCR (rep-PCR) techniques. All 25 isolates tested had a genetic profile similar to that of the *O. rhinotracheale* type strain (American Type Culture Collection 51463) that was isolated from a turkey in the United Kingdom.

Pathogenicity

Pathogenicity differences appear to exist between isolates of *O. rhinotracheale*. Three South African *O. rhinotracheale* field isolates inoculated into the caudal abdominal air sacs of 28-day-old broiler chickens showed significant differences in the production of airsacculitis and arthritis (85). In addition, van Veen *et al.* (102) found that Dutch and South African isolates were more pathogenic than an American isolate in broiler chickens when aerosol challenged.

The pathogenicity of 119 isolates from turkeys and chickens using the embryo lethality test were studied (39). This study showed that the inoculation of about 500 cfu of *O. rhinotracheale* into the allantoic sac of 11-day-old embryos discriminated between pathogenic and nonpathogenic *O. rhinotracheale* isolates. On the basis of death rate, isolates considered to be nonpathogenic had an embryo death rate 10–20%, moderately pathogenic had a 21–60% embryo death rate, and highly pathogenic isolates had a death rate of >60%.

Soriano *et al.* found *in vitro* adherence of *O. rhinotracheale* isolates to chicken tracheal epithelial cells (76).

Pathobiology and Epidemiology

Incidence and distribution

After being recognized in 1994, numerous isolations of *O. rhinotracheale* have been reported throughout the world (1, 2, 4, 11, 13, 14, 16, 21, 24–26, 31, 32, 35, 37, 45, 47, 49, 58, 60, 66, 70, 75, 76, 80, 83, 84, 108).

Natural and Experimental Hosts

O. rhinotracheale has been isolated throughout the world from numerous bird species, including chicken, chukar partridge, duck, goose, guinea fowl, gull, ostrich, partridge, pheasant, pigeon, quail, rook and turkey (17, 97, 104). In commercial poultry, all ages appear to be susceptible, although pathogenicity appears more significant in older birds.

Many case reports of *O. rhinotracheale* infection report a concomitant infection with other respiratory pathogens, such as *Escherichia coli* (19, 70), *Bordetella avium* (16), Newcastle disease virus (84), infectious bronchitis virus (26, 60, 71), avian metapneumovirus (8, 33, 46, 55), *Mycoplasma synoviae* (108) and *Chlamydophila psittaci* (98). Most experimental studies have concluded that, when experimentally inoculated by itself, *O.*

rhinotracheale causes minimal pathologic lesions in chickens and turkeys and that the severity of lesions are enhanced when there is a concurrent infection with respiratory viruses or bacteria (5, 19, 22, 28, 94, 96, 102).

However, some studies report production of pathologic lesions similar to those seen in field cases in chickens and turkeys using *O. rhinotracheale* alone (69, 79, 85, 102).

Transmission, Carriers, and Vectors

O. rhinotracheale appears to spread horizontally by direct and indirect contact through aerosols or drinking water. *O. rhinotracheale* was found to survive 1 day at 37°C, 6 days at 22°C, 40 days at 4°C, and at least 150 days at –12°C (53). The survival of *O. rhinotracheale* at lower temperatures may be associated with the higher incidence of reported infections during the winter months. It did not survive 24 hours at 42°C.

There is circumstantial evidence that vertical transmission occurs (89, 103). In addition, *O. rhinotracheale* has been isolated from the ovaries, oviduct, hatching eggs, infertile eggs, dead embryos, and dead-in-shell chickens and turkeys (5, 23, 59, 83, 89). However, when *O. rhinotracheale* was inoculated into embryonated chicken eggs, the embryos were killed by the ninth day and *O. rhinotracheale* was not isolated from the eggs suggesting it is not transmitted via eggs during hatching (106).

Incubation Period

Experimental inoculation of 22-week-old turkeys with *O. rhinotracheale* resulted in depression, coughing and decreased feed intake within 24 hour (79). In 48 hour, turkeys were coughing bloody mucus. Five days PI, the coughing had decreased and the surviving turkeys were less depressed.

In experimental infections in 5-week-old chickens, *O. rhinotracheale* infected the respiratory organs within 2 days postinoculation and clinical signs were seen after 4 days (96).

Clinical Signs

The severity of clinical signs, duration of the disease and mortality of *O. rhinotracheale* outbreaks are extremely variable. They can be influenced by many environmental factors such as poor management, inadequate ventilation, high stocking density, poor litter conditions, poor hygiene, high ammonia levels, concurrent diseases and the type of secondary infection.

Clinical signs in broiler chickens generally appear at 3–6 weeks of age with a mortality rate of 2–10% showing depression, decrease in food intake, reduced weight gains, and transient nasal discharge and sneezing, followed by facial edema (28, 60, 97). *O. rhinotracheale* can also cause sudden death (up to 20% in a couple of days) in young birds with infections of the brains and skull (29) with or without respiratory symptoms.

In broiler breeders the disease affects the birds in the laying period, primarily at the peak of production or soon before entering production. There is a slight increase in mortality, a decrease in feed intake, and some mild respiratory symptoms. Mortality is variable and relatively low in uncomplicated cases. There can be a drop in egg production, decrease in egg size, and poor eggshell quality. Fertility and hatchability are unaffected in many cases (31).

In commercial laying-type chickens, decreased egg production, increased misshapen eggs, and increased mortality have been associated with *O. rhinotracheale* infection (80).

Roepke (66) found a higher severity of clinical signs and mortality in older turkeys, and the majority of young infected flocks appeared clinically normal. In many cases young poults are affected between 2 and 8 week of age (16). Normal mortality ranges between 1–15% during the acute phase (8 days), but infections can be accompanied with mortality rates of up to 50% (6, 20). Initial symptoms are coughing, sneezing, and nasal discharge followed, in some cases, by severe respiratory distress, dyspnea, prostration, and sinusitis. These symptoms are accompanied with a reduction in feed consumption and water intake. In turkey breeder flocks, there can also be a decrease in egg production and an increase in the number of unsuitable hatching eggs (20, 97).

O. rhinotracheale has been reported to cause neurological signs or paralysis through arthritis, meningitis, osteitis, and osteomyelitis in chickens and turkeys (25, 82, 97).

Pathology

Gross

In broiler chickens, the common gross lesions include pneumonia, pleuritis, and airsacculitis. At slaughter or post-mortem examination, foamy, white, yogurt-like exudate can be seen in the air sacs (predominantly abdominal) (Fig. 19.18), most of the time accompanied by unilateral pneumonia (94). Lesions caused by *O. rhinotracheale* can lead to condemnation rates of 50% or more (99). In addition, subcutaneous edema over the cranium with adjacent osteitis, osteomyelitis and encephalitis has been reported in chickens (29, 30, 78).

In turkeys, there is edema and unilateral or bilateral consolidation of the lungs with fibrinous exudate on the pleura (Fig. 19.19). In addition, there could be fibrinosuppurative airsacculitis, pericarditis, peritonitis, and mild tracheitis. In some cases, swelling of the liver and spleen, as well as degeneration of heart muscles, has been observed (37). Infections of the joints and vertebrae can be seen in older birds.

Microscopic

Most histologic lesions can be seen in the lungs, pleura, and air sacs. In field cases, the lungs (Fig. 19.20) are congested, and throughout the parenchyma, there are large collections of fibrin admixed with macrophages and heterophils lying free within the lumen of air capillaries and parabronchi. There are pronounced and diffuse interstitial infiltrates of macrophages with smaller numbers of heterophils. There are widespread coalescing foci of necrosis often centered within the lumen of parabronchi with extension of the necrosis into the adjacent parenchyma. These necrotic foci usually are filled with dense aggregates of necrotic heterophilic infiltrate or exudate, and there can be scattered small clusters of bacteria seen within the necrotic foci. Numerous blood capillaries can be distended and filled with fibrin thrombi. The pleura and air sacs can be severely thickened and edematous with interstitial fibrin deposits, diffuse heterophilic infiltrate, scattered small foci of necrotic heterophilic infiltrate, and fibrosis.
19.18.   Thickened, opaque air sacs with profuse, foamy, white to yellow, "yogurt-like" exudate associated with infection of *Ornithobacterium rhinotracheale* in 36-day-old broiler chickens. Possible concurrent infection with infectious bronchitis virus. (Salem)

19.19.   Pneumonia and pleuritis associated with *Ornithobacterium rhinotracheale* infection in 31-week-old turkey. (Shivaprasad)

Immunity

Minimal information is available regarding immunity to *O. rhinotracheale*. The active immunity induced by inactivated vaccines was found to be serotype specific, but live vaccination can induce a degree of cross-protection between some serotypes (74). Passive immunity can be induced for up to 3–4 weeks by maternally derived antibodies.

Diagnosis

It is difficult to make a presumptive diagnosis based on clinical signs and necropsy findings. A definitive diagnosis must be
19.20. Severe fibrinoheterophilic inflammation of lung associated with *Ornithobacterium rhinotracheale* infection in 31-week-old turkey. H & E. ×15. (De Rosa)

based on the isolation and identification of *O. rhinotracheale* and/or detection of antibodies.

Isolation and Identification of Causative Agent

Bacterial Isolation and Identification
The trachea, lungs, and air sacs are the best tissues from which to isolate *O. rhinotracheale*. The infraorbital sinus and nasal cavity are also suitable sites for culture, but *O. rhinotracheale* can be masked easily by the overgrowth of other bacteria. Culturing heart blood and liver tissue under field condition has revealed negative results (37), although it has been isolated from those organs, as well as joints, brain, ovary and oviduct after experimental infections (5, 87).

O. rhinotracheale can be isolated on common, nonselective blood or chocolate agar. Colonies grow in 24 hours, but it is best to hold inoculated plates for 48–72 hours in air enriched with 7.5–10% CO_2. Colonies will appear pinpoint to small (approximately 1–2 mm diameter), gray to gray-white, circular, and convex with an entire edge. Gram stain will reveal characteristic pleomorphic gram-negative bacteria. Colonies are catalase-

negative and oxidase-positive. Pure *O. rhinotracheale* cultures have a distinct odor, similar to that of butyric acid. Additional testing is necessary to confirm the identification of *O. rhinotracheale*.

In contaminated samples with fast growing bacteria, such as *E. coli*, *Proteus* sp. or *Pseudomonas* sp., *O. rhinotracheale* colonies may be overgrown and are difficult to detect in routine investigation. Because it has been shown that most *O. rhinotracheale* isolates are resistant to gentamicin (5), Back recommended the use of 10 µg of gentamicin per ml of blood agar medium in an effort to isolate *O. rhinotracheale* from contaminated samples. Blood agar containing 5 µg per ml of gentamicin and polymyxin B was also effective (88).

The API-20NE system (bioMérieux, France) was found useful for the identification of *O. rhinotracheale* (95). Ninety-nine percent of isolates were found to have biocodes 0-2-2-0-0-0-4 (65%) or 0-0-2-0-0-0-4 (34%). For those isolates that were positive for arginine dihydrolase test, biocodes 0-3-2-0-0-0-4 or 0-1-2-0-0-0-4 were found.

The API-ZYM system (bioMérieux, France) can be used to determine the enzymatic activity. In this system, the consistent findings are negative reactions for lipase, ß-glucuronidase, ß-glucosidase, α-mannosidase and α-fucosidase (18).

Another rapid commercial gram-negative bacterial identification system was used to investigate 110 *O. rhinotracheale* strains and found to be a suitable adjunct to classical tests (63).

The rapid slide agglutination test has been used for diagnostic purposes (11, 12). In a study of 112 isolates, however, autoagglutinable strains were regularly found (92).

The agar-gel precipitation test (AGP), using known positive antisera, can be used to identify and serotype *O. rhinotracheale* isolates (95).

Another method used for the identification of suspect isolates is the PCR (34, 45, 89).

Antigen Detection
PCR was used for the detection of *O. rhinotracheale* in tracheal swabs of heavily infected broilers (45). In addition, immunofluorescence antibody test (92) and immunohistochemical staining were used to detect *O. rhinotracheale* in chickens (99). Subsequently, Van Veen *et al.* (101) found that the immunofluorescence assay and the peroxidase-antiperoxidase test were equally sensitive. Using these tests, they were able to identify a higher percentage of *O. rhinotracheale* infected chicken broiler flocks at slaughter when compared with conventional diagnostic methods, i.e., serology and/or bacteriology.

Serology
Serology is useful for flock monitoring or as an aid in the diagnosis of *O. rhinotracheale* infection.

The serum plate agglutination test (SPAT) has been used as a rapid test for the detection of antibodies against *O. rhinotracheale* (12, 27, 42). One SPAT was developed using a nonserotyped Minnesota isolate of *O. rhinotracheale* and reported to have good sensitivity and susceptibility (6). However, in another study (52) the SPAT detected only 65% of infected birds during

the first 2 week of infection and declined significantly thereafter. This suggests that the SPAT detects IgM antibodies, which are efficient in agglutination with specific antigens. In addition, most SPAT-reactions are serotype-specific, although cross-reactions do occur (91).

ELISAs have been developed using different serotypes and extracted antigens of *O. rhinotracheale*. Boiled extract antigens, which are used for serotyping, tend to give the best results for serotype-specific tests (95). Conversely, SDS-antigen extraction (38) and extracted outer membrane proteins of *O. rhinotracheale* (52) will result in more cross-reactions allowing detection of antibodies against different serotypes with one test. Field surveys using these ELISAs or commercial ELISA kits (available in Europe) have been useful for monitoring flocks and the diagnosis of *O. rhinotracheale* infections (7, 38, 42, 64, 68, 70, 86, 95).

Erganis *et al.* (27) developed a dot immunobinding assay (DIA) which appeared to be less sensitive than other agglutination tests.

Popp and Hafez (61) investigated the effect of amoxicillin treatment on the antibody kinetics following experimental infection. They found that immediate treatment did not influence the antibody response, whereas treatment that started 7 days PI resulted in a lower antibody response.

Differential Diagnosis

Respiratory lesions associated with *O. rhinotracheale* are similar to those caused by numerous bacteria, such as *E. coli, Pasteurella multocida*, *R. anatipestifer*, *Avibacterium paragallinarum* and *Chlamydophyla psittaci.*

Intervention Strategies

Management Procedures

O. rhinotracheale appears to be highly contagious and strict biosecurity measures should be followed to prevent its introduction into a flock. However, after a ranch is infected, *O. rhinotracheale* becomes endemic, especially in multiple-age farms and in areas with intensive poultry production (40, 66).

Vaccination

Vaccination of broiler chickens with injectable, inactivated vaccines was found effective (93, 103), but is probably impractical in most commercial flocks. Vaccination of broiler breeders with inactivated vaccines stimulated the development of high maternal antibodies (10, 15) which were sufficient to protect progeny against experimental challenge for up to 4 week of age (93) and produced lower mortality and condemnation rates in the progeny from vaccinated breeders (15). In addition, using a sprayed, live vaccine, at 14 days of age, resulted in the lowest percent of airsacculitis and pneumonia in challenged birds.

Schuijffel *et al.* (73) demonstrated that cross-protective immunity against different *O. rhinotracheale* serotypes can be induced by live vaccination in chickens. The genes encoding 8 crossreactive antigens were amplified, cloned in an expression vector, and expressed in *E. coli*. Purified recombinant proteins with a molecular mass ranging from 35.9–62.9 kDa were mixed and tested as a subunit vaccine for protection against challenge with homologous and heterologous *O. rhinotracheale* serotypes. Subunit vaccination resulted in the production of antibodies reactive to the recombinant proteins on Western blot, and this eightvalent vaccine provided both homologous and heterologous protection against *O. rhinotracheale* challenge in chickens. In a subsequent study (74), they found that these 8 antigens are highly conserved among different *O. rhinotracheale* serotypes, but the different antigens were not expressed by all serotypes. In addition, their four component subunit vaccine was able to protect chickens against challenge with a heterologous *O. rhinotracheale* serotype.

Sprenger *et al.* (81) vaccinated 6-week-old turkeys either intranasally with a live vaccine or subcutaneously with a killed *O. rhinotracheale* vaccine, and challenged them intratracheally with live *O. rhinotracheale* at 14 or 21 week of age. Airsacculitis and pneumonia occurred less frequently in vaccinated birds than in unvaccinated birds after challenge, and *O. rhinotracheale* was recovered from unvaccinated, challenged birds but not from vaccinated, challenged or from unchallenged birds.

Field trails using monovalent or trivalent bacterins in meat turkey flocks resulted in production of antibodies for a short duration (36). In addition, the mortality and condemnation rates were lower in the vaccinated group compared to the unvaccinated group.

A temperature-sensitive mutant of *O. rhinotracheale* was developed (51) and used as a live vaccine in turkeys (50). Turkeys were vaccinated at 5 days of age via the drinking water, and challenged 7 weeks post-vaccination. Vaccinated birds had a significantly lower mean score for gross lesions when compared to unvaccinated birds, as well as a lower rate of reisolation and number of colony forming units of *O. rhinotracheale* per gram of lung tissue.

Vaccination of young turkeys with autogenous bacterins successfully reduced the number of outbreaks of *O. rhinotracheale* infections in turkeys in Israel (11).

Roepke (65) administered an autogenous live vaccine (oral route) in 6-week-old turkeys that resulted in a decrease in pathologic lesions and mortality when the birds were older. It is interesting to note that the birds were simultaneously sprayvaccinated with a live avian paramyxovirus 1 vaccine without any problems.

Due to the possibility of infection by several serotypes, it may be necessary to use different serotypes in the vaccines.

Treatment

The treatment of *O. rhinotracheale* infections with antibiotics is very difficult because of the variable susceptibility of strains. *O. rhinotracheale* can acquire reduced susceptibility or resistance against antibiotics such as amoxicillin, ampicillin, doxycycline, enrofloxacin, flumequine, gentamicin, lincomycin, trimethoprim-sulfonamide, tetracycline and tylosin (21, 54, 56, 77, 97, 100).

Susceptibility can be dependent on the regime used by the poultry industry in various geographical locations. For example, in countries were eggs are regularly dipped in an antibiotic such as enrofloxacin almost all isolates will show resistance to that antibiotic (89).

In 1996, Hafez reported that water medication using amoxicillin at a dose of 250 ppm for 3–7 days gave satisfactory results in most cases, and application of chlortetracycline at a dose of 500 ppm in drinking water for 4–5 days appeared to be effective (31). However, recent studies have shown that treatment with amoxicillin is no longer efficacious (56). In some cases, injections with various tetracyclines and penicillins were found to be effective.

Sixty-eight *O. rhinotracheale* isolates from the United States were found susceptible to ampicillin, erythromycin, penicillin, spectinomycin, and tylosin, and 54 of the 68 isolates were susceptible to neomycin, sarafloxacin, and tetracycline (59). It was also found that German isolates had a significantly lower percentage susceptible to erythromycin and sarafloxacin when compared with isolates from the United States.

Bordetellosis (Turkey Coryza)

Mark W. Jackwood and Y. M. Saif

Introduction

Definition and Synonyms

Bordetellosis in poultry is a highly contagious upper respiratory tract disease caused by *Bordetella avium.* The disease is still commonly referred to as turkey coryza. Other synonyms that have been largely abandoned are alcaligenes rhinotracheitis (ART), adenovirus-associated respiratory disease, acute respiratory disease syndrome, *Bordetella avium* rhinotracheitis (BART), and turkey rhinotracheitis. The numerous names used for this disease reflect the initial confusion that has surrounded its etiology.

Economic Significance

Colonization of ciliated epithelium by *B. avium* results in protracted inflammation and distortion of the respiratory mucosa. In young turkeys, the disease is characterized by sneezing, mouth breathing, altered vocalization, stunted growth, clear oculonasal discharge, submandibular edema, tracheal collapse, and a predisposition to other infectious diseases. In chickens, the disease is similar, but *B. avium* appears to be an opportunistic pathogen. A careful analysis of the economic impact of bordetellosis has not been made; however, impaired growth and mortality resulting from secondary colisepticemia probably cause several million dollars in losses annually to the turkey industry in the United States.

Public Health Significance

Members of the *Bordetella* genus are well known for their capacity to colonize ciliated epithelium and produce respiratory disease in vertebrates. Despite similarities between whooping cough of humans (caused by *B. pertussis*) and bordetellosis of turkeys, there is no evidence that *B. avium* can either colonize or produce disease in humans (42).

History

Turkey rhinotracheitis (coryza) attributable to a bacterium of the genus *Bordetella* was first reported by Filion *et al.* (40) from Canada in 1967. Nearly a decade later, a similar syndrome was recognized, and in Germany the causative agent was identified as *Bordetella bronchiseptica*-like (56); whereas in the United States, it was associated with a respiratory adenovirus (106). In the United States, adenoviruses frequently were associated with the disease (21), but attempts to reproduce it experimentally often failed (32, 117). The postmortem finding of bursal atrophy led to speculation that infectious bursal disease virus (IBDV) may have a role in turkey rhinotracheitis (100, 118). Turkeys inoculated experimentally with IBDV failed, however, to develop clinical disease or lesions, and concurrent inoculation with IBDV and *B. avium* failed to exacerbate experimental bordetellosis (70). Other infectious agents, including mycoplasmas, paramyxoviruses, Yucaipa virus, and chlamydia (2), have been considered in the etiology of turkey rhinotracheitis (85). In 1980, the etiologic agent was reported to be *Alcaligenes faecalis* (110), and two types of the bacterium were observed and designated type I and type II. Then, in 1984, following phenotypic, serologic, and nucleic acid characterization, the name *Bordetella avium* was proposed and generally accepted (78). In addition, it was shown that *Alcaligenes faecalis* type I isolates were the same as *B. avium*, and *A. faecalis* type II isolates were designated *B. avium*-

like to differentiate them from the etiologic agent of bordetellosis (68, 71). Further characterization of *B. avium*-like isolates led researchers to designate that organism as *Bordetella hinzii* (129). *Bordetella hinzii* has been associated with septicemia and bacteremia in older or immune-compromised people (30, 76) and in one patient with cystic fibrosis (41). Finally, in 1985, an acute, highly contagious upper respiratory disease of turkeys was recognized in England and Wales (3). The cause of that disease, which also has been called turkey rhinotracheitis, has been shown to be a pneumovirus (28) (see "Pneumovirus Infection," Chapter 3).

Etiology

Classification

Bordetellosis of turkeys is caused by *Bordetella avium* alone or in combination with environmental stresses and other respiratory pathogens. Experimental transmission (105) of the disease to susceptible poults by Simmons *et al.* (117) in the United States clearly established the etiologic agent as a small gram-negative bacillus. The bacterium, tentatively identified as *Alcaligenes faecalis*, closely resembled *Bordetella bronchiseptica*, except for its failure to split urea. A systematic study by Kersters *et al.* (78) compared 28 pathogenic turkey isolates from diverse sources with 50 culture-collection strains of closely related bacteria. Kersters *et al.* based their conclusions on morphologic, physiologic, nutritional, serologic, electrophoretic, and DNA-RNA hybridization and determined that the bacterial cause of turkey rhinotracheitis represented a new species of *Bordetella*; the name *Bordetella avium* sp. nov. was proposed. Further molecular characterization of *B. avium* has confirmed its unique taxonomic position among species of the *Bordetella* and *Alcaligenes* genera (14, 58, 72, 96, 130, 142). Recently the complete genome of *B. avium* (strain 197N) was elucidated (114). The genome is approximately 3.73 Mb in length and has an overall similarity of 97% (nucleotides) and 75% (proteins) with *B. pertusis, B. parapertusis*, and *B. bronchiseptica*. Almost a third of the predicted proteins for *B. avium* do not have an orthologue in *B. bronchiseptica* verifying that *B. avium* is the most distant member of the *Bordetella* genus.

Morphology and Staining

Bordetella avium is a gram-negative, nonfermentative, motile, strictly aerobic bacillus (71, 78) (see Table 19.5). Filamentous forms have been observed following the growth of *B. avium* in broth media high in nutrients (33).

Growth Requirements

It grows readily on MacConkey, Bordet-Gengou, veal infusion, trypticase soy blood agar, brain heart infusion (BHI), and many other solid media (4) but not on minimal essential medium (71). Trypticase soy and BHI broth support optimal growth when aeration is provided by agitation (9). Leyh *et al.* (83) have developed a defined minimal medium for growth of *B. avium* and detection of auxotrophic mutants.

Table 19.5.   Physical properties of *Bordetella avium*.

Characteristics	References
Gram-negative rod (0.4–0.5 mm 3 1–2 mm)	78, 121
Strict aerobe	78, 121
Motile	77, 121
Capsulated	77, 121
Fimbriated (2 mm diameter)	69
Colonies, 0.2–1 mm at 24 hours; round, glistening	58, 78
Convex (some strains dissociate to larger colonies)	
Hemagglutination of guinea pig erythrocytes	47, 71
Erythrocytes of other species	58, 110
Growth temperature, optimal at 35°C, killed at 45°C	9
Generation time, 35–40 minutes at 35°C	9
Strict tropism for ciliated epitehlium	7, 49
Toxins	
Dermonecrotic (heat labile) toxin	42, 107, 108
Heat stable toxin	124
Osteotoxin	45
Tracheal cytotoxin	45
Guanine 1 cytosine composition of DNA, 61.6–62.6 mol%	78
19.21.   Colonies of *Bordetella avium* strain 002 (left) and *B. hinzii* strain 128 (right) grown on MacConkey and blood agar, 48 hours at 37°C.

Colony Morphology

Most strains of *B. avium* produce small, compact, translucent, pearllike colonies (type I) with entire edges and glistening surfaces (78). Type 1 colonies are typically 0.2–1 mm in diameter after 24 hours of incubation and 1–2 mm in diameter after 48 hours of incubation. Many isolates develop a slightly raised brown-tinged center when grown 48 hours on MacConkey agar (Fig. 19.21). A small percentage of strains dissociate into a rough colony type with a dry appearance and a serrated irregular edge (74). Rough colonies were found to be nonpathogenic (74). A third colony type, characterized by a circular, convex colony with an entire edge, smooth surface, and larger size than type I colonies, has also been reported (58).

Biochemical Properties

Bordetella avium is a nonfermenting bacterium and is generally unreactive in biochemical tests. Biochemical properties of the organism are listed in Table 19.6. It is catalase and oxidase positive but the urease test and nitrate reduction test are negative.

Table 19.6. Biomechanical properties of *Bordetella avium*.

Biochemical test	Results	References
Oxidase (Kovac's reagent)	Positive	78, 121, 142
Catalase	Positive	58, 121, 142
Urease	Negative	55, 78, 121
Nitrate reduced to nitrite	Negative	57, 76, 110
Growth on MacConkey agar (lactose not fermented)	Positive	78, 121
Triple sugar iron agar	Alkaline slant, no change in butt	14, 71, 121
Alkalinize amides and organic salts (Greenwood's low peptone)	Several positive	14, 18, 19, 58

Susceptibility to Chemical and Physical Agents

Most commonly used disinfectants appear to kill *B. avium* when used according to manufacturers' recommendations. Survival of *B. avium* is prolonged by low temperatures, low humidities, and neutral pH (26). On simulated carrier materials, such as dust and feces from turkey houses, the organism survived 25–33 days at 10°C with a relative humidity 32–58%, whereas at 40°C with similar humidity the organism survived less than 2 days (26). Survival of the organism for at least 6 months in undisturbed damp litter has been reported (13). In BHI broth culture, bacteria are killed within 24 hours at 45°C (9). Survival may be greatly prolonged at 10°C on smooth surfaces such as glass or aluminum (26). Fumigation of an uncleaned room with methyl bromide effectively stopped transmission of the disease to day-old susceptible poults (116).

Resistance to streptomycin, sulfonamides, and tetracycline by some strains of *B. avium* is encoded on up to five plasmids ranging in size from 16–51.5 kb (31, 86); however, most strains are sensitive *in vitro* to a large number of antibacterials. Treatment of *B. avium*-infected turkeys with oxytetracycline administered parenterally or by aerosol results in either no effect or a transient reduction in bacterial numbers, even though the strain of *B. avium* was sensitive to oxytetracycline *in vitro* (38, 126, 140).

Antigenic Structure and Toxins

The antigenic structure of *B. avium* and related bacteria has been studied by agar gel precipitation, cross-agglutination, and Western immunoblotting (9, 52, 69, 71, 78). All evidence to date suggests that *B. avium* isolates from various sources are closely related antigenically (78). Using antisera produced in rabbits, Kersters *et al.* (78) identified 6 different surface antigens, 3 of which were cross-reactive among 3 strains of *B. avium*. In addition, they found 2 or 3 precipitation lines in common with *B. bronchiseptica.*

Further antigenic relatedness was demonstrated with *Alcaligenes denitrificans* and *Achromobacter xylosoxidans* (78). Jackwood *et al.* (71) have demonstrated antigenic cross-reactivity between *B. avium* and *B. hinzii* (see later discussion) bacteria. Using convalescent serum and tracheal washings in immunoblotting procedures, Hellwig and Arp (52) have shown that infected turkeys recognize at least 8 outer-membrane proteins of *B. avium.* These proteins range in size from about 14 to 116 kd.

Leyh and Griffith (82) examined the outer-membrane protein profiles of 50 virulent *B. avium* isolates and found 2 major sarkosyl-insoluble proteins of 21 and 37 kD, and at least 13 other lesser proteins, using sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). *B. avium* was found to have an electrophoresis profile distinctly different from those of both *B. hinzii* and *B. bronchiseptica.*

Varley and Carter (143) examined 7 *Bordetella* isolates from turkeys in the United Kingdom from the early 1980s using SDS-PAGE and compared those with known strains of *B. avium, B. bronchiseptica*, and *Alcaligenes faecalis.* All electrophoretic profiles were similar to both known *B. avium* and *A. faecalis* strains, indicating the usefulness of the procedure in distinguishing between *Bordetella* sp. but not for *A. faecalis.* Gentry-Weeks *et al.* (44) identified 5 outer-membrane proteins with molecular masses of 21, 38, 40, 43, and 48 kD being produced in *Escherichia coli* into which genes from *B. avium* had been cloned. Moore and Jackwood (95) produced monoclonal antibodies to a whole-cell *B. avium* preparation that recognized a 41-kD protein. These monoclonal antibodies were used to inhibit *B. avium* guinea pig red blood cell hemagglutination and could also be used to demonstrate the binding of the 41-kD protein to guinea pig erythrocytes. Hemagglutination was also inhibited following treatment of whole-cell *B. avium* with proteinase K indicating that part of the hemagglutinin is on the outside of the cell and with periodic acid, which cleaves carbohydrates from protein. This strongly suggests that the *B. avium* hemagglutinin is a carbohydrate closely associated with the 41-kD surface protein.

In a related study, Arp *et al.* (11) demonstrated complete inhibition of guinea pig red blood cell hemagglutination by *B. avium* using the gangliosides GD_{1a} and GT_{1b} and partial inhibition of hemagglutination using *N*-acetylneuraminic acid. When these same compounds, along with bovine submaxillary mucin and horseshoe crab lectin, were used to treat *B. avium,* adherence to the tracheal mucosa in turkeys was inhibited *in vivo*. The authors speculated that these compounds may be chemically related to the receptors for *B. avium* on the tracheal mucosa.

Five toxins are associated with *B. avium*: a heat-labile toxin (107), a dermonecrotic toxin (42), a tracheal cytotoxin (42), a heat-stable toxin (124), and an osteotoxin (45). Toxins of *B. avium* are considered to be virulence factors, and their activities are described in that section.

Strain Classification

Antigenicity

Studies of *B. avium* from various sources have revealed a great similarity in electrophoretic patterns of outer-membrane proteins (53, 78, 143). Furthermore, antigenic profiles examined by cross-agglutination, agar-gel precipitation, and Western immunoblotting showed little variation among *B. avium* strains (52, 78). *Bordetella avium* shares several cross-reactive antigens with *B. hinzii* and other *Bordetella* species (52, 71).

Genetic and Molecular

Despite the apparent genetic and molecular similarity among *B. avium* strains, differences have been noted in toxin production (20, 107, 124), adherence to tracheal mucosa (10), plasmid profiles (73, 125), antibiotic sensitivity (73), pathogenicity (54, 112), and colony morphology (74, 78). Recently, restriction enzyme analysis and ribotyping were used to characterize isolates of *B. avium*, and 12 different fingerprint profiles were observed (111). A *Hinf*I/*Dde*I restriction enzyme analysis was found to be useful as an epidemiological tool (104). In addition, those profiles were clearly distinguishable from other species of *Bordetella.*

Pathogenicity

Differences in pathogenicity have been reported among *B. avium* strains (110, 112). Differences in pathogenicity, associated with colony morphology and hemagglutination, led to categorization of isolates into various groups or types (14, 71, 110). Continuing study of the molecular characteristics of *B. avium* and related bacteria has identified several differentiating features of *B. avium* (Table 19.7). Strains previously referred to as group 1 (110) and type 1 (71) should now be called *B. avium.* Strains referred to as "*B. avium*-like," earlier (72), were assigned to a new species designated *B. hinzii* and will be reserved for nonpathogenic bacteria closely related to *B. avium* (141).

Virulence Factors

Major virulence factors of *B. avium* can be divided into those involved in either adhesion, local mucosal injury, or systemic effects. Adhesion to cilia of respiratory epithelium is a consistent trait of *B. avium* and other species of *Bordetella.* The surface structures or molecules of *B. avium* responsible for adhesion have been reported (11, 95), and the fimbriae (pili) and hemagglutinin may have roles (10, 68). Although fimbriae have been suggested as possible adhesive factors of *B. avium* (68), morphologically similar fimbriae are also common on adhesion-defective mutants and *B. avium*-like bacteria (53, 68). Hemagglutination (HA) of guinea pig erythrocytes correlates closely with virulence (42, 71) but appears to be unrelated to fimbriae (68). Two transposon-induced mutants selected for loss of HA activity had reduced adherence *in vivo* (10). Reversion of one mutant to HA-positive status resulted in the reconstitution of adherence.

Temple *et al.* (134), working with a hemagglutination-negative mutant of *B. avium*, reported that no clinical signs of disease were observed when given to 1-day-old or 1-week-old turkeys. As with other *Bordetella* species, it seems likely that more than

Table 19.7.   Differentiation of *Bordetella avium* and *B. hinzii*.

Characteristics	B. avium	B. hinzii
Pathogenicity	Postive	Negative

one surface molecule is responsible for adhesion to cilia. Spears *et al.* (129), working with lipopolysaccharide (LPS) mutants of *B. avium*, showed that mutations in the *wlbA* and *wlbL* genes, two of the 12 genes associated with LPS biosynthesis, induced a clumped-growth phenotype and decreased tracheal colonization and serum resistance. A recent study showed that the core region and possibly the O antigen were associated with that phenotype (115).

Several local effects have been attributed to toxins of *B. avium.* An acute cytotoxic and ciliostatic effect of *B. avium* on turkey tracheal organ cultures was reported by Gray *et al.* (48, 50) and others (87). Rimler (107) described a heat-labile toxin capable of killing mice and young turkeys. The toxin was later shown to produce necrotic and hemorrhagic lesions in the skin of turkeys and guinea pigs after intradermal injection and similar lesions in the liver and pancreas of turkeys following intraperitoneal injection (106, 108). Recent work has shown that *B. avium* produces a dermonecrotic toxin with physical, antigenic, and biologic properties comparable to those reported for the heat-labile toxin (42). The dermonecrotic toxin is a cell-associated, 155-kD protein with biologic activity comparable to dermonecrotic toxins of *B. pertussis* and *B. bronchiseptica* (42). The toxin appears not to be responsible for ciliostasis (108) or local epithelial damage (136). Gentry-Weeks *et al.* (43) produced spontaneous-phase variants of *B. avium* that lacked dermonecrotic toxin and four outer-membrane proteins when grown in media containing nicotinic acid and $MgSO_4$. These variants had a different colony morphology but retained the ability to agglutinate guinea pig red blood cells. Passage in susceptible turkeys caused these variants to revert to the wild type. A role for the dermonecrotic toxin has been established in the pathogenesis of bordetellosis in turkeys by Temple *et al.* (134), who reported that a dermonecrotic toxin-negative mutant was nonpathogenic when given to 1-day-old or 1-week-old turkeys.

Another toxin of *B. avium* implicated in local mucosal injury is the tracheal cytotoxin (TCT) isolated by Gentry-Weeks *et al.*

(42). The TCT of *B. pertussis,* which is chemically identical to that produced by *B. avium,* has been shown to specifically damage ciliated epithelial cells leading to a loss of epithelium and poor clearance of mucus (47). The TCT of *B. avium* is an anhydropeptidoglycan monomer with a mass of 921 kD. Whether TCT is the mediator of cytotoxic activity reported earlier by Gray *et al.* (48, 50) is unclear.

Simmons *et al.* (124) have identified a *B. avium* heat-stable toxin capable of causing diarrhea and death in mice inoculated intraperitoneally; however, no evidence shows that the toxin produces adverse effects in poultry. None of 18 *B. avium* strains from Australia had the mouse-lethal toxin that was found in several reference strains from other turkey-producing areas in the world (20). An osteotoxin recently was found to be associated with *B. avium.* It has been identified as beta cystathionase and is lethal to MC3T3-E1 osteogenic cells, fetal bovine trabecular cells, UMR106-01 (BSP) rat osteosarcoma cells, and embryonic bovine tracheal cells (45). This toxin might be responsible for the cartilage lesions that lead to tracheal softening and collapse. Examination of several *B. avium* strains for the production of extracytoplasmic adenylate cyclase (42, 108) or pertussis toxin (42) failed to detect either one by immunologic and functional assays. Earlier studies by Simmons *et al.* (123) suggested that *B. avium* produces a histamine-sensitizing factor similar to that produced by other *Bordetella* species.

Virulence factors in *Bordetella* spp. have been shown to be coordinately regulated at the genetic level by the *bvg* (bordetella virulence gene) locus. Expression of virulence factors can be modulated by environmental conditions including temperature, sulfate ions, and nicotinic acid. This phenomenon is termed antigenic variation and has been reported in *B. avium* (74)*.* In addition, genetic evidence for a *bvg* locus in *B. avium* has been reported (43,114). In a study to detect virulence genes of *B. pertussis* by Southern hybridization, it was determined that the *bvgS* gene was present in *B. avium* but the *bvgA* was not (43). Since that report, the *B. avium bvg* homolog has been cloned and sequenced, which showed a frame shift in the poly (C) tract suggesting a different phase variation mechanism in *B. avium* from other *Bordetella* (27, 114).

Acquisition of iron (Fe) from the host, an essential characteristic for most bacteria, was shown to be important for colonization and proliferation of *B. avium* (98). The *B. avium* Fe utilization locus consists of a putative outer-membrane heme receptor (BhuR) that mediates acquisition of Fe from hemin and hemoproteins, and six other accessory genes (rhuIR and bluSTUV). Expression of BhuR is regulated by sigma factor rhuI which is likely expressed in a Fe uptake regulator (Fur) dependent manor in response to environmentally available Fe (79, 80, 81).

A number of systemic pathophysiologic effects have been attributed to *B. avium* infection. These effects include elevation of serum corticosterone (93), enhanced leukocyte migration (90), altered electrocardiograms (145), reduced body temperature (34), reduced levels of monoamines in brain and lymphoid tissues (35, 36), reduced levels of liver tryptophan 2,3-dioxygenase (144), and reduced thyroid hormones in conjunction with fasting (37). Beginning with the original recognition of turkey rhinotra-

cheitis in North Carolina, reports from flock service people have suggested defective immune function in affected poults (120). Vaccination of these poults with live vaccines resulted in unexpected deaths. This background, along with the observation of reduced bursa size in some poults with rhinotracheitis (118), led to a series of experiments to determine effects of *B. avium* infection on immune function. Initial studies in poults infected with *B. avium* (120) found a decreased lymphocyte blastogenesis response to concanavalin A and a depletion of thymic lymphocytes. Subsequent studies of cell-mediated immunity in *B. avium*-infected poults showed the reverse effect with enhanced graft-versus-host and delayed hypersensitivity responses (91, 92), both measures of cell-mediated immunity.

Pathobiology and Epidemiology

Incidence and Distribution

Bordetellosis is an important disease in major turkey-producing regions of the United States, Canada (23), Australia (18), and Germany (56). The etiology of turkey rhinotracheitis in Great Britain, France, Israel, and South Africa, however, frequently may include viruses and other bacteria in addition to *B. avium* (51, 85). Hopkins *et al.* (63) detected *B. avium* antibodies by enzyme-linked immunosorbent assay (ELISA) in 42 of 44 wild turkeys being translocated in Arkansas. Thus, *B. avium* may be a significant problem in wild turkeys, or it may be that wild turkeys act as a reservoir for the infection. McBride *et al.* (89) surveyed three backyard turkey flocks located within 1 mile of commercial turkey farms in California and found all turkeys sampled at each location to be seropositive to *B. avium* when tested by microagglutination. A survey between 1998 and 2000 found *B. avium* antibodies in sera from 100 individuals representing 41 different species of wild and domestic birds (103). In addition, Raffel *et al.* (103) isolated *B. avium* from mallards (*Anas platyrhynchos*), wild turkey (*Meleagris gallopavo*), and Canada goose (*Branta canadenisis*). Hollamby *et al.*(61) detected antibodies against *B. avium* in peafowl (*Pavo cristatus*).

Natural and Experimental Hosts

The natural host of *B. avium* is the turkey, although isolations of *B. avium* have also been made from chickens and other avian species (58, 122). Strains of *B. avium* isolated from avian species other than turkeys are pathogenic for day-old turkeys (58). A study of the prevalence of *B. avium* in North Carolina broiler flocks during the winter months revealed a 62% infection rate (16). Furthermore, a higher isolation rate was found from flocks with respiratory disease. Attempts to reproduce rhinotracheitis experimentally in chickens revealed that only 2 of 8 *B. avium* strains colonized the trachea and produced disease (15); however, a later study (14) suggested the isolations from chickens may have included both *B. avium* and *B. hinzii* bacteria. Finally, it was reported that *B. avium* appears to be an opportunistic pathogen in chickens (66). Prior exposure to an upper-respiratory disease vaccine, such as infectious bronchitis virus or Newcastle disease virus, was necessary to induce clinical signs in leghorn chickens.

Turkey and chicken strains of *B. avium* are similar (78), and

cross-infection can occur between the species (122). Bordetello-sis in chickens tends to be less severe than in turkeys (94, 122). A strain of *B. avium,* pathogenic for turkeys and Japanese quail, failed to produce clinical disease in guinea pigs, hamsters, and mice (88). Naturally occurring infection with *B. avium* typically is recognized in turkeys 2–6 weeks old (23, 56, 101), although older turkeys and breeder flocks may also develop clinical disease (75, 77). Experimental inoculation of poults more than 1–2 weeks old frequently results in colonization but with only mild disease.

Transmission and Carriers

Bordetellosis is highly contagious. The disease is readily transmitted to susceptible poults through close contact with infected poults or through exposure to litter or water contaminated by infected poults (116). Infection is not transmitted between adjacent cages, thus providing evidence against aerosol transmission (116). Litter contaminated by a flock infected with *B. avium* is likely to remain infective for 1–6 months (13, 26). Although a carrier state has not been demonstrated in turkeys recovered from bordetellosis, the possibility seems likely.

Incubation Period

The incubation period is 7–10 days when susceptible poults are exposed to infected poults by close direct contact (116). Intranasal or intraocular inoculation of day-old poults with 10^5 to 10^7 colony-forming units of *B. avium* results in clinical signs (nasal exudate) of bordetellosis in 4–6 days (6, 49, 112).

Clinical Signs

An abrupt onset of sneezing (snick) in a high percentage of 2–6-week-old turkeys over the course of a week is suggestive of bordetellosis. Older turkeys may also develop a dry cough (77). A clear nasal discharge can be expressed by placing gentle pressure over the bridge of the beak between the nostrils. During the first 2 weeks of disease, the nares and feathers of the head and wings become crusted with wet, tenacious, brownish exudate (Fig. 19.22), and some birds develop submaxillary edema. Mouth breathing, dyspnea, and altered vocalization in the second week of clinical signs result when the nasal cavity and upper trachea become partially occluded with mucoid exudate. Tracheal softening can be palpated through the skin of the neck in some birds beginning in the second week of disease. Behavioral changes include reduced activity, huddling, and decreased consumption of feed and water. Concurrent infections and poor weight gains contribute to poor flock performance and numerous birds with stunted growth (9). Signs of disease begin to subside after a course of 2–4 weeks (49, 101, 112, 139).

Morbidity and Mortality

Bordetellosis in turkeys is typically characterized by high morbidity and low mortality. In turkeys 2–6 weeks of age, morbidity reaches 80–100% (112), whereas the mortality rate is less than 10%. Infection of a breeder flock with *B. avium* resulted in only 20% morbidity with no mortality (77). High mortality rates (>40%) in young turkeys frequently are associated with concur-

rent isolation of *Escherichia coli* (23, 112). Experimental studies of concurrent *B. avium* and *E. coli* infections in 2–4-week-old turkeys revealed defective clearance of *E. coli* from tracheas (39, 137) and increased severity of airsacculitis attributable to *E. coli* (138). Adverse environmental temperatures (9), high humidity (127), poor air quality, and concurrent respiratory pathogens may increase mortality rates (112). Cook *et al.* (29) studied the interaction of turkey rhinotracheitis virus (TRTV), a pneumovirus, with *B. avium* and a *Pasteurella*-like organism in turkeys. When the TRTV was administered alone, the virus could be isolated from only the trachea, but when given in combination with the bacteria, it was capable of invasion and could be isolated from the heart, liver, spleen, kidney, and cecal tonsils. Hinz *et al.* (59) described an outbreak of *B. avium* in combination with *Chlamydia psittaci* in 6 different turkey flocks on a large multiple-age grow-out operation. Mortality in the affected flocks ranged from 7–20%, and the high mortality was attributed to secondary infections from *Klebsiella pneumoniae, E. coli,* and *Pseudomonas fluorescenc.*

Pathology

Gross

Gross lesions are confined to the upper respiratory tract and vary with the duration of infection. Nasal and tracheal exudates change in character from serous initially to tenacious and mucoid during the course of disease. Tracheal lesions consisting of generalized softening and distortion of the cartilaginous rings, dorsal-ventral compression, and fibrinomucoid luminal exudate are highly suggestive of bordetellosis (6, 139). In isolated cases, there is severe infolding of the dorsal tracheal wall into the lumen immediately below the larynx (Fig. 19.23) (6, 140). In cross-section, tracheal rings appear to have thick walls and a dimin-

ished lumen. Distortion of tracheal cartilages persists at least 53 days postinfection (6). Accumulation of mucoid exudate in an area of tracheal infolding frequently leads to death by suffocation (6). Hyperemia of the nasal and tracheal mucosae and edema of interstitial tissues of the head and neck are apparent during the first 2 weeks of infection.

Microscopic

Cilia-associated bacterial colonies, progressive loss of ciliated epithelium, and depletion of mucus from goblet cells are distinctive characteristics of bordetellosis (6). Colonization of ciliated epithelium begins on the nasal mucosa, progresses down the trachea, and moves into primary bronchi within 7–10 days. Bacteria adhere specifically to cilia and have not been found attached to other cell types (7). As seen by scanning electron microscopy, surfaces of adherent bacteria are covered with numerous knoblike surface projections (Fig. 19.24). Colonized cells having increased eosinophilia of the apical cytoplasm may protrude slightly from the mucosa (140). Bacterial colonies (Fig. 19.25) are most apparent on the tracheal mucosa 1–2 weeks after onset of clinical signs, before loss of ciliated cells is extensive (6, 7).

Ultrastructural

During the first 2 weeks of signs, ciliated tracheal epithelium is gradually lost and replaced by nonciliated cuboidal epithelium (Fig. 19.26). These immature hyperplastic cells have basophilic cytoplasm with variable numbers of small mucous granules (6, 140). Late in the disease, squamous metaplasia of tracheal epithelium may occur (Fig. 19.27). Linear, eosinophilic inclusions occur in the cytoplasm of tracheal epithelium during the first 3 weeks of disease (6, 7). Ultrastructurally, these inclusions are proteinaceous crystals composed of parallel filaments surrounded by membrane (7). During the third and fourth week of disease, the tracheal mucosa becomes distorted by numerous folds and mounds of dysplastic epithelium. Depending on the severity of the disease, the tracheal epithelium returns to normal 4–6 weeks after the onset of signs (6, 49), when *B. avium* can no longer be isolated.

Discharge of copious mucoid exudates from the upper respira-
19.25. Trachea from a poult infected 3 weeks previously with *Bordetella avium*. Characteristic lesions of brodetellosis include cilia-associated bacterial colonies (arrow), loss of ciliated epithelium, dilated mucous glands depleted of mucus, and interstitial infiltration of plasma cells and lymphocytes.

tory tract is accompanied by depletion of mucus from isolated goblet cells and mucous glands along the mucosa (6, 140). Alveolar glands become cystic and lined by immature epithelium with small mucous granules (Fig. 19.25). Goblet cells remain largely depleted of mucous granules from the first through the third week of clinical disease.

Cellular exudates in the tracheal lamina propria begin with multifocal infiltrates of heterophils and change to predominantly

19.27.   Squamous metaplasia of tracheal epithelium occurs in some poults late in the course of bordertellosis.

lymphocytes and plasma cells as clinical signs subside (6, 49). In the third through fifth week of disease, a diffuse increase in mucosal plasma cells is accompanied by multifocal lymphoid nodules in the submucosa. Mucosal surface exudates change from mucopurulent to fibrinopurulent after the first week of disease (7)

Pulmonary lesions are restricted to primary bronchi and bronchus-associated lymphoid tissue (138, 139). In contrast to the tracheal mucosa, the bronchial mucosa maintains a near normal appearance including ciliated columnar epithelium and goblet cells (139). Mild colonization of isolated ciliated cells by *B. avium* is accompanied by a mild infiltrate of heterophils. Bronchus-associated lymphoid tissue, normally found at the junction of primary and secondary bronchi, becomes grossly apparent, and lymphoid nodules protrude into the bronchial lumen (139). Other changes of lymphoid tissues include the depletion of cortical lymphocytes from the thymus during the early disease (120)

In summary, distinctive microscopic lesions of diagnostic value include cilia-associated bacterial colonies, cytoplasmic inclusions, cystic mucosal glands, and generalized loss of ciliated epithelium.

Pathogenesis of the Infectious Process

Initial adhesion of bacteria to ciliated cells of the oronasal mucosa leads to progressive colonization from the upper trachea to the primary bronchi over the next week. Expansion of the bacterial population along the respiratory mucosa stimulates acute inflammation and the release of mucus from goblet cells leading to sneezing, coughing, and nasal obstruction. Spread of infection against the flow of mucociliary clearance occurs as motile "swarmer" bacteria break free from microcolonies and move within the layer of mucin to other ciliated cells. Apparently, tracheal mucus does not contain receptor analogs to impede the spread of the bacteria. During the next week, many of the cells
colonized by *B. avium* slough into the tracheal lumen, leaving large surfaces devoid of cilia.

How *B. avium* damages the tracheal mucosa and cartilage remains unknown, but the tracheal cytotoxin may be involved. The formation of cytoplasmic protein crystals and delayed restitution of normal mucosa are suggestive of a toxin that alters cell growth and differentiation. The molecular basis for softening and the collapse of tracheal rings may result from abnormal connective tissue metabolism leading to qualitative and quantitative changes in collagen and elastin (144).

As ciliated cells are progressively lost, the flow of mucus and exudates becomes sluggish, particularly in the upper trachea and nasal cavity. Obstruction of nasolacrimal ducts causes foamy ocular exudate to accumulate at the medial canthus of the eye. Signs of bordetellosis result from local and systemic products of the inflammatory response, soluble bacterial toxins, and physical obstruction of large air passages.

Within a week of the onset of clinical signs, local and systemic immune responses develop to *B. avium* antigens. Antibody transported from serum and antibody produced by submucosal plasma cells accumulates in respiratory secretions. Local antibody interacts with free "swarmer" *B. avium* cells to inhibit their motility and to prevent adhesion to other ciliated cells. Colonies of bacteria among the cilia are largely protected from host defenses; however, numerous bacteria are shed along with colonized epithelial cells. The bacterial population diminishes over the next several weeks as colonized cells are lost, and newly formed ciliated cells are protected from colonization by antibody.

Some convalescent birds are probably slow to clear all *B. avium* from their respiratory tissues and serve as a source of infection for susceptible flocks. As mucosal immunity wanes over the next 4–8 weeks, any residual population of *B. avium* in the nasal cavity or sinuses can again expand to produce clinical infection or be transmitted to susceptible birds.

Immunity
Active
An active immune response is generated in most turkeys inoculated with live *B. avium* or various bacterins. The serum antibody

response to a temperature-sensitive mutant of *B. avium* is variable, depending on vaccination dosage, turkey age, and environmental factors affecting colonization (9, 25, 54, 60, 64, 67, 75). Recent studies have suggested that poults less than 3 weeks of age respond poorly to *B. avium* vaccines (60, 67).

Most turkeys develop a humoral immune response to infection with *B. avium* (6, 65, 133). Serum antibodies, detected by microtiter agglutination, appear within 2 weeks after experimental exposure to *B. avium* and reach peak levels by 3–4 weeks postexposure (6, 65). The period of peak antibody titer is followed within 1 week by resolution of clinical disease and a decline in bacterial numbers in the trachea (6). This, combined with evidence for maternal immunity, suggests an important role for humoral immunity in the prevention and recovery from infection (13, 57).

Infection with *B. avium* has been recognized as potentially immunosuppressive since Simmons *et al.* (120) reported thymic lesions and suppression of lymphocyte blastogenesis. Although subsequent tests have revealed no evidence for defects in cellular immunity (90, 91, 92), infection with *B. avium* apparently interferes with immunity to live *Pasteurella multocida* and hemorrhagic enteritis vaccines (109, 120). Reduced monoamine concentrations in brain and lymphoid tissues and elevated serum corticosterone have been recorded in turkeys infected with *B. avium* (35, 36, 93). Although such hormonal changes are probably not unique to bordetellosis, they may help explain the immunosuppression seen in the field.

Passive

Neighbor *et al.* (99) evaluated maternal antibody in poults from immunized and nonimmunized hens. Resistance to clinical disease and gross lesions was greatest in poults with maternal antibody, as measured by ELISA. Convalescent serum and tracheal secretions from turkeys infected with *B. avium* inhibit adherence of the bacteria to the tracheal mucosa in turkeys (8). Moreover, adherence of *B. avium* is inhibited whether convalescent serum is administered locally or parenterally. The passive administration of convalescent serum is believed to mimic many aspects of maternal immunity. Suresh *et al.* (133) evaluated antibody levels in serum, tracheal washings, and lacrimal secretions from turkeys experimentally infected with *B. avium*. Turkeys were sacrificed at weekly intervals through 8 weeks postinoculation. Maternal antibody was undetectable by 3 weeks of age, and the appearance of serum and mucosal antibody was associated with clearance of *B. avium* from the trachea. Using serum and tracheal secretions collected from turkeys during a 4-week course of infection, at least 8 *B. avium* surface proteins were identified using Western immunoblots (52).

Diagnosis

The diagnosis of bordetellosis is currently based on clinical signs and lesions, isolation of *B. avium* from the respiratory tract, a positive serologic test, or some combination of these. Additional diagnostic techniques that have been developed include a monoclonal antibody-based latex bead agglutination test (132), an in-

direct fluorescent antibody staining technique using a monoclonal antibody (131), a capillary gas chromatography assay for cellular carbohydrates using per-acetylated aldonitriles and *O*-methyloximes (97), and a polymerase chain reaction technique (105, 113).

Isolation and Identification of Causative Agent

Bacterial isolation is accomplished on MacConkey agar inoculated with a swab sample from the tracheal mucosa. Samples collected from the choanal opening and nostril, or by passing a swab into the trachea through the larynx, commonly yield large numbers of nonpathogenic bacteria (119, 128). When turkeys are available for necropsy examination, swab samples should be collected aseptically through an opening in the midcervical trachea. After 24 hours of incubation on MacConkey agar, colonies of *B. avium* are clear and pin-point in size. Although most contaminating bacteria form large mucoid colonies (often lactose fermenters), which mask *B. avium* in the more concentrated streak pattern, the minute colonies of *B. avium* may be recognized in the more diluted streak pattern. By incubating culture plates up to 48 hours, *B. avium* colonies are more easily recognized and may develop a brownish raised center (Fig. 19.21). Early in the course of infection, pure cultures can be obtained from the trachea, but in later stages, *E. coli* and other opportunistic bacteria may be isolated (112). Physical and biochemical characteristics that serve to distinguish *B. avium* from closely related bacteria are presented in Tables 19.6 and 19.7.

Serology

Serologic testing has proven to be useful experimentally and in the natural disease for detection of serum antibodies to *B. avium*. Jackwood and Saif (65) developed a microagglutination test (MAT) using a killed, neotetrazolium-chloride-stained *B. avium* antigen in a microtiter system. The MAT has been shown to correlate well with bacterial isolation. It seems likely that serologic tests remain positive for a period after *B. avium* can no longer be cultured. In a field study by Slavik *et al.* (128), flocks with a history of respiratory disease were more commonly positive serologically for *B. avium*, even though bacteria were not isolated. In experimentally infected poults, antibody is detectable by the MAT from 2 weeks postinoculation (PI) until at least 5–7 weeks PI (6, 9, 65). Peak titers occur at about 3–4 weeks PI. For each of the preceding tests, agglutination occurs at serum dilutions of from 1:320 to 1:512 (6, 65). Use of heterologous *B. avium* antigen has little effect on agglutination titers (9).

Hopkins *et al.* (62) developed an ELISA for detection of serum antibodies to *B. avium* using a whole-bacteria antigen, a 1:200 serum dilution, and a 1:3200 dilution of commercially available anti-turkey IgG conjugate. Serologic results obtained with ELISA correlate well with those from the MAT, but ELISA is more sensitive for detection of maternal antibody in day-old poults (62). Although *B. avium* has antigens in common with closely related *B. hinzii* bacteria, no evidence indicates that these related bacteria cause a positive serologic reaction to *B. avium* in nature. Several different variations of ELISA procedures have been developed for *B. avium* (12, 22, 99, 133, 135). The varia-

tions include a dot-immunobinding assay (135) and a particle concentration fluorescence immunoassay (22). All of these detect maternal antibody and are reproducible and sensitive. Recently a commercially available ELISA kit has become available, and it has proven to be very useful (84).

Differential Diagnosis

Bordetellosis must be differentiated from other primary and secondary causes of rhinotracheitis. Mycoplasmosis, chlamydiosis, and respiratory cryptosporidiosis may mimic or contribute to many of the clinical signs of bordetellosis (2, 59, 77, 85). Of the viral agents, Newcastle disease virus, Yucaipa virus, adenovirus, influenza virus, and pneumovirus should be considered (28, 85). Although *B. avium* alone can produce all of the clinical signs and lesions of bordetellosis in the natural disease, *B. avium* is more frequently accompanied by Newcastle disease, *Mycoplasma* spp., and opportunistic bacteria such as *E. coli.*

Currently, the greatest diagnostic challenge is to differentiate *B. avium* from *B. hinzii* bacteria in primary cultures. Distinguishing characteristics of these closely related bacteria are presented in Table 19.7; however pathogenicity testing in day-old poults is definitive. Intranasal inoculation of day-old poults with a 24-hour broth culture of *B. avium* is expected to produce clinical disease and nasal discharge in susceptible poults within 3–5 days.

Intervention Strategies

Management Procedures

Bordetella avium is highly contagious by direct contact and through contamination of water, feed, and litter. Strict biosecurity measures are required to prevent infection of clean flocks, and rigorous cleanup procedures are required to eliminate the organism from contaminated premises. A minimal cleanup procedure for contaminated premises should include complete removal of litter, thorough washing of all surfaces, disinfection of watering systems and feeders, and the application of a disinfectant followed by either formaldehyde fumigation or by the application of a dilute formaldehyde solution to all surfaces. *Bordetella avium* is tracked easily from one facility to another, so the use of disinfectant foot baths, clean outer clothing, and even a required shower between visits to different houses and locations is essential. Because the severity of bordetellosis is exacerbated by adverse environmental and infectious factors, attempts should be made to optimize temperature, humidity, and air quality while avoiding or delaying the use of live attenuated vaccines.

Vaccination

Vaccines available commercially for the prevention of bordetellosis in turkeys include a live temperature-sensitive (ts) mutant of *B. avium* (Art Vax™, Schering-Plough Animal Health, Union, NJ) and a whole-cell bacterin ADJUVAC-ART, which used to be available from Sanofi Animal Health, Inc., Overland Park, KS. The live ts-mutant vaccine was induced by nitrosoguanidine mutation of a virulent *B. avium* isolate obtained from North Carolina (24). Original studies indicated that the ts mutant colonized the nasal mucosa and induced moderate levels of serum antibodies (24). Although subsequent use of the vaccine in Utah indicated substantial protection (25, 75), other controlled experiments indicated only moderate reduction in lesion severity or delayed the onset of clinical disease (54, 60, 64, 67). The ts mutant has the capacity to adhere to respiratory epithelium, but its slow growth rate may critically limit its ability to colonize and induce protective immunity (9, 10). Use of the ts-mutant vaccine, according to label directions in day-old poults, failed to prevent infection and disease; however, use of the vaccine in poults 3 weeks of age and older prevented disease but not infection (60, 67). Concern exists that turkeys less than 3 weeks of age may be unable to respond adequately to *B. avium* antigens or are unable to mount an adequate local immune response. Glunder *et al.* (46) inoculated killed *B. avium* with adjuvant into 1, 7, 10, 14, and 21 day old poults and found that regardless of age at vaccination, serum antibodies were first detected at 28 days of age.

Houghten *et al.* (64) compared a spray method of vaccination with the method recommended by the manufacturer for the ts-mutant vaccine. Turkeys were immunized at 2 days of age, using a spray cabinet, followed 14 days later with another coarse spray exposure to the ts-mutant vaccine. Another group of turkeys was similarly immunized by eyedrop exposure followed 14 days later by oral exposure. The spray and eyedrop/oral methods of immunization were equally effective in reducing the severity of tracheal lesions, but neither method prevented infection of the trachea by virulent challenge strains.

Several studies have indicated that breeder hen vaccination may be useful for prevention of bordetellosis in progeny poults (13, 57, 99). Vaccination of breeder hens with either heat-killed (57) or formalin-killed (13) adjuvanted bacterins delayed the onset and severity of clinical disease in challenge-exposed poults. Passive immunization of 3-week-old poults with convalescent serum reduces adherence of *B. avium* to the tracheal mucosa in a dose- and time-dependent manner (8). Taken in total, these studies suggest that maternal antibody of the IgG class may confer temporary immunity to newly hatched poults. Additionally, vaccination of poults with purified pilus preparations and adjuvanted bacterins results in significant protection against *B. avium* colonization and clinical disease (1).

Because *B. avium* and *B. hinzii* bacteria are antigenically related, Jackwood and Saif (69) designed experiments to determine whether poults infected with nonpathogenic *B. hinzii* bacteria would develop immunity to *B. avium.* The *B. hinzii* bacteria failed to persist for a significant period in the respiratory tract and failed to induce either a serologic response or protection to *B. avium* challenge. Development of improved vaccines for bordetellosis requires better characterization of protective antigens of *B. avium* and an understanding of the turkey's immune response to them.

Treatment

Treatment of bordetellosis with antibiotics administered in the water, by injection, or by aerosol has produced minimal clinical improvement in most cases. Treatment of an infected breeder flock with 1.8 g tetracycline-HCl and 2×10^6 IU potassium peni-

cillin-G per gallon of drinking water for 3 days produced clinical improvement within 24 hours (77). Treatment of bordetellosis in young turkeys with an aerosol of oxytetracycline-HCl reduced mortality associated with subsequent Newcastle disease vaccination compared with untreated flocks (38). Although these clinical testimonials suggest a favorable response to treatment, it remains unclear whether clinical improvement results from antibacterial effects against *B. avium* or to secondary pathogens such as *E. coli.*

In a group of experimentally infected poults, parenteral administration of long-acting oxytetracycline had no apparent effect on *B. avium* infection (126). Treatment of experimental bordetellosis with oxytetracycline-HCl administered by aerosol caused a transient reduction of bacterial numbers in the trachea and a delay in clinical signs and lesion development (140). However, by 4 days after treatment, bacterial numbers and disease severity were similar between treated and nontreated groups (140).

Yersin *et al.* (146) were able to demonstrate up to a 40% reduction in the loss of cilia following the treatment of *B. avium*-infected turkeys with niacin added to the drinking water at 70 mg/L. Niacin treatment also reduced clinical signs, increased body weight, and reduced adherence of bacteria to the tracheal epithelium when treated turkeys were compared with untreated infected turkeys. The authors speculate that the mechanism for this therapeutic effect may be the result of the inhibition of glucocorticoid-induced DNA strand breakage and subsequent ADP-ribosylation of nuclear DNA. This action would allow for the continued protein synthesis necessary to maintain ATP-mediated functions in the cilia of the trachea. Pardue and Luginbuhl (102) observed that administration of 0.016% oxy-halogen formulation in the drinking water at 4, 7, 10, 14, and 17 days of age reduced many of the signs associated with bordetellosis in turkeys.

Chapter 20

Infectious Coryza and Related Bacterial Infections

Pat J. Blackall and Edgardo V. Soriano[*]

Introduction

Infectious coryza (IC) is an acute respiratory disease of chickens caused by the bacterium *Avibacterium paragallinarum*, once known as *Haemophilus paragallinarum* (13)*.* The taxonomic changes that resulted in the recognition of *Av. paragallinarum* also allocated the bacterium once known as *Pasteurella galli-narum* to the same genus as *Av. gallinarum* (13). Hence, this chapter has integrated our current knowledge on both bacterial species, *Av. paragallinarum* and *Av. gallinarum,* and the diseases associated with both bacteria.

The clinical syndrome of infectious coryza has been described in the early literature as roup, contagious or infectious catarrh, cold, and uncomplicated coryza (156). The disease was named infectious coryza because it was infectious and affected primarily the nasal passages (6). No specific syndrome name has been allocated to the disease conditions associated with *Av. gallinarum*.

Economic Significance

The greatest economic losses associated with infectious coryza result from poor growth performance in growing birds and marked reduction (10–40%) in egg production in layers. The disease can have a much greater impact than the relatively simple scenario described above. As an example, an outbreak of the disease in older layer birds in California, which was not associated with any other pathogen, caused a total mortality of 48% and a drop in egg production from 75% to 15.7% over a 3-wk period (27).

Infectious coryza can have significant impact in meat chickens. In California, two cases of infectious coryza, one complicated by the presence of *Mycoplasma synoviae,* caused increased condemnations, mainly due to airsacculitis, that varied from 8% to 15% (52). In Alabama, an infectious coryza outbreak in broilers that was not complicated by any other disease agent, caused a condemnation rate of 69.8%, virtually all due to airsacculitis (70).

When infectious coryza occurs in chicken flocks in developing countries, the added presence of other pathogens and stress factors can result in disease outbreaks that are associated with greater economic losses than those reported in healthy flocks in developed countries. In China, outbreaks of infectious coryza have been associated with morbidities of 20% to 50% and mortalities of 5% to 20% (44). In Morocco, outbreaks on 10 layer farms

caused egg drops that ranged from 17 to 41% and mortalities of 0.7 to 10% (95). A study of village chickens in Thailand has shown that the most common cause of death in chickens less than 2 months old and those more than six months old was infectious coryza (148). It was only in chickens that were between 2 and 6 months of age that other diseases such as Newcastle disease and fowl cholera killed more chickens than infectious coryza (148). Infectious coryza has also been reported in kampung (village) chickens in Indonesia (108, 142). Overall, there is considerable evidence that infectious coryza outbreaks can have a much greater impact in developing countries than in developed countries.

Outbreaks of disease associated with *Av. gallinarum* have not been commonly reported. Mortalities in chickens have been reported at 5–10% (28) and 10–34% (54). In turkeys, mortalities of 18–26% have been reported (8). In most cases of disease associated with *Av. gallinarum*, the possibility that other infectious agents such as viruses and mycoplasmas were involved in the overall disease complex exists.

Public Health Significance

There is no public health significance to *Av. paragallinarum*. There are three reports of *Av. gallinarum* being a possible cause of disease in humans (1, 2, 4). However, these reports lack definitive molecular or phylogenetic data and some have been suggested to be misidentifications (59). On the balance of the available evidence, *Av. gallinarum* does not appear to have public health significance.

History

As early as 1920, Beach (5) believed that infectious coryza was a distinct clinical entity. The etiologic agent eluded identification for a number of years, since the disease was often masked in mixed infections and with fowlpox in particular. In 1932, De Blieck (49) isolated the causative agent and named it *Bacillus hemoglobinophilus coryzae gallinarum.*

The first report to draw attention to organisms that appear to resemble the organism *Av. gallinarum* was Schneider (132). The description of the species *P. gallinarum* occurred in 1955 (64).

Etiology
Classification

Based on studies conducted during the 1930s, the causative agent of IC was classified as *H. gallinarum* because of its requirement

---

for both X-(hemin) and V-(nicotinamide adenine dinucleotide—NAD) factors for growth (57, 131). In 1962, Page (104) reported that all isolates recovered from cases of IC required only the V-factor for growth. This led to the proposal and general acceptance of a new species, *H. paragallinarum* (7), for organisms requiring only the V-factor. It has been reported that the methods used in the early papers to determine X- and V-factor requirements of the causative agent of IC are defective and that *H. paragallinarum* probably never existed (24).

V-factor independent isolates of *Av. paragallinarum* have been recovered from chickens with coryza in South Africa and Mexico (35, 62, 71, 94).

The use of DNA sequencing of the 16S ribosomal RNA gene has clearly shown that there is a unique group within the bacterial family Pasteurellaceae (including both *H. paragallinarum* and *P. gallinarum*) that are associated with avian hosts—with these bacteria being rarely if ever isolated from any other host (102). Building on this knowledge, a comprehensive study based on both phenotypic and genotypic methods has clearly shown that both *H. paragallinarum* and *P. gallinarum,* as well as two other avian-associated species *P. avium* and *P. volantium,* form a new genus termed *Avibacterium* within the family Pasteurellaceae (13). The members of the new genus are *Av. paragallinarum, Av. gallinarum, Av. avium* and *Av. volantium* (13). For the rest of this text, the new terminology—*Av. paragallinarum, Av. gallinarum* and so on—will be used even if the relevant original literature has used the older terminology. There is no convincing evidence, to date, of a role in disease conditions for *Av. avium, Av. volantium* or the taxon currently known as *Avibacterium* species A (13).

Morphology and Staining

Av. paragallinarum and *Av. gallinarum* are both gram-negative nonmotile bacteria. In 24-hr cultures, both appear as short rods or coccobacilli 1–3 μm in length and 0.4–0.8 μm in width, with a tendency for filament formation. A capsule may be demonstrated in virulent strains of *Av. paragallinarum* (65, 127). *Av. paragallinarum* undergoes degeneration within 48–60 hr, showing fragments and ill-defined forms. Subcultures to fresh medium at this stage will again yield the typical rod-shaped morphology.

Growth Requirements

The reduced form of NAD (NADH; 1.56–25 μg/mL medium) (104, 116) or its oxidized form (20–100 μg/mL) (121) is necessary for the *in vitro* growth of most isolates of *Av. paragallinarum.* The exceptions are the isolates described in South Africa and Mexico that are NAD independent (35, 62, 71, 94). Sodium chloride (NaCl) (1.0–1.5%) (116) is essential for growth of *Av. paragallinarum*. Chicken serum (1%) is required by some strains (65), whereas others merely show improved growth with this supplement (21). Brain heart infusion, tryptose agar, and chicken-meat infusion are some basal media to which supplements are added (65, 84, 121). A medium that is particularly developed for the isolation of *Av. paragallinarum* in the face of contaminating gram-positive organisms has been described (146). Complex media are often used to obtain dense growth of organisms for characterization studies (10, 110, 112). The pH of various media

varies from 6.9 to 7.6. A number of bacterial species excrete V-factor that will support growth of *Av. paragallinarum* on media that lack V-factor (104).

In contrast, *Av. gallinarum* has no need for NAD for in-vitro growth and grows on a range of basic media such as dextrose starch agar (64) and blood agar (98).

The determination of the growth factor requirements of the avian hemophili is not an easy process. Commercial growth factor disks used for this purpose may yield a high percentage of cultures that falsely appear to be both X- and V-factor dependent (17). The brand of disks and the medium to be used should be carefully checked for their suitability. For well-equipped laboratories, the porphyrin test (80) is recommended for X-factor testing. For classical X- and V-factor testing, the use of purified hemin and NAD as supplements to otherwise complete media may also be considered.

Av. paragallinarum is commonly grown in an atmosphere of 5% carbon dioxide; however, carbon dioxide is not an essential requirement, since the organism is able to grow under reduced oxygen tension or anaerobically (57, 104). *Av. gallinarum* also does not require carbon dioxide but a more uniform colony development does occur if isolates are incubated under an atmosphere of 5–10% carbon dioxide (13).

For *Av. paragallinarum*, the minimal and maximal temperatures of growth are 25 and 45°C, respectively, the optimal range being 34–42°C. Both *Av. gallinarum* and *Av. paragallinarum* are commonly grown at 37–38°C.

Colony Morphology

Av. paragallinarum typically gives tiny dewdrop, nonhemolytic colonies up to 0.3 mm in diameter on suitable media. In obliquely transmitted light, mucoid (smooth) colonies are iridescent, while rough colonies are noniridescent (67, 112, 122). A range of other intermediate colony forms have been observed.

Av. gallinarum colonies on serum or dextrose-starch agar are iridescent, circular, smooth, and entire and may reach up to 1.5 mm after 24 hr incubation (particularly if in 5–10% carbon dioxide) (40). A grayish-yellow pigment is typically produced (13).

Biochemical Properties

The ability to reduce nitrate to nitrite and ferment glucose without the formation of gas is common to all members of the genus *Avibacterium*. Oxidase activity and a failure to produce indole or hydrolyse urea or gelatin are also uniform characteristics (13). Considerable confusion surrounds the carbohydrate fermentation patterns of the V-factor dependent species. Much of the variability recorded in the literature may be due to the use of different basal media. False-negative results are mainly associated with poor growth and can also be a significant problem (10). In general, recent studies have used a medium consisting of a phenol red broth containing 1% (w/v) NaCl, 25 μg/mL NADH, 1% (v/v) chicken serum and 1% (w/v) carbohydrate. For routine identification, the use of the phenol red broth just described and a dense inoculum is a most suitable approach for determining carbohydrate fermentation patterns. Alternatively, agar-based methods (10, 146) may be used.

Table 20.1.   Differential tests for the genus *Avibacterium*.

Taxon	*Avibacterium gallinarum*	*Avibacterium paragallinarum*	*Avibacterium volantium*	*Avibacterium avium*	*Avibacterium sp. A.*
Catalase	+	−	+	+	+
Symbiotic growth	−	V	+	+	+
ONPG	d	−	+	−	V
Acid from					
L-arabinose	−	−	−	−	+
D-galactose	+	−	+	+	+
Maltose	+	+	+	−	V
D-mannitol	−	+	+	−	V
D-sorbitol	−	+	V	−	−
Trehalose	+	−	+	+	+
α-glucosidase	+	−	+	+	+

All species are gram-negative and nonmotile. All species reduce nitrate, are oxidase positive and ferment glucose. Most isolates of *Avibacterium paragallinarum* require an enriched carbon dioxide (5–10%) atmosphere, and most will show an improved growth in the presence of 5–10% chicken serum. Most isolates of *Avibacterium gallinarum* show an improved growth in an enriched carbon dioxide (5–10%) atmosphere.

Table 20.1 presents those properties that allow a full identification of all members of the genus *Avibacterium*. The failure of *Av. paragallinarum* to ferment either galactose or trehalose and its lack of catalase clearly separate this organism from the other members of the genus.

Susceptibility to Chemical and Physical Agents

Av. paragallinarum is a delicate organism that is inactivated rather rapidly outside the host. Infectious exudate suspended in tap water is inactivated in 4 hr at ambient temperature; when suspended in saline, the exudate is infectious for at least 24 hr at 22°C. Exudate or tissue remains infectious when held at 37°C for 24 hr and, on occasion, up to 48 hr; at 4°C, exudate remains infectious for several days. At temperatures of 45–55°C, hemophili are killed within 2–10 min. Infectious embryonic fluids treated with 0.25% formalin are inactivated within 24 hr at 6°C, but the organism survives for several days under similar conditions when treated with thimerosal, 1:10,000 (157).

Av. paragallinarum may be maintained on blood agar plates by weekly passages. Young cultures maintained in a "candle jar" will remain viable for 2 wk at 4°C. Chicken embryos 6–7 days old may be inoculated with single colonies or broth cultures via the yolk sac; yolk from embryos dead in 12–48 hr will contain a large number of organisms which may be frozen and stored at −20 to −70°C or lyophilized (156). A medium that has proven to be a good suspension medium for lyophilization of *Av. paragallinarum* from agar cultures is used at the Animal Research Institute and contains 6% sodium glutamate and 6% bacteriological peptone (filter sterilized). After any storage, whether frozen or lyophilized, revival should include inoculation of a suitable liquid growth medium (egg inoculation is even better) as well as an agar medium.

There is little specific knowledge on the susceptibility of *Av. gallinarum* to either chemical or physical agents. Cultures have been shown to survive well when held at room temperature on Dorset egg slopes at room temperature (98).

Strain Classification
Antigenicity
Page (104, 105) classified his organisms of *Av. paragallinarum* with the plate agglutination test using whole cells and chicken antisera into serovars A, B, and C. While Page's serovar A strain 0083 and B strain 0222 are available today, all the serovar C strains were lost during the mid-1960s. Matsumoto and Yamamoto (88) isolated strain Modesto which was later classified as a strain of serovar C by Rimler *et al.* (114). It is now recommended to use a hemagglutination inhibition (HI) test to serotype isolates by the Page scheme (15). This HI test uses fixed chicken erythrocytes and results in fewer nontypable isolates than the original agglutination technology (15).

The distribution of Page serovars differs from country to country. Page serovar A has been reported in Malaysia (161), serovar C in Taiwan (86), serovars A and B in China (44, 164) and Germany (66), serovars A and C in Australia (14) and India (150) and serovars A, B and C in Argentina (146), Brazil (23), Ecuador (78, 136), Egypt (3) Indonesia (108, 142), Mexico (58), the Philippines (99), South Africa (36), Spain (106) and the USA (104, 105).

Another method of assigning isolates of *Av. paragallinarum* to a Page serovar is based on the use of a panel of monoclonal antibodies developed by workers in Japan (26) but the technique is available only in a few laboratories due to the limited availability of the monoclonal antibodies. Other sets of MAbs have been described but either lack serovar-specificity (38, 163) or detect only Page serovar A (140).

The suggestion that Page serovar B of *Av. paragallinarum* is not a true serovar, but rather consists of variants of serovar A or C that have lost their type-specific antigen (84, 127), is erroneous— Page serovar B is a clearly a true serovar (151).

An alternative serologic classification of *Av. paragallinarum* based on an HI test using potassium thiocyanate-treated and -sonicated cells, rabbit hyperimmune sera, and glutaraldehyde-fixed chicken erythrocytes has been developed (82). The modified Kume scheme consists of serogroups A, B, and C which match the Page serovars of A, B, and C (16). The nine currently recognized Kume serovars are A-1, A-2, A-3, A-4, B-1, C-1, C-2, C-3, and C-4 (16). Many isolates that were nontypable in the Page scheme by agglutination tests were easily typed using the Kume scheme (56).

The Kume scheme has not been widely applied, as it is technically demanding to perform. Hence, only a few laboratories are able to perform the serotyping on a routine basis. Kume serovars A-4, C-2, and C-4 have been reported in Australia (16, 56), serovars A-3, B-1 and C-1 in Ecuador (136), serovars A-1, A-2, B-1, and C2 in Germany (56, 82), serovars A-1 and C-1 in Japan (82), serovars A-1, A-2, B-1 and C-2 in Mexico (62, 135), serovars A-1, B-1, C-2, and C-3 in South Africa (56, 82), serovars A-1, B-1, and C-2 in the USA (56, 82), and serovar C-3 in Zimbabwe (29).

Other serological tests described in the literature include an agar-gel precipitin (AGP) test (68) and a serum bactericidal test (124). Neither of these tests has been widely used.

Two serotyping schemes for *Av. gallinarum* have been reported (96, 98) but there appears to have been no adoption of either of these serotyping schemes.

Immunogenicity or Protective Characteristics

Infectious coryza is relatively unique among common bacterial infections in that a bacterin (inactivated whole cell vaccine) is protective against the disease when the bacterin is adequately prepared. From the early days of bacterin production, it was obvious that protection was limited (88). Later studies confirmed a correlation between Page serovars and immunovar specificity (22, 84, 114). Chickens vaccinated with a bacterin prepared from one Page serovar were protected only against homologous challenge from that Page serovar. There is evidence that the cross-protection within Page serovar B is only partial (152).

A complete cross-protection study using the reference strains of the nine Kume serovars of *Av. paragallinarum* has been recently completed (138). Within Kume serogroup A, serovars A-1, A-2, and A-3 are strongly cross-protective while there is good cross-protection between serovars A-1 and A-4. Within Kume serogroup C, there was a good level of cross-protection for serovars C-1, C-2, and C-3, with some exceptions. Kume serovars C-1, C-2 and C-3 all provided protection against a C-1 challenge. In contrast, with the serovar C-2 and C-3 challenge, the respective homologous group was significantly better protected than the heterologous groups. The only instance of a vaccine being able to provide cross-protection across Kume serogroups that was at the same level as the homologous level was for the serovar C-4 vaccine and the serovar B-1 challenge. This study thus broadly confirmed the widely accepted dogma that serogroups A, B, and C represent three distinct immunovars.

There is only one serovar, B-1, within serogroup B of the Kume scheme. However, there are reports of undefined hetero-geneity within the B serogroup. Bivalent vaccines containing Page serovars A and C provide protection against Page serovar B strain Spross, but not against two South African isolates of Page serovar B (152). Furthermore, there is only partial cross-protection within various strains of Page serovar B (152). Poor vaccine protection against IC due to serovar B strains in Argentina has been suggested to be due to antigenic differences between field isolates and the "standard" serovar B strains in commercial vaccines from North America or Europe (147). These difficulties have resulted in at least one commercial vaccine that contains multiple Page serovar B strains to provide better protection (78). Vaccination/challenge exposure studies are needed to study the antigenicity and immunospecificity of recent serovar B isolates.

In both Argentina and Brazil, there are isolates of Page serovar A that are not recognized by a monoclonal antibody specific for this serovar (23, 146), leading to speculation these "variant" Page serovar A isolates may be sufficiently different from typical serovar A vaccine strains to cause vaccine failure (146).

There have been suggestions that Kume serovar C-3 as well as other serovars of NAD-independent *Av. paragallinarum* are so antigenically different that they are causing vaccine failure (32, 36, 37, 72). However, it has been shown that a commercial vaccine, specified as containing serovars A, B and C without details of the actual strains, provided acceptable levels of protection against NAD-independent isolates of Page serovar A and Kume serovar C-3 (79).

Overall, these recent results and field observations clearly indicate the need for further vaccination/challenge studies on *Av. paragallinarum*, particularly with recent field isolates. There is no doubt that, on an on-going basis, there will continue to be debate on the topic of whether commercially available trivalent infectious coryza vaccines, containing serovars A, B and C, provide adequate protection if there are significant antigenic differences between vaccine and field strains.

There is little knowledge about the immunogenicity of *Av. gallinarum*. Autogenous vaccines have been used (98) although there is no literature on the effectiveness of these products or the existence of different immunovars.

Molecular Techniques

DNA fingerprinting by restriction endonuclease analysis has been shown to be a suitable typing technique, providing useful insights in epidemiologic studies of both *Av. paragallinarum* (20) and *Av. gallinarum* (8). Ribotyping is another molecular technique that has proven useful—providing insight into the links between the NAD-independent *Av. paragallinarum* isolates from South Africa (92), the epidemiologic relationships among Chinese isolates of *Av. paragallinarum* (90) and the heterogeneity and epidemiological links amongst *Av. gallinarum* isolates (8, 45). ERIC-PCR, a DNA fingerprinting method that uses the polymerase chain reaction technique, has been shown to be capable of typing *Av. paragallinarum* isolates (139).

These nucleic acid techniques (including the species-specific PCR discussed below) are advancing to the stage where they offer a rapid and convenient method for identification and typing. These techniques are likely to replace time-consuming and

cumbersome cultural, biochemical and serological means of identification and typing in the near future.

Pathogenicity

As a general observation, the pathogenicity of *Av. paragallinarum* can vary according to factors such as the growth conditions, passage history of the isolate and the state of the host. There is now considerable specific evidence of variation in pathogenicity amongst *Av. paragallinarum* isolates. The reference strains of Kume serovars A-1, A-4, C-1, C-2, and C-3 showed higher virulence than the strains for serovars A-2, A-3, B-1, and C-4 (137). On the basis of field observations in South Africa, Horner *et al.* (72) have suggested that the NAD-independent isolates may cause airsacculitis more commonly than the classic NAD-dependent *Av. paragallinarum* isolates. In contrast, experimental infections have shown that South African NAD-dependent isolates are more virulent than NAD-independent isolates (30, 31). The virulence of the NAD-dependent serovar C-3 strains was sufficient to cause clinical signs in vaccinated chickens and has been suggested as explaining the large number of coryza outbreaks in vaccinated flocks in South Africa (34). Experimental transformation of a serovar C-3 NAD-dependent isolate to NAD-independence markedly reduced the virulence of the transformant (143). Within a serovar, variation in virulence has also been reported—Yamaguchi *et al.* (151) found that one of four strains of *Av. paragallinarum* serovar B failed to produce clinical signs.

Experimental infections of chickens with *Av. gallinarum* generally result in little mortality (64). Field isolates from Israel have caused swollen wattles in 6-week-old chickens (98) while both an American field isolate and the type strain have caused endocarditis in mature leghorn chickens given high intravenous doses (149). Intra-muscular injection of chickens with an Argentinean isolate resulted in severe myositis at the inoculation site (145). An American field isolate, when give by the intra-muscular route, caused severe myositis at the inoculation site as well as pericarditis, perihepatitis, airsacculitis, and synovitis (55, 133). As the type strain failed to give similar results, there is evidence of strain variation in pathogenicity (55, 133).

Virulence Factors

A range of factors has been associated with the pathogenicity of *Av. paragallinarum.* Considerable attention has been paid to HA antigens. In both Page serovar A and C, mutants lacking HA activity have been used to demonstrate that the HA antigen plays a key role in colonization (122, 155). A gene, termed *hagA*, encoding a hemagglutinin has been identified and fully sequenced (69). The deduced sequence of this gene is closely related to the *H. influenzae* P5 protein, a protein that acts as an adhesin binding to respiratory mucin. It is possible that a similar mechanism may be involved in *Av. paragallinarum* infection (69).

The capsule has also been associated with colonization, and has been suggested to be the key factor in the lesions associated with IC (122, 129). The capsule of *Av. paragallinarum* has been shown to protect the organism against the bactericidal activity of normal chicken serum (125). It has been suggested that a toxin

released from capsular organisms during *in vivo* multiplication was responsible for the clinical disease (81). The complete *Av. paragallinarum* capsule transport gene locus has been sequenced and shows high homology with other known capsule transport systems (50).

Av. paragallinarum is capable of acquiring iron from chicken and turkey transferrin, suggesting that iron sequestration may not be an adequate host defense mechanism (101). In contrast, two strains of *Av. avium* were unable to acquire iron from these transferrins despite apparently having the same receptor proteins (101).

Crude polysaccharide extracted from *Av. paragallinarum* is toxic to chickens and may be responsible for the toxic signs that may follow administration of bacterin (74). The role, if any, of this component in the natural occurrence of the disease is unknown.

A range of other putative virulence factors have been reported. A putative RTX-like protein and metalloproteases have been identified by phenotypic methods (118) while a hemocin has been confirmed by both phenotypic and genotypic methods (144). The detection of a putative RTX protein is interesting as other members of the family Pasteurellaceae have RTX proteins as major virulence factors. The hemocin of *Av. paragallinarum* is active against *Gallibacterium anatis* biovar *haemolytica* and some isolates of *P. multocida* but not against isolates of *Av. gallinarum* (144). It is possible that hemocin resistance may partly explain the reports of co-infections between *Av. paragallinarum* and *Av. gallinarum* (119, 134). The demonstration that cultures of *Av. paragallinarum* produce *in vitro* membrane vesicles that contain proteases, the putative RTX protein and hemagglutinins raises the possibility of these vesicles being involved in the development of infectious coryza (109).

There is no specific knowledge on any virulence factors associated with *Av. gallinarum*.

Pathobiology and Epidemiology

Incidence and Distribution

Infectious coryza occurs wherever chickens are raised. The disease is a common problem in the intensive chicken industry— significant problems have been reported in California, south-eastern United States and most recently in the north-eastern regions of the United States. The disease has also been reported in other, less intensive situations. As an example, infectious coryza has been a problem in kampung (village) chickens in Indonesia (108).

While reports are scarce and scattered, *Av. gallinarum* is probably present wherever chickens are raised. Outbreaks of disease associated with *Av. gallinarum* have been reported in chickens in Europe (98), North and South America (54, 145), and Africa (93).

Natural and Experimental Hosts

The chicken is the natural host for *Av. paragallinarum*. There are several reports that the village chickens of Asia are as susceptible to infectious coryza as normal commercial breeds (108, 162). While there have been reports of IC due to *Av. paragallinarum* in a number of bird species other than chickens, reviewed by

Yamamoto (158), these reports need to be interpreted carefully. As a range of hemophilic organisms, none of which are *Av. paragallinarum,* have been described in birds other than chickens (51, 63, 107), only those studies that involve detailed bacteriology can be regarded as definitive proof of the presence of *Av. paragallinarum* in birds other than chickens. The following species are refractory to experimental infection: turkey, pigeon, sparrow, duck, crow, rabbit, guinea pig, and mouse (156, 157).

Av. gallinarum has been consistently associated with chickens (45). Outbreaks of disease associated with this species have also been reported in guinea fowl in Africa (93) and turkeys in Europe (8). A single isolate has been reported from a healthy duck (97) and a goose of unspecified health status (98).

Age of Host Most Commonly Affected

All ages of chickens are susceptible to *Av. paragallinarum* (158), but the disease is usually less severe in juvenile birds. The incubation period is shortened, and the course of the disease tends to be longer in mature birds, especially hens with active egg production.

Transmission, Carriers, Vectors

Chronic or healthy carrier birds have long been recognized as the main reservoir of IC infection. The application of molecular fingerprinting techniques has confirmed the role of carrier birds in the spread of IC (20). Infectious coryza seems to occur most frequently in fall and winter, although such seasonal patterns may be coincidental to management practices (e.g., introduction of susceptible replacement pullets onto farms where IC is present). On farms where multiple-age groups are brooded and raised, spread of the disease to successive age groups usually occurs within 1–6 wk after such birds are moved from the brooder house to growing cages near older groups of infected birds (46). Infectious coryza is not an egg-transmitted disease.

Whereas the sparrow could not be implicated as a vector, epidemiologic studies suggested that *Av. paragallinarum* may be introduced onto isolated ranches by the airborne route (159).

There is no knowledge on the routes of transmission, carrier status or vectors for *Av. gallinarum*.

Incubation Period

The characteristic feature of IC is a coryza of short incubation that develops within 24–48 hr after inoculation of chickens with either culture or exudate. The latter will more consistently induce disease (112). Susceptible birds exposed by contact to infected cases may show signs of the disease within 24–72 hr. In the absence of a concurrent infection, IC usually runs its course within 2–3 wk.

Clinical Signs

The most prominent features of IC are an acute inflammation of the upper respiratory tract including involvement of nasal passage and sinuses with a serous to mucoid nasal discharge, facial edema, and conjunctivitis. Figure 20.1 illustrates the typical facial edema. Swollen wattles may be evident, particularly in males. Rales may be heard in birds with infection of the lower respiratory tract.

A swollen head-like syndrome associated with *Av. paragallinarum* has been reported in broilers in the absence of avian pneumovirus, but in the presence or absence of other bacterial pathogens such as *M. synoviae* and *M. gallisepticum* (52, 119). Arthritis and septicemia have been reported in broiler and layer flocks, respectively, in which the presence of other pathogens has contributed to the disease complex (119).

Birds may have diarrhea, and feed and water consumption usually is decreased; in growing birds this means an increased number of culls, and in laying flocks a reduction in egg production (10 to 40%). A foul odor may be detected in flocks in which the disease has become chronic and complicated with other bacteria.

The most common signs seen in outbreaks of disease where *Av. gallinarum* has played a potential role have been those of an acute respiratory disease, coughing and sneezing, with some outbreaks involving peri-orbital swelling and keratoconjunctivitis. Swollen wattles have been reported in cases in Israel (98) and Africa (93).

Morbidity and Mortality

IC is usually characterized by low mortality and high morbidity. Variations in age and breed may influence the clinical picture (9). Complicating factors such as poor housing, parasitism, and inadequate nutrition may add to severity and duration of the disease. When complicated with other diseases such as fowlpox, infectious bronchitis, laryngotracheitis, *Mycoplasma gallisepticum* infection, and pasteurellosis, IC is usually more severe and prolonged, with resulting increased mortality (119, 156). Even in the absence of any other pathogen, older birds can suffer a high mortality as shown by an outbreak in California where the total mortality reached 48% (27).

While not common, high mortalities have been seen associated with *Av. gallinarum* in broilers (up to 34%) (54) and in turkeys (up to 26%) (8).

Pathology

Gross

Av. paragallinarum produces an acute catarrhal inflammation of mucous membranes of the nasal passages and sinuses. There is frequently a catarrhal conjunctivitis and subcutaneous edema of the face and wattles. Typically, pneumonia and airsacculitis are rarely present; however, reports of outbreaks in broilers have indicated significant levels of condemnations (up to 69.8%) due to airsacculitis (Figure 20.2), even in the absence of any other recognized viral or bacterial pathogens (52, 70).

The lesions associated with *Av. gallinarum* infections have been diverse and include airsacculitis, conjunctivitis, pericarditis, perihepatitis and sinusitis (45).

Microscopic

Fujiwara and Konno (60) studied the histopathologic response of chickens from 12 hr to 3 mo after intranasal inoculation with *Av. paragallinarum*. Essential changes in the nasal cavity, infraorbital sinuses, and trachea consisted of sloughing, disintegration, and hyperplasia of mucosal and glandular epithelia, and edema and hyperemia with heterophil infiltration in the tunica propria of

20.1.   Chickens artificially infected with *Avibacterium paragallinarum*. A. Mature male with coryza and facial edema. B. Mature female showing conjunctivitis, nasal discharge, and open-mouth breathing.

20.2.   Field infection with IC showing caseopurulent air sac lesions.

the mucous membranes. Pathologic changes first observed at 20 hr reached maximum severity by 7–10 days, with subsequent repair occurring within 14–21 days. In birds with involvement of the lower respiratory tract, acute catarrhal bronchopneumonia was observed, with heterophils and cell debris filling the lumen of secondary and tertiary bronchi; epithelial cells of air capillaries were swollen and showed hyperplasia. Catarrhal inflammation of air sacs was characterized by swelling and hyperplasia of the cells, with abundant heterophil infiltration. In addition, a pronounced infiltration of mast cells was observed in the lamina propria of the mucous membrane of the nasal cavity (130). The products of mast cells, heterophils, and macrophages may be responsible for the severe vascular changes and cell damage leading to coryza. A dissecting fibrinopurulent cellulitis similar to

that seen in chronic fowl cholera has been reported in broiler and layer chickens (52).

Shivaprasad and Droual (133) examined the histopathology caused by experimental infection with the *Av. gallinarum* strain associated with severe mortality in broilers in California. The lesions caused by this field isolate were more severe than those associated with the type strain and included severe subacute to chronic pyogranulomatous pneumonia, airsacculitis, pericarditis, perihepatitis, synovitis, and myositis. There was severe lymphoid depletion of the bursa of Fabricius (133).

Immunity

Chickens that have recovered from active infection with *Av. paragallinarum* possess varying degrees of immunity to reexposure. Pullets that have experienced IC during their growing period are generally protected against a later drop in egg production. Resistance to reexposure among individual birds may develop as early as 2 wk after initial exposure by the intrasinus route (120).

It has been shown that experimentally infected chickens develop a cross-serovar (Page scheme) immunity (113). In contrast, as discussed earlier, bacterins provide only serovar-specific immunity (114). This suggests that cross-protective antigens are expressed *in vivo* that are either not expressed or expressed at very low levels *in vitro*.

The protective antigens of *Av. paragallinarum* have not been definitively identified. It has been suggested that the capsule of *Av. paragallinarum* contains protective antigens (123). Using both a Page serovar A and C strains, a crude polysaccharide extract was shown to provide serovar-specific protection (74).

Considerable attention has been paid to the role of HA antigens as protective antigens. It has been long noted that for Page

serovar A organisms, there is a close correlation between HI titer and both protection (85) and nasal clearance of the challenge organism (81) in vaccinated chickens. Purified HA antigen from a Page serovar A organism has been shown to be protective (75). Takagi and colleagues have shown that a monoclonal antibody specific for the HA of Page serovar A provides passive protection, and that the HA antigen purified by use of this antibody is also protective (140, 141). It is worth noting that vaccines that do not stimulate HI titers can still be protective (61, 138) suggesting that other antibodies do have a role in protection.

Based on studies conducted to date, there is considerable evidence that the protective antigens of *Av. paragallinarum* are surface located. The antigens implicated have been the antigens detected during Page serotyping, HA antigens, and some component or components of the polysaccharide content of the cell. It seems probable that a number of different antigens (outermembrane proteins, polysaccharides, lipopolysaccharides) are all likely to be involved.

While autogenous bacterins of *Av. gallinarum* have been used and have been shown to stimulate antibodies (98), there is no detailed understanding of the efficacy of these products or the key antigens for protection.

20.3. Satellite phenomenon. Tiny dewdrop colonies of *Avibacterium paragallinarum* growing adjacent to *Staphylococcus* culture (broad streak) on a blood agar plate.

Diagnosis

Isolation and Identification of Causative Agent

While *Av. paragallinarum* is considered to be a fastidious organism, it is not difficult to isolate, requiring simple media and procedures. Specimens should be taken from two or three chickens in the acute stage of the disease (1–7 days' incubation). The skin under the eyes is seared with a hot iron spatula and an incision made into the sinus cavity with sterile scissors. A sterile cotton swab is inserted deep into the sinus cavity where the organism is most often found in pure form. Tracheal and air sac exudates also may be taken on sterile swabs. Where transport delays are possible, the swabs should be placed in a commercial transport medium containing supplements to improve viability of the organism (39). The swab is streaked on a blood agar plate, which is then cross-streaked with a *Staphylococcus* culture and incubated at 37°C in a large screw-cap jar in which a candle is allowed to burn out (Figure 20.3). *Staphylococcus epidermidis* (104) or *S. hyicus* (21), which are commonly used as "feeders," should be pretested because not all strains actively produce the V-factor. Terzolo *et al.* (146) have reported the successful use of an isolation medium that contains selective agents that inhibit the growth of gram-positive bacteria. This medium has the advantage of not using either a "feeder" organism or additives such as NADH.

At the simplest level, IC may be diagnosed on the basis of a history of a rapidly spreading disease in which coryza is the main manifestation, combined with the isolation of a catalase-negative bacterium showing satellitic growth. At this level, the sinus exudate or culture should be inoculated into two or three normal chickens by the intrasinus route. The production of a coryza in 24–48 hr is diagnostic; however, the incubation period may be delayed up to 1 wk if only a few organisms are present in the inoculum, such as in long-standing cases.
Better equipped laboratories should attempt a more complete biochemical identification as described earlier. Additional studies of this nature are essential when isolates of NAD-independent *Av. paragallinarum* are suspected. To perform this biochemical testing, the suspect isolates are best grown in pure culture on medium that does not require the addition of a nurse colony. While many different media have been developed to support the growth of *Av. paragallinarum*, the medium called TM/SN (21) has proven very effective. The medium described by Terzolo *et al.* (146) is particularly suited for those laboratories where the cost of such ingredients as NADH and bovine serum albumin is too expensive. The carbohydrate fermentation tests shown in Table 20.1 can be done in either a phenol red broth base (112) or in an agar plate format (10). The agar plate method can be performed in conventional petri dishes (9 cm), allowing multiple isolates to be tested at once, or in small petri dishes (2 cm), allowing one to three isolates to be economically characterized. The agar plate method (10) has also been modified to be performed as a tube method (146).

A PCR test that is specific for *Av. paragallinarum*, rapid and able to detect all known variants is available (42). The PCR, termed the HP-2 PCR, has been validated for use on colonies on agar or on mucus obtained from squeezing the sinus of live birds (42). When used directly on sinus swabs obtained from artificially-infected chickens in pen trials performed in Australia, the HP-2 PCR has been shown to be the equivalent of culture—but much more rapid (42). When used in China, direct PCR examination of sinus swabs outperformed traditional culture when used on routine diagnostic submissions (41). The problems of poor samples, delayed transport and poor quality (but expensive) media mean that culture will have a higher failure rate in developing countries than in developed countries—making the PCR an attractive diagnostic option.

The HP-2 PCR is a robust test—sinus swabs stored for up to 180 days at 4°C or –20°C were positive in the PCR (43). In contrast, culture of known positive swabs failed to detect *Av. paragallinarum* after 3 days of storage at 4°C or –20°C (43).

The HP-2 PCR has proven very useful in South Africa where the diagnosis of infectious coryza is complicated by the presence of NAD-independent *Av. paragallinarum* and *Ornithobacterium rhinotracheale* as well as the traditional form of NAD-dependent *Av. paragallinarum* (91).

Isolation of *Av. gallinarum* is best done using sheep blood agar plates incubated at 37°C under a 5–10% carbon dioxide atmosphere. Phenotypic tests (see Table 20.1) should be performed using conventional methodologies. No molecular diagnostic test has been developed for *Av. gallinarum*.

Serology

There is no totally suitable serological test for the diagnosis of infectious coryza. However, despite this absence of a "perfect" test, serological results are often useful for retrospective/ epidemiological studies in the local area. A review of the techniques that have been used in the past is presented by Blackall *et al.* (19).

At this time, the best available test methodology is the HI test. While a range of HI tests have been described, three main forms of HI tests have been recognized—these being termed simple, extracted and treated HI tests (25). Full details of how to perform these tests are available elsewhere (25). In the following text, the advantages and disadvantages of the three HI tests are briefly and critically discussed.

The simple HI is based on whole bacterial cells of Page serovar A *Av. paragallinarum* and fresh chicken erythrocytes (77). Although simple to perform, this HI test can only detect antibodies to serovar A. The test has been widely used to both detect infected as well as vaccinated chickens (19). A variation of this test (whole bacterial cells and glutaraldehyde-fixed chicken erythrocytes) has been shown to detect antibodies due to all nine Kume serovars in vaccinated chickens (138).

The extracted HI test is based on KSCN-extracted and sonicated cells of *Av. paragallinarum* and glutaraldehyde-fixed chicken erythrocytes (128). This extracted HI test has mainly been validated for the detection of antibodies to Page serovar C organisms. The test has been shown to be capable of detecting a serovar-specific antibody response in Page serovar C vaccinated chickens (128). A major weakness with this assay is that, in chickens infected with serovar C, the majority of the birds remain seronegative (153).

The treated HI test is based on hyaluronidase-treated whole bacterial cells of *Av. paragallinarum* and formaldehyde-fixed chicken erythrocytes (154). The extracted HI has not been widely used or evaluated. It has been used to detect antibodies to Page serovars A, B, and C in vaccinated chickens with only serovar A and C vaccinated chickens yielding high titers (152). The test has been used to screen chicken sera in Indonesia for antibodies arising from infection with serovars A and C (142).

Vaccinated chickens with titers of 1:5 or greater in the simple or extracted HI tests have been found to be protected against sub-

sequent challenge (128). There is not enough knowledge or experience yet to draw any sound conclusions on whether there is a correlation between titer and protection for the treated HI test.

Overall, the serological test of choice remains either the simple HI test (77) for either infections or vaccinations associated with serovar A, the extracted or treated HI tests (128, 154) for vaccinations associated with serovar C and only the treated HI test (154) for infections associated with serovar C. There has been so little work performed on serological assays for infections or vaccinations associated with serovar B that it is not possible to recommend any test.

Both plate agglutination and gel precipitin tests have been described for the detection of antibodies to *Av. gallinarum* (98) but there has been no apparent use of these assays.

Differential Diagnosis

Infectious coryza must be differentiated from other diseases such as chronic respiratory disease, chronic fowl cholera, fowlpox, ornithobacterosis, swollen head syndrome, and A-avitaminosis, which can produce similar clinical signs. Since *Av. paragallinarum* infections often occur in mixed infections, one should consider the possibility of other bacteria or viruses as complicating IC, particularly if mortality is high and the disease takes a prolonged course (see Pathogenicity; Morbidity and Mortality).

As the conditions linked with *Av. gallinarum* are generally linked with upper respiratory disease, a similar range of disease conditions as those listed above need to be considered. A thorough bacteriological characterization is necessary to ensure correct identification of suspect *Av. gallinarum* isolates.

Intervention Strategies

Management Procedures

Since recovered carrier birds are the main source of infectious coryza, practices such as buying breeding males or started chicks from unknown sources should be discouraged. Only day-old chicks should be secured for replacement purposes unless the source is known to be free of IC. Isolation rearing and housing away from old stock are desirable practices. To eliminate the agent from a farm, it is necessary to depopulate the infected or recovered flock(s) because birds in such flocks remain reservoirs of infection. After cleaning and disinfection of the equipment and houses, the premises should be allowed to remain vacant for 2–3 wk before restocking with clean birds.

Recent studies have shown that the continuous use of appropriate disinfectants in drinking water and by daily fogging can reduce the duration and severity of clinical signs of infectious coryza (33, 73).

Vaccination

Types of Vaccines

Commercial IC bacterins are widely available. As the literature of the various factors influencing the efficacy of bacterins has been reviewed (12), only key points are considered here. Most commercial products are currently based on broth-grown cultures. They must contain at least 10^8 colony-forming units/mL to be ef-

fective (88). The following section reviews only the literature on broth-based bacterins.

There is disagreement in the literature as to the effect of different inactivating agents on the efficacy of bacterins. Thimerosal has been shown to be effective (22, 48, 88), as has formalin (47, 117). In three of the four studies directly comparing formalin and thimerosal, formalin reduced the efficacy of the vaccines (22, 48, 87, 88). These studies suggest that while vaccines containing formalin as the inactivating agent can be protective, it is possible that a similar vaccine containing thimerosal would be even more efficient.

A number of adjuvants have been shown to be effective for IC bacterins, in particular, aluminium hydroxide gel, mineral oil, and saponin (18). The report of mineral oil being less effective than aluminium hydroxide gel (111) may have resulted from a formulation problem rather than any inherent deficiency in the ability of mineral oil to act as an effective adjuvant. As with any bacterin that contains adjuvants, particularly mineral oil, the potential adverse reaction at the site of injection (53) should be considered when using such products.

As inactivated IC bacterins provide, at best, protection only against the Page serovars included in the vaccine, it is vital that bacterins contain the Page serovars present in the target population. The confirmed existence of Page serovar B as a true serovar with full pathogenicity, as well as its widespread occurrence, means that this serovar must be included in inactivated bacterins in areas where serovar B is present. However, since different strains of serovar B provide only partial cross-protection among themselves (152), it may be necessary to prepare an autogenous bacterin for use in areas where the B serovar is endemic or consider commercial bacterins that contain multiple serovar B strains (78). The finding that some Kume serovars within serogroup C are not fully cross-protective (138) needs to be considered in areas where multiple Kume C serovars are known to exist.

Since dissociation of *Av. paragallinarum* has been reported (126), care should be taken in selecting the proper seed culture, media, and incubation period to obtain the most immunogenic product.

Mixed bacterins containing inactivated infectious bronchitis virus, Newcastle disease virus, and *Av. paragallinarum* have been described (103, 160). A combined *Av. paragallinarum–M. gallisepticum* bacterin was reported to provide protection against transient and chronic coryza (115). However, antibody response to *Av. paragallinarum* was suppressed in chickens inoculated with a similar product (89).

There appears to have been no widespread use of *Av. gallinarum* vaccines.

Field Vaccination Protocol and Regimes

IC bacterins are generally injected in birds between 10 and 20 wk of age and yield optimal results when given 3–4 wk prior to an expected natural outbreak. Two injections given approximately 4 wk apart before 20 wk of age seem to result in better performance of layers than a single injection. When administered to growing birds, the bacterin reduces losses from complicated res-

piratory disease. Both subcutaneous and intramuscular routes have been effective (22, 48, 88). Injection of the bacterin into the leg muscle gave better protection than when injected into the breast muscle (76). The intranasal route was not effective (22). Oral delivery of an IC bacterin was effective, but this route required 100 times as many cells as with the parenteral route (100). Significant immunity has been demonstrated for about 9 mo following vaccination (22, 83, 88).

Treatment

Various sulfonamides and antibiotics are useful in alleviating the severity and course of IC and have been reviewed (19). It should be noted drug resistance in *Av. paragallinarum* does occur (11) and hence the performance of antimicrobial sensitivity tests is recommended. Relapse often occurs after treatment is discontinued and the carrier state is not eliminated (157). Erythromycin and oxytetracycline are two commonly used antibiotics.

Chapter 21
Mycoplasmosis

Introduction

Stanley H. Kleven

Mycoplasmas are very small prokaryotes devoid of cell walls, bounded by a plasma membrane only (24). This accounts for the "fried egg" type of colony morphology, resistance to antibiotics that affect cell wall synthesis, and complex nutritional requirements. Mycoplasmas tend to be quite host-specific; some infect only a single species of animal, while others may have the ability to infect several different host species. They are found in humans, many animal species, plants, and insects. In general, mycoplasmas colonize mucosal surfaces and most species are noninvasive. Some species, including *Mycoplasma gallisepticum* (32), are now known to have the ability to penetrate cells.

Characterization

Mycoplasma species from avian sources generally require a protein-rich medium containing 10–15% added animal serum. Further supplementation with some yeast-derived component is often beneficial. Growth of *M. synoviae* requires the addition of nicotinamide adenine dinucleotide (NAD) (see *M. synoviae* section). A medium described by Frey (13) or a medium described by Bradbury (1) is commonly used for the cultivation of avian mycoplasmas.

Mycoplasma organisms tend to grow rather slowly, usually prefer 37–38°C, and are rather resistant to thallium acetate and penicillin, which are frequently employed in media to retard growth of contaminant bacteria and fungi. Colonies form on agar media after 3–10 days at 37°C; however, nonpathogenic species such as *M. gallinarum* and *M. gallinaceum* may develop colonies within 1 day (*M. gallinarum* and *M. gallinaceum* are frequently isolated as contaminants during attempts to isolate pathogenic avian mycoplasmas). Typical colonies are small (0.1–1.0 mm), smooth, circular, and somewhat flat with a denser central elevation (see Fig. 21.1). Variations in colony morphology have been described, but cannot be relied upon to differentiate the various species. Individual cells vary from 0.2 to 0.5 μm and are basically coccoid to coccobacilliform, but slender rods, filaments, and ring forms have been described.

Fermentation of carbohydrates is variable, but all species may be divided into those that ferment glucose with acid production and those that do not. Glucose is frequently added to broth media

to enhance growth of the carbohydrate-fermenting species and to provide an indication of growth when glucose fermentation produces acid in media containing added phenol red. Phosphatase activity is often present, as is arginine decarboxylase. Most species that do not ferment glucose use the amino acid arginine as their major source of energy. *M. iowae* and some other species, however, ferment glucose and hydrolyze arginine.

One useful characteristic of *M. gallisepticum, M. meleagridis,* and *M. synoviae* is hemagglutination of erythrocytes from chickens or turkeys. Hemagglutinating antigens are used for hemagglutination-inhibition serologic tests for these three pathogenic species.

Direct staining of mycoplasma colonies on agar surfaces or colony imprints with specific fluorescent antibody (7, 29) is most commonly used to determine the species of avian mycoplasma isolates. Other suitable methods include growth inhibition (6), immunodiffusion (20), and others. More recently, molecular methods such as sequencing of the 16S rRNA gene (14), DNA probes (15), and polymerase chain reaction (18, 19, 34) have been used.

Classification

Mycoplasmas are members of the class Mollicutes, Order I, Mycoplasmatales. Genus I, *Mycoplasma,* has more than 120 species, a DNA G+C content of 23–40%, a genome size of 600–1350 kb, requires cholesterol for growth, occurs in humans and animals, and has a usual optimum growth temperature of 37°C. Genus II, *Ureaplasma,* is differentiated on the basis of hydrolysis of urea. Acholeplasmas are classified in Order III, Acholeplasmatales, family I, Acholeplasmataceae, genus I, *Acholeplasma.* They are characterized by lack of a growth requirement for cholesterol (24). Phylogenetic analysis of the 16S ribosomal RNA gene has been used to analyze genetic relationships among mycoplasmas (30).

Earlier serotype designations for avian mycoplasmas (8) have now been replaced by species names. A current listing of avian mycoplasma species is found in Table 21.1. In addition, there are numerous mycoplasma isolates from various species of birds, including strain 1220, a pathogen of domestic geese (28), isolates
21.1. Colonies of *Mycoplasma gallisepticum* on agar. ×40 (Hofstad)

from various avian species including ratites and penguins, as well as unidentified isolates from domestic poultry.

The most up to date listing of *Mycoplasma* species can be found on the web site of the National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov/). Minimum requirements for the description of new species of *mycoplasma* are determined by the International Committee on Systematics of Prokaryotes Subcommittee on the Taxonomy of *Mollicutes* (31). An updated version of the guidelines is complete and should be found in the *International Journal of Systematic and Evolutionary Microbiology* within the next year.

Mycoplasma gallisepticum Infection
David H. Ley

Introduction

Definition and Synonyms

Mycoplasma gallisepticum (MG) infections are commonly known as "chronic respiratory disease" (CRD) of chickens and "infectious sinusitis" of turkeys. *M. gallisepticum* diseases are

characterized by respiratory rales, coughing, nasal discharge, and conjunctivitis; and frequently in turkeys, infraorbital sinusitis. Clinical manifestations are usually slow to develop and the infec-tion or disease may have a long course. "Air sac disease" de-scribes a severe airsacculitis that is the result of MG or *Myco-plasma synoviae* infection complicated by a respiratory virus infection (e.g. infectious bronchitis or Newcastle disease) and usually *Escherichia coli*.

Economic Significance

M. gallisepticum is the most pathogenic and economically significant mycoplasmal pathogen of poultry. Airsacculitis in chickens or turkeys resulting from MG infections, with or without complicating pathogens, causes increased condemnations at processing. Economic losses from condemnations or downgrading of carcasses, reduced feed and egg production efficiency, and increased medication costs are additional factors that make this one of the costliest disease problems confronting commercial poultry production worldwide. Prevention and control programs, which may include surveillance (serology; culture, isolation and identification) and vaccination, account for additional costs.

Public Health Significance

M. gallisepticum infects a relatively narrow range of exclusively avian host species and has no public health significance.

History

The first accurate description of the disease in turkeys was probably made in 1905 by Dodd (98) in England, and termed "epizootic pneumoenteritis." Dickinson and Hinshaw (96) named the disease "infectious sinusitis" of turkeys in 1938. In 1935, Nelson (303) described coccobacilliform bodies associated with an infectious coryza of chickens. Later he associated the organisms with a coryza of slow onset and long duration, and eventually was able to grow the coccobacilliform bodies in embryonating eggs, tissue culture, and cell-free medium. In 1943 Delaplane and Stuart (93) cultivated in embryos an agent isolated from chickens with CRD, and later from turkeys with sinusitis. In the early 1950s Markham and Wong (268) and Van Roekel and Olesiuk (389) reported the successful cultivation of the organisms from chickens and turkeys, and suggested they were both members of the pleuropneumonia group (*Mycoplasma* spp.).

Etiology

Classification

M. gallisepticum is an avian pathogen within the genus *Mycoplasma* (class Mollicutes) which includes approximately 100 other species infecting animals (including humans), insects or plants (326). Mollicutes are eubacteria without cell walls and the smallest self-replicating (can be grown on artificial cell-free media) prokaryotes (326). *M. gallisepticum* was first classified and differentiated from other avian mycoplasmas by serotyping (408, 409) and was commonly designated serotype A (210, 410). The species designation *M. gallisepticum* was made in 1960 by Edward and Kanarek (103). In 1993 mycoplasmas with phenotypic and antigenic similarities to MG were differentiated by molecular techniques and designated *M. imitans* (48, 161).

Mycoplasma phylogeny and taxonomy continue to be reexamined by the application of molecular tools eg. DNA sequence analysis of the 16S rRNA gene (326, 393), 16S rRNA PCR and denaturing gradient gel electrophoresis (278), and tRNA gene PCR (358). The complete genome sequence has been determined for MG strain R_{low} (319), and a database dedicated to the comparative genomics of Mollicutes, including MG, has been established (32).

Morphology and Staining

M. gallisepticum stains well with Giemsa and by light microscopy organisms generally appear coccoid, approximately 0.25–0.5 μm in size. Based on electron microscopy (EM) studies Tajima *et al.* (368) described capsular material associated with MG cells in contact with chicken tracheal epithelium. Also by EM organisms appear round or may show a filamentous or flask-shaped polarity of the cell body. This polarity appears prior to division (291) and is due to the presence of well-organized terminal organelles (blebs or tip structures) (69). Such structures are involved in motility, chemotaxis, (209, 232, 287) and host-pathogen interactions eg. cytadherence (hence also termed attachment organelles) and pathogenicity (24).

Growth Requirements

M. gallisepticum replication requires a rather complex medium usually enriched with 10–15% heat-inactivated swine, horse, or avian serum. Several types of liquid or agar media will support the growth of avian mycoplasmas (217). Frey *et al.* (129) developed a culture medium that incorporated all essential ingredients including yeast autolysate and glucose. When prepared with 10–15% swine serum, it is a convenient and very effective medium for cultivation of most mycoplasmas. Extraneous bacterial and fungal contamination usually is controlled by the inclusion of thallous acetate (1:4000) and penicillin (up to 2000 IU/ml). *M. gallisepticum* is one of the avian *Mycoplasma* spp. that ferments glucose which lowers the pH causing the phenol red indicator to change from red to orange/yellow making it possible to visually detect growth in broth. Optimal growth in broth medium generally occurs at approximately pH 7.8 with aerobic incubation at 37°C and usually is evident in 3–5 days, but some field isolates may take longer and require multiple passages (245). Growth may not be evident, but 2 or 3 serial passages at 5–7-day intervals may increase the number of isolations. Direct plating of exudates or tissue swabs onto mycoplasma agar may result in colonies after 4–5 days of incubation, but initial culture in broth is generally a more sensitive isolation method. Inoculated plates should be covered and incubated at 37°C in a very moist atmosphere and may require at least 3–7 days of incubation before typical mycoplasmal colonies are sufficiently large to be observed with a dissecting microscope (217). *M. gallisepticum* may also be isolated or propagated in embryonated chicken eggs. See "Isolation and Identification of Causative Agent".

Colony Morphology

M. gallisepticum colonies form on agar medium inoculated directly or following passage from broth or agar cultures (217). It often is very difficult to obtain colony growth directly from clinical specimens. Evidence of colony growth is best studied with the aid of a dissecting microscope with indirect lighting. Characteristic colonies appear as tiny, smooth, circular, translucent masses that may have a dense central area ("fried egg" appearance). They rarely are more than 0.2–0.3 mm in diameter and fre-

quently occur in ridges along the streak line, because closely adjacent colonies readily coalesce. Variations in colony morphology of isolates representing various species of avian mycoplasmas have been noted, but *Mycoplasma* spp. designations cannot be determined by colony characteristics alone.

Biochemical Properties
Biochemical and related biologic properties of MG have been described (171, 410). *M. gallisepticum* ferments glucose and maltose, with production of acid but not gas. It does not ferment lactose, dulcitol, or salicin. Sucrose is rarely fermented; results with galactose, fructose, trehalose, and mannitol are variable. It does not hydrolyze arginine and is phosphatase-negative. It reduces 2,3,5-triphenyl tetrazolium and neotetrazolium. *M. gallisepticum* causes complete hemolysis of horse erythrocytes incorporated into agar medium and agglutinates turkey and chicken erythrocytes.

Susceptibility to Chemical and Physical Agents
It is assumed that most of the commonly employed chemical disinfectants are effective against MG. Inactivation has been produced by phenol, formalin, ß-propiolactone, and merthiolate. Resistance to penicillin and low concentration (1:4000) of thallous acetate make these valuable additives to mycoplasma culture media as inhibitors of bacterial and fungal contamination.

Broth cultures of MG remained viable for 2–4 years when stored at –30°C, and viable organisms were recovered from lyophilized broth culture stored at 4°C for at least 7 years, and from lyophilized infective chicken turbinates stored at 4°C for 13–14 years (410). Broth cultures of MG that had been frozen at –60°C since 1965 were viable upon subculturing more than 20 years later (413). Lyophilized broth cultures including MG, *M. synoviae* (MS), and *M. meleagridis* (MM) were routinely found to be viable when subcultured at 10–15 years. However, loss of MG viability in liquids should be anticipated depending on the strain, medium or diluent, and temperature. *M. gallisepticum* F strain in powdered skim milk, phosphate-buffered saline (PBS), tryptose phosphate broth, and distilled water stored at 4°, 22°, and 37°C was stable in all diluents for 24 hours when stored at 4° or 22° but not 37°C (213). An MG inoculum stock culture showed a post-thaw drop of titer (color changing units) of 10^3 in 24 hours at 4°C and 10^5 at room temperature (242).

M. gallisepticum was inactivated in infected chicken hatching eggs that reached 45.6°C during a 12–14 hour heating procedure (411).

Antigenic Structure and Toxins
The antigenic characteristics of MG and relatively species-specific polyclonal antibody response to the organism have been used to identify both the organism (growth inhibition and immunofluorescence tests) and immunologic response (serologic tests) to infection (14, 217). These tests were empirically developed and optimized to enhance their sensitivity and species-specificity with little or no knowledge of the organism's antigenic structure. Proteins constitute more than two-thirds of the mycoplasma membrane mass, with the rest being membrane

lipids (328). The plasma membrane of MG contains approximately 200 polypeptides (177) that typically for mycoplasmas are associated with surface antigenic variation, adhesion to host cells, motility, and nutrient transport (287, 400).

Considerable effort has been made to identify MG antigens, especially those with adhesin or hemagglutinin properties, which may play key roles in the pathogenesis of, and immune response to, infection. Adhesins are integral membrane proteins having regions exposed on the cell surface that attach to receptor sites on host epithelial cells, which allow for colonization and infection, and as such are considered important virulence factors and antigens. *M. gallisepticum* proteins or lipoproteins with molecular weights ranging from 60–75 kDa have been described as immunodominant adhesins or hemagglutinins (21, 29, 51, 126, 208, 270).

Originally, two MG gene families, pMGA and *pvpA*, were described which encode major surface proteins with pathogenic, antigenic, and immune evasion properties (270, 273, 419). The pMGA multigene family was found to encode variant copies of a major cell surface lipoprotein hemagglutinin of 67 kDa (p67) (33, 148, 177, 272). Immunoblotting techniques revealed that the surface antigens p52 and p67 (pMGA) were specific to MG and the closely related species *M. imitans*. No antigenic difference was revealed within these species with anti-p52 serum, while anti-p67 serum confirmed the antigenic variability of p67 (178). The pMGA gene family occupies a minimum of 7.7% of the genome of strain F and 16% of the genome of strain R (33), which are significant genomic commitments to antigenic variability and hypothesized function of immune evasion (273). The pMGA gene family also provides a mechanism for rapid and reversible switches in its expression of proteins (antigenic switching) in response to antibodies or other environmental cues (146, 147, 271). In 2003 the pMGA gene and protein were renamed *vlhA* and VlhA respectively (319). The *vlhA* gene family encodes hemagglutinin in MG, and the *vlhA* genes are located in several loci around the chromosome and antigenic variation is generated by alternating transcription of over 40 translationally competent genes (7, 307).

PvpA is an MG size-variable integral membrane protein that shows high-frequency phase variation in its expression and adds to the complexity of antigenic variation in MG (241, 419). Antigenic variation and expression of PvpA and p67a, major immunogenic surface proteins, were correlated with antibody response *in vivo*, suggesting that immune modulation may have a key role in generating surface diversity (241). Size variation of the PvpA protein was observed among MG strains, ranging from 48 to 55 kDa; by immunoelectron microscopy the PvpA protein was localized on the mycoplasma cell surface at the terminal tip structure (46). The preceding information and that from many other reports indicates that the MG genome is highly committed to antigenic variation and variable expression of surface proteins (16, 40, 58, 133, 137, 155, 316).

Other adhesins identified in MG are GapA (or Mgc1) and Mgc2 (153, 169, 193). Like PvpA, the Mgc2 adhesin of MG localizes at the terminal tip structure of the cell surface (169). GapA is a primary cytadhesin that appears to work in a coordinated way with at least one other cytadherence-related protein,

CrmA undergoing concomitant phase variation in expression (153, 295, 318, 319, 321, 401). Expression of these two components has been correlated with binding to erythrocytes (401) and efficient attachment to cultured cells (318). These results demonstrated that both GapA and CrmA are required for MG cytadherence and pathogenesis (318, 320).

Some MG cytadhesin genes and proteins have homologues in other *Mycoplasma* spp., including some that are human pathogens, suggesting that there may be some conservation of cytadhesin genes and proteins among pathogenic mycoplasmas infecting widely divergent hosts (153, 169, 193, 277, 339).

Potent toxins have not been associated with mycoplasmas (328). See "Virulence Factors."

Strain Classification

Certain isolates of MG are known by their isolate or other designations and sometimes are called strains. Various strains of MG should not be confused with the numerous serotype designations that identified avian mycoplasmas prior to speciation within the genus *Mycoplasma*. Some MG isolates from both chickens and turkeys were described as "variant" or "atypical," because they were often difficult to isolate and less pathogenic, transmissible, and immunogenic than expected of field isolates (97, 198, 265, 412). Furthermore, because of demonstrated variability in antigenic phenotypes, MG strains, including well-established reference strains, may differ markedly in their antigen profiles and their virulence-related surface properties (340). Therefore, it has become increasingly important to develop methods to characterize and identify MG strains and strain variability. Recognition of intraspecies (strain) genotypic and phenotypic heterogeneity may be by serologic methods, or electrophoretic analysis of cell proteins or DNA, but has become more discriminatory and reproducible with the application of molecular techniques.

Antigenicity

Antigenic variation of MG strains and isolates has long been recognized empirically with reports of "atypical" or "variant" strains (97, 198, 412), and demonstrated by serologic assays (39, 97, 224, 251, 270, 316), immunoblots, and monoclonal antibodies (20, 58, 88, 133, 137, 175, 208, 241, 276, 316, 340, 353).

It is now well known that significant antigenic variability among MG strains can affect the sensitivity and specificity of serological tests, depending on the strain infecting the flock and the strain used to prepare antigen. Kleven *et al.* (224) tested MG strains with homologous and heterologous hemagglutination-inhibition (HI) assays and found that homologous HI titers were generally higher than heterologous titers. They also reported that MG strain A5969, commonly used as an HI antigen strain in many laboratories, was relatively insensitive for detecting antibodies against all of the strains studied and that none of the antigens tested was efficient in detecting HI antibodies against all other strains studied (224). Similarly, studies on the detection of antibody response to vaccination with MG strain ts-11 suggested that the major membrane antigen of MG had slightly different antigenic profiles in different strains, thereby necessitating the use of autologous (homologous) antigens in serodiagnostic as-

says to increase sensitivity of the tests for mycoplasma antibodies (305). Antigenic variability among MG strains presents a great challenge to the development and optimization of antigen/antibody-based assays (e.g., serologic, immunofluorescence, and growth inhibition organism identification tests).

The range of MG strain antigenicity, as well as its variability, is based at least in part on the organism's genomic commitment to immune evasion and adaptation to changes in the host environment, resulting in the expression of MG antigenic surface proteins that demonstrate high frequency variation, switching, and immune modulation (37, 39, 40, 133, 147, 240, 241, 255, 401). See "Antigenic Structure and Toxins," "Pathogenesis of the Infectious Process," "Immunity," and "Vaccination."

Immunogenicity or Protective Characteristics

As discussed previously, antigenic variability among and within MG strains and a range of immune responses to them have been recognized in the field and studied in the laboratory, culminating in current concepts of immune evasion, phenotypic switching, phase variation, etc. and the ongoing elucidation of the underlying mechanisms. See "Antigenic Structure and Toxins," "Pathogenesis of the Infectious Process," and "Immunity".

The immunogenicity (and relative low virulence) and protective characteristics of three MG strains (F, ts-11, and 6/85) have been applied to their commercial development as live vaccines (see "Live *M. gallisepticum* Vaccines"). Immunogenic and protective characteristics have also been described for some other MG strains that may be vaccine candidates including: house finch and house finch-like strains (122, 123, 311), and the GT5 strain (reconstituted from the avirulent R_{high} strain with the gene encoding the major cytadhesin GapA) (320). See "Pathogenesis of the Infectious Process," "Immunity," and "Vaccination."

Genetic or Molecular

M. gallisepticum strains have been differentiated from one another by direct comparison of protein banding patterns resulting from sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), or restriction fragment length polymorphism (RFLP) of DNA (206, 219, 224, 346). DNA and ribosomal RNA gene probes (204, 297, 418) and physical chromosomal mapping (380) have also been used to characterize MG intraspecies (strain) differences. These procedures for MG strain identification are costly, complex, and time consuming. Arbitrary primed PCR (AP-PCR) or random amplification of polymorphic DNA (RAPD) are polymerase chain reaction-based methods for MG strain identification that have proven efficient and very useful for epidemiological studies and for the identification of vaccine strains and field isolates (31, 73, 74, 75, 114, 117, 121, 144, 221, 244, 384). However, RAPD banding patterns are prone to variability and are difficult to reproduce and standardize, making interpretation challenging and subjective. More recently, *pvpA* or *mgc2* gene PCR followed by RFLP (PCR-RFLP) of the amplicon and/or sequence analysis has been used for MG strain identification (256, 263). Amplified fragment length polymorphism (AFLP) has been successfully used to explore the genomic variability of several *Mycoplasma* spp. including MG (75, 117, 172, 225, 349).

Molecular differentiation of MG by pulse-field electrophoresis (PFGE)(274), and targeted sequencing of various genes eg. *pvpA*, *gapA*, *mgc2* have also been reported (121, 172, 221).

Pathogenicity

Isolates and strains of MG vary widely in their relative pathogenicity, depending on the genotypic and phenotypic characteristics of the isolates, method of propagation, the number of passages through which they have been maintained, and the challenge route and dosage. Yolk-passaged organisms from MG-inoculated embryonated chicken eggs were often considered to be more infective than broth-passaged organisms.

The S6 strain of Zander (4, 112, 424) was an early pathogenic isolate from the brain of a turkey with infectious sinusitis. The A5969 strain was given that designation by Jungherr *et al.* (190) for a pathogenic culture supplied by Van Roekel. The R strain of MG was isolated by Dale Richey at the University of Georgia Poultry Disease (now Diagnostic) Research Center in 1963 from a chicken with airsacculitis. The R strain has been used widely for bacterin production and as a pathogenic strain for MG challenge studies (149, 214, 220, 338, 373, 416). The genotypic and phenotypic properties (including pathogenicity) of low (R_{low}) and high (R_{high}) passage R strains have been under intensive study, especially since the complete genome sequencing of R_{low} (319). R_{low} is capable of cytadherence, cell invasion, and is pathogenic while R_{high} shows diminished capacities in comparison (277, 320, 321, 402). Much *et al.* (294) reported that after aerosol inoculation of chickens, MG was re-isolated from the inner organs of birds infected with R_{low} but not recovered from the inner organs of birds infected with R_{high}. They concluded that these two mycoplasma populations derived from strain R differed in their capacity to cross the mucosal barrier, and that cell invasion may play a major role in the observed systemic spreading of MG (294).

The live F strain MG vaccine has proven relatively more pathogenic for turkeys than usually noted in chickens (243, 253, 338). The 6/85 and ts-ll vaccine strains are less pathogenic for chickens and turkeys then the F strain (1, 109, 110, 220, 269, 398, 399).

House finch and house finch-like strains of MG have shown relatively low pathogenicity for chickens and turkeys (122, 123, 311).

Clearly, there are MG strains that are primary pathogens for a number of avian host species. However, MG infections and diseases may be associated with a complex of host, environmental and microbial factors, so possibilities of multi-factorial etiologies and polymicrobial diseases involving MG should be considered. See "Pathogenesis of the Infectious Process".

Virulence Factors

Razin *et al.* (328) observed that the molecular mechanisms of mycoplasmal pathogenicity have remained largely elusive and that the clinical picture of mycoplasmal infections was more suggestive of damage due to host immune and inflammatory responses rather than to direct toxic effects by mycoplasmal cell components. Virulence factors associated with MG include motility and cytadhesion (24, 165, 209, 277, 287, 295); the ability to vary surface components, which may function in immune

evasion and/or adaptation to host environments (37, 241, 271, 272, 273); and (possibly) the ability to invade cells (232, 294, 402). Papazisi *et al.* (319) sequenced the complete genome of MG strain R_{low} and identified a number of potential virulence factors involved in cytadherence, binding biomolecules, and heat shock proteins. Signature sequence mutagenesis, which allows for comprehensive screening of the MG genome for the identification of novel virulence-associated determinants from a mixed mutant population, was used to identify a virulence-associated gene encoding dihydrolipoamide dehydrogenase (174). See "Antigenic Structure and Toxins," "Pathogenesis of the Infectious Process," and "Immunity."

Pathobiology and Epidemiology

Incidence and Distribution

M. gallisepticum infections have resulted in important flock health and decision-making problems in chickens and turkeys in all areas of commercial production in the United States and are worldwide in distribution (223, 240).

In the United States, the incidence of MG in commercial poultry decreased considerably during the past 50 years, as the result of extensive control programs under the National Poultry Improvement Plan (NPIP) (14). The NPIP has been especially effective in controlling infections in primary and multiplier breeder flocks. However, outbreaks continue to occur in meat flocks, and MG infection is endemic in many large multiple-age commercial egg production units (see "Intervention Strategies"). There is increasing evidence that small backyard or "free-range/village" poultry flocks may be subclinically infected and sources of infection for commercial flocks (111, 194, 279, 377).

Beginning in 1994, MG was identified as the cause of conjunctivitis in free-ranging house finches and some other songbird species in the eastern United States and Canada (244, 245). The disease in house finches expanded to the bird's western range by 2002–05 (101, 248).

Natural and Experimental Hosts

M. gallisepticum infections naturally occur primarily in gallinaceous birds, particularly chickens and turkeys in commercial production. However, MG has also been isolated from naturally occurring infections in pheasants, chukar partridge, peafowl, bobwhite quail, and Japanese quail (41, 82, 296, 330). *M. gallisepticum* has also been isolated from ducks and geese (43, 61, 182), and from a yellow-naped Amazon parrot (47) and greater flamingos (105). *M. gallisepticum* was not isolated in culture but was detected by polymerase chain reaction (PCR) in 4 mature rooks (*Corvius frugilegus*) with pericarditis and pneumonia in a Scotland, UK survey of wild birds (323).

A report by Davidson *et al.* (92) of MG isolated from wild turkeys (*Meleagris gallopavo*) noted that the turkeys involved were in confinement, not free-ranging in their natural habitat. A follow-up survey of the same population 8 years later found no conclusive evidence that MG was present, indicating that MG did not persist or spread in this wild turkey population (260). Other surveys of wild turkeys have found MG sero-negative (173, 258)

and sero-positive (80, 130) populations. However, MG has rarely been isolated from wild turkeys, perhaps due in part to the common occurrence of other *Mycoplasma* spp., especially *M. gallopavonis* (80, 130).

Low prevalences (5 and 2.7%) of antibodies to MG were detected by serum plate agglutination (SPA) from lesser prairie-chickens sampled from southwestern Kansas USA in 2000 and 2001, but no confirmatory serologic or organism identification methods were used (158).

Prior to 1994, there were reports of mycoplasma isolations from various other free-ranging birds, but the significance of occasionally reported MG was not clearly established. Similarly, attempts to determine the pathogenicity of MG for various free-ranging birds were not very conclusive. However in 1994 free-ranging house finches (*Carpodacus mexicanus*) with peri-orbital swelling and conjunctivitis were observed in the mid-Atlantic and Eastern United States, and MG was isolated and shown to be the etiology (125, 226, 245, 259, 261, 365, 366). The disease quickly became widespread, affecting house finches throughout their entire eastern range and negatively impacting their population (94, 95, 162, 163, 304, 336). By 2002–05 the disease in house finches had extended to their western range (101, 248). *M. gallisepticum* conjunctivitis has been reported at much lower prevalence for American goldfinches, pine grosbeaks, and evening grosbeaks, with single confirmed isolations reported from a purple finch and blue jay (164, 244, 286). One field survey found tufted titmice positive by MG PCR but no isolates were made, and individuals from 10 additional songbird species were MG SPA positive only (262). In another field survey 358 birds representing 13 different families showed no clinical signs but 13 species from nine families had positive MG SPA reactions with all birds negative by PCR (116). Experimental infections produced clinical disease in pine siskins and tufted titmice, but house sparrows were infected without clinical disease (116).

Random amplified polymorphic DNA (RAPD) analyses of MG isolates spanning temporal, geographic and songbird species ranges resulted in banding patterns essentially identical to each other but different from other MG strains and isolates tested (244). These results indicated that this outbreak of MG in songbirds was caused by one and the same field strain (RAPD-type) and not by any vaccine strain (F, ts-11, 6/85) or isolate analyzed from poultry (244). More recent and further analyses (75, 324) showed some genomic variability among songbird MG isolates (see "Strain Classification") but supported previous observations that during the initial stages of the MG epidemic in songbirds, isolates from different geographic locations and songbird species had genotypes that appeared to be highly similar, further supporting a single point source of origin. One 2001 isolate from New York was clearly different from the other songbird samples and clustered together with the vaccine and reference strains, indicating that substantial molecular evolution or a separate introduction may have occurred (75).

Experimental infections using a house finch MG isolate found that infection and disease can result in chickens and turkeys but that biosecurity measures that restrict direct contact between poultry and infected house finches reduce the potential for trans-

mission (311, 359). However, an MG isolate from commercial turkeys was very similar to isolates from house finches by RAPD and DNA sequence analyses suggesting the possibility that this was an incident of commercial poultry naturally infected by a songbird-like MG strain (122).

Specific-pathogen-free and/or mycoplasma-free domestic breeds of chickens, turkeys, and their embryonated eggs are the most commonly used experimental hosts for MG (49). Budgerigars, partridges, and house finches have also been used as experimental hosts (59, 116, 131, 226, 281, 335, 365, 366).

M. gallisepticum probably can infect susceptible birds at any age, although very young birds are seldom submitted with naturally occurring disease. However, young birds generally are considered somewhat more susceptible to experimental infections (49, 140).

Transmission, Carriers, and Vectors

Horizontal transmission occurs readily by direct or indirect contact of susceptible birds with infected clinical or subclinical birds resulting in high infection/disease prevalence within flocks. The upper respiratory tract and/or conjunctiva are portals of entry for the organism in aerosols or droplets (49). *M. gallisepticum* seldom survives for more than a few days outside of a host, so clinical or subclinical carrier birds are essential to the epidemiology of MG diseases. However, additional transmission and more widespread disease outbreaks may occur via fomites: contaminated airborne dust, droplets, or feathers, coupled with suboptimal biosecurity and personnel practices. Survival time of MG is dependent on at least conditions of substrate, pH, temperature and humidity. *M. gallisepticum* remained viable in chicken feces for 1–3 days at 20°C, on muslin cloth for 3 days at 20°C or 1 day at 37°C, and in egg yolk for 18 weeks at 37°C or 6 weeks at 20°C (70). *M. gallisepticum* survived in the human nasal passage for 24 hours; on straw, cotton, and rubber for 2 days; on human hair for 3 days; and on feathers for 2–4 days (78). Field isolates of MG did not survive longer than 7 days on paper discs at 30°C, 37°C and outdoor temperatures (298). Of 160 environmental samples tested from infected poultry flocks 103 were positive using MG specific PCR, but only 6 were positive by culture indicating that PCR is more sensitive for assessing dissemination of the organism than culture, which unlike PCR requires viable organisms for positive results (275).

Horizontal spread of MG within a chicken flock has been described in four phases: a latent phase (12–21 days) before antibody was first detected in inoculated birds; a period (1–21 days) in which infection gradually appeared in 5–10% of the population; a period (7–32 days) in which 90–95% of the remaining population developed antibody; a terminal phase (3–19 days) in which the remainder of the population became positive (282). Increasing the population density increased the rate at which horizontal spread occurred. Feberwee *et al.* (119) described an experimental model of horizontal transmission in chickens to study transmission dynamics and efficacy of intervention strategies.

Some potential reservoirs of MG carrier birds in the United States are backyard flocks (111, 279), multiple-age commercial layer flocks (215, 288), and some free-ranging songbird species

(122, 125, 244, 248, 286, 359). Good management and biosecurity practices are necessary to ensure that MG infections are not introduced from these and other sources to MG-free flocks.

Vertical transmission (*in ovo*/transovarian) of MG is known to occur in eggs laid by naturally infected hens (chickens or turkeys) and has been induced following experimental infections of susceptible leghorn chickens (152, 252, 314). The highest rates of transmission were found during the acute phase of the disease when MG levels in the respiratory tract peaked (151, 252). In separate studies, peak egg transmission was detected four weeks after MG challenge in approximately 25% of the eggs (152) and at three to six weeks post challenge in more than 50% of the eggs (347). On a flock basis, egg transmission rates decline as the postinfection interval lengthens. Transmission rates of approximately 3% at 8–15 weeks (334) and approximately 5% at 20–25 weeks (152) have been reported. During chronic infections under field conditions egg transmission is likely to occur at much lower levels (240). Horizontal transmission of MG from infected progeny that hatch, even very few infected birds resulting from very low transmission rates, is likely to involve entire flocks that receive any infected birds. *M. gallisepticum* control programs (14) must focus on primary and multiplier breeder flocks because of the severe epidemiological consequences of egg transmission. Serologic monitoring of breeder flocks at very short intervals (turkeys every 3 weeks, chickens every 2 weeks) could optimize the ability to detect and prevent the consequences of egg transmission.

Incubation Period

In experimental infections of chickens or turkeys, with uniform and high dosages, the MG incubation period varies from 6–21 days. Sinusitis often develops in experimentally inoculated turkeys within 6–10 days. However, development of clinical signs following a known exposure, even in turkeys that are considered highly susceptible, can be highly variable depending on MG strain virulence, complicating infections (polymicrobial infections), and environmental and other stressors (49, 97). Therefore under natural conditions it is very difficult to estimate the possible date of exposure based on the appearance of clinical signs. Many variable factors seem to influence the onset and extent of clinical disease so meaningful incubation periods cannot be stated. Chickens and turkeys often develop clinical infections near the onset of egg production, suggesting a low level of subclinical infection (perhaps due to egg transmission) that becomes clinical in response to stressors. This apparent extended incubation period was especially common in offspring of infected chickens or turkeys hatched from eggs dipped in antibiotic solutions for control of MG infection. The possible role of contamination from other (external) sources of infection is not always clear and can rarely be proved beyond reasonable doubt. Many outbreaks of MG appeared to represent this type of infection with delayed onset in which serologic evidence first appeared in older birds, often without clinical signs (265, 383, 412). In other situations, especially in turkeys exposed to virulent MG strains, clinical signs may be apparent before positive serology and are the first indicator of infection (249).

Clinical Signs
Chickens
The most characteristic signs of naturally occurring MG disease in adult flocks are tracheal rales, nasal discharge, and coughing. Feed consumption is reduced, and birds lose weight. In laying flocks, egg production declines but usually is maintained at a lowered level (288). However, flocks may have serologic evidence of infection with no obvious clinical signs, especially if they encountered the infection at a younger age and have partially recovered. Male birds may have the most pronounced signs, and the disease is often more severe during winter. In broiler flocks, most outbreaks occur after 4 weeks of age. Signs are frequently more marked than those observed in mature flocks. Severe outbreaks with high morbidity and mortality observed in broilers are frequently due to concurrent infections and environmental factors (216). See "Morbidity and Mortality."

Conjunctivitis developed in chickens following eye-drop inoculation of Australian field strains of MG combined with infectious bronchitis virus (356). Cases of keratoconjunctivitis caused by MG were reported in commercial layer chickens in Japan, first appearing around 30 days of age (310). Chickens showed swelling of the facial skin and the eyelids, increased lacrimation, congestion of conjunctival vessels, and respiratory rales.

Turkeys
Turkeys are more susceptible to MG than chickens, commonly developing more severe clinical signs including sinusitis (Fig. 21.2), respiratory distress, depression, decreased feed intake, and weight loss. Inoculation by the eye-drop, intranasal, or intratracheal routes often results in fewer and milder lesions than intrasinus or intra-air sac inoculation (49). Turkeys sometimes do not develop sinusitis unless organisms are injected directly into the sinus (97). As in chickens, more severe outbreaks with high morbidity and mortality frequently result with the involvement of complicating factors such as colibacillosis or environmental stressors (216).

Nasal discharge with foamy eye secretions frequently precedes the more typical swelling of the paranasal (infraorbital) sinuses. Partial to complete closure of the eyes results sometimes from severe swelling of the sinuses. Feed consumption may remain near normal as long as the birds can see to eat. As the disease progresses, affected birds fail to gain weight and body mass may even decrease. Tracheal rales, coughing, and labored breathing may become evident if tracheitis or airsacculitis is present. An encephalitic form of MG has been reported in 12–16-week-old commercial meat turkeys displaying torticollis and opisthotonos (77). In breeding flocks, there may be a drop in egg production or at least lowered production efficiency.

Morbidity and Mortality
Embryos
Inoculation of broth cultures or exudates containing MG into 7-day-old embryonated chicken eggs via the yolk sac route usually results in embryo deaths within 5–7 days. One or more yolk passages may be necessary before typical deaths and lesions are produced. Dwarfing, generalized edema, liver necrosis, and en-

21.2.   Turkey with advanced case of infectious sinusitis showing marked swelling of infraorbital sinuses and nasal exudate.

larged spleens are most typical. The organism reaches its highest concentration in the yolk sac, yolk, and chorioallantoic membrane (CAM) just prior to embryo death. Studies showed that MG strains varied in their *in ovo* pathogenicity and that there was no correlation between *in ovo* pathogenicity and other *in vivo* or *in vitro* methods for pathogenicity evaluation (239). *M. gallisepticum* embryo mortality was prevented in eggs containing maternal MG antibodies, although MG could be re-isolated from the yolk sac membrane of live embryonated eggs after 17 days of incubation (239). Inoculation of embryonated eggs is rarely employed for the primary isolation of avian mycoplasmas now that adequate culture media are available.

Chickens
M. gallisepticum infection usually affects nearly all chickens in a flock but disease is variable in severity and duration. It tends to be more severe and of longer duration in the cold months and affects younger birds more severely than mature birds, although there may be a considerable loss from lowered egg production in laying flocks.

Although MG is considered the primary cause of chronic respiratory disease (CRD), other organisms frequently cause complications. Severe air sac infection, frequently designated as complicated CRD, or air sac disease, is the condition more commonly encountered in the field. Newcastle disease (ND) or infectious bronchitis (IB) may precipitate outbreaks of MG infection. *E. coli* is a frequent complicating organism. The effects of MG, *E. coli*, and IB virus (IBV) infections alone or together in chickens have been reported (113, 156, 157, 125). Severe air sac infection was reproduced when all three agents were combined, and *E. coli* did not readily infect the air sacs without previous infection by MG alone or in combination with either IBV or ND virus. Investigators have noted increased severity and duration of the disease when both MG and IBV were present (356).

Mortality may be negligible in adult laying flocks, but there can be a reduction in egg production (68, 288). In broilers the mortality may range from low in uncomplicated disease to as much as 30% in complicated outbreaks, especially during the colder months. Retarded growth, downgrading of carcasses, and condemnations constitute further losses.

Turkeys
M. gallisepticum infection of turkeys causes disease in most of a flock, although turkeys may not exhibit sinusitis and the lower respiratory form of infection may be most prominent (97). Infection with MG may last for months in untreated flocks. Clinical signs, morbidity, and mortality associated with MG infection in turkeys may be highly variable. Typically, meat turkeys experience outbreaks between 8–15 weeks of age. Initially, mild respiratory signs may progress in 2–7 days to a severe cough in 80–90% of the flock. Swollen sinuses with nasal discharge may affect 1–70% of birds in affected flocks. Condemnations primarily result from airsacculitis and related systemic effects.

Pathology
Gross
Gross lesions consist primarily of catarrhal exudate in nasal and paranasal passages, trachea, bronchi, and air sacs. Sinusitis is usually most prominent in turkeys but is also observed in chickens and other affected avian hosts. Air sacs frequently contain caseous exudate, although they may present only a beaded or lymphofollicular appearance. Some degree of pneumonia may be observed. In severe cases of typical air sac disease in chickens or turkeys, there is the triad of airsacculitis, fibrinous or fibrinopurulent perihepatitis, and adhesive pericarditis resulting in high mortality and extensive condemnations at processing. However, these lesions may occur with chlamydiosis or septicemia and are not pathognomonic for MG. Commercial layer chickens with MG keratoconjunctivitis had marked edema in the facial subcutis and eyelids, with occasional corneal opacity (310). Conjunctivitis with periorbital swelling and inflammation are characteristics of MG in house finches and other songbirds (244, 245, 286) and has been seen in chukar partridges (281). Oviducts distended with exudate (salpingitis) have been associated with decreased egg production in MG-infected flocks (100, 308).

21.3. This cross-section of the nasal cavity shows the infraorbital sinus and nasolacrimal duct. The mucosa of each is increased in thickness due to a nodular and diffuse infiltration of lymphocytes and other lymphoid cells. The increase in number of lymphoid nodules is called the *lymphofollicular reaction*.
21.4. The epithelium of the infraorbital sinus (Sinus) is increased in thickness, and there is a nodular proliferation of lymphoid cells in the connective tissue beneath the lining epithelium. The mucosa of the nasolacrimal duct is increased in thickness due to the lymphoid cell infiltration. Exudate is in the sinus.

Microscopic

Microscopic pathology of MG in chickens and turkeys is characterized by marked thickening of the mucous membranes of affected tissues from infiltration with mononuclear cells and hyperplasia of the mucous glands (72, 168, 388) (Fig. 21.3). Focal areas of lymphoid hyperplasia are commonly found in the submucosa (Fig. 21.4). In trachea, an almost complete destruction of cilia was observed and swollen epithelial cells with MG adhering to villi (72, 102) 81). In tracheal ring cultures, ciliostasis resulted from MG infection (354, 369, 385). Tracheal gross and microscopic lesions, particularly increased mucosal thickness, have been used as measures of MG infection and disease (309, 397). Following experimental infection of chickens, trachea mucosal thickness increased significantly from 1–2 weeks and then decreased from 2–3 weeks (139). Lungs have pneumonic areas, lymphofollicular changes and granulomatous lesions. Detailed examinations of MG-infected chicken air sacs via light microscopy, scanning EM, and histomorphometric evaluation have been reported (382).

Keratoconjunctivitis in layer chickens associated with MG was characterized by epithelial hyperplasia, severe cellular infiltration, and edema of the subepithelial and central fibrovascular connective tissue stroma, which resulted in marked thickening of the eyelids (310). In the subepithelial lamina propria, proliferation of plasma cells and lymphocytes accompanying germinal centers was marked and resulted in irregular elevations of the overlying hyperplastic epithelial layer (310).

Histologic examination of turkey brains in cases of encephalitic MG revealed moderate to severe encephalitis with lymphocytic cuffing of vessels, fibrinoid vasculitis, focal parenchymal necrosis, and meningitis (77).

Salpingitis associated with reduced egg production in layer chickens was characterized by marked thickening of the oviductal mucosa due to epithelial hyperplasia and marked lymphoplasmacytic infiltration (308).

Ultrastructural

Ultrastructural details of MG interaction with the tracheal epithelium of chickens *in vivo* and *in vitro* have been reported (2, 102, 170, 229, 367). Tracheal lesions occurred in close association with the presence of mycoplasmas and were characterized by degeneration of the epithelial cells and inflammatory cellular infiltration of the mucosa (367). Mycoplasmas were predominantly found extracellularly and only rarely in phagocytic vacuoles of epithelial cells. Mycoplasmas were attached to epithelial cells by their terminal organelles (blebs or tip structures) close to the host cell membrane. A release of mucous granules followed by exfoliation of ciliated and non-ciliated epithelial cells and infrequent loss of cilia from individual cells was noted (102). Repair of the epithelial surface was affected by basilar epithelial cells differentiating and filling in the spaces formed by exfoliated cells. During infection, there was increasing epithelial thickness due to cellular infiltration and edema (102).

Incubation of MG with chicken red blood cells resulted in alterations of cell surface morphology and perforations (228, 230); results that may support recent evidence that MG can penetrate and be present within cells (402).

Pathogenesis of the Infectious Process

Except for infections acquired by egg transmission, the upper respiratory tract and/or conjunctiva generally are accepted to be the portals of entry for naturally acquired MG infections. *M. gal-*

lisepticum is considered to be primarily a surface parasite of the respiratory tract and conjunctiva, although spread to other organs (e.g., brain (77, 378)) indicates that transient systemic infections occur, resulting in acute and chronic diseases at multiple sites. Oviduct infections (308, 325) may result from proximity to infected air sacs (334). Attachment of mycoplasmas to host cells is a prerequisite for successful colonization, infection, and pathogenesis (91, 153, 237, 295, 327) and is considered an important virulence factor (see "Virulence Factors" and "Strain Classification/ Antigenicity"). *M. gallisepticum* organisms attach to epithelial cells by their terminal organelle (bleb or tip structure) which also plays a role in gliding motility, another component of pathogenesis (69, 350, 367). Comparative studies using MG strains R_{low} (virulent) and R_{high} (avirulent) identified the cytadhesin protein GapA and accessory protein CrmA, and found that both are required for cytadherence and pathogenesis (295, 318, 321), and that phase variation of these proteins correlates with hemadsorption phenotypic switching (401).

In tissue culture, MG was found capable of entering non-phagocytic host cells, a property that could provide the organism with the opportunity for resisting host defenses and selective antibiotic therapy, establishing chronic infections, and passing through the respiratory mucosal barrier to cause systemic infections (402). Much *et al.* (294) found that R_{low} and R_{high} strains differed markedly in their ability to invade non-phagocytic eukaryotic cells, and after aerosol inoculation of chickens MG was re-isolated from the inner organs of birds infected with R_{low} but not R_{high}. Results showed that these strains differed in their capacity to cross the mucosal barrier, and suggested that cell invasion may play a major role in the systemic spread of MG and avoidance of host defenses allowing for its survival and persistence of infection (294). Furthermore, since adhesion is a prerequisite for cell invasion, the lack of GapA expression in R_{high} may account for its inability to cause systemic infection and air sac lesions (294).

Changes in tracheal epithelial surfaces induced by MG infection *in vivo* and *in vitro* included release of mucous granules followed by destruction and exfoliation of ciliated and nonciliated epithelial cells (72, 102). In chicken embryos, MG infection resulted in extensive deciliation, surface erosion, and inflammatory cell infiltration (229). These changes, and ciliostasis as noted in tracheal organ cultures infected with MG (369, 385), likely play both primary and secondary roles in the pathogenesis of MG diseases.

Suppression or stimulation of B and T lymphocytes and cytokine induction (139, 231, 328) may also play roles in pathogenesis. A prominent feature of MG infection is a lymphoproliferative response at the site of infection, and MG-infected cells have been shown to produce chemotactic factors attracting the migration of heterophils and lymphocytes (227, 233). Incubation of MG with chicken red blood cells (RBC) resulted in altered cell surface morphology, decreased cell size, and perforations of the cells, suggesting that cell penetration may occur and that RBC damage may result in pathologic consequences (228, 230).

In the absence of exacerbating environmental stressors or infection with other pathogens, MG infection in the trachea may be self-limiting (406) but organisms may persist (carrier state) even in the presence of humoral or local antibody (39, 214, 406). The high frequency phenotypic variation of major surface antigens (133, 147, 401) and cell invasion (294) may be explanations for MG chronic infections, despite a strong immune response (240) (see "Immunity").

Complicating infections (polymicrobial disease), especially colibacillosis, and including some live vaccines, are known to result in more severe MG diseases (157, 181, 216, 299, 302). Other factors that are likely to contribute to more severe MG diseases include immunosuppression and poor environmental conditions or other stressors (34).

Immunity

Chickens or turkeys that have recovered from clinical signs of MG diseases are known to have some degree of immunity. However, recovered birds may still carry the organism (39) and can transmit infections to susceptible birds by contact or egg transmission. The early literature concerning the immune response to MG was reviewed by Luginbuhl *et al.* (257). The importance of antibodies and the bursa of Fabricius to the development of MG resistance and serologic response to the organism has been demonstrated (3, 179, 234). However, poor correlation between levels of specific circulating antibody and protection has also been well documented (234, 254, 306, 373, 398). Increasing antibody titers to MG were found in tracheal washings of infected chickens with a concomitant decrease in organisms and tracheal lesion scores (76, 406). Antibodies persisted in recovered chickens, and upon re-exposure, they had a faster rate of MG elimination and less severe tracheal lesions than observed after the first exposure. These results and others indicated that antibodies in respiratory secretions played a role in resistance to MG (22, 106, 179, 404, 406). Respiratory tract antibodies produced in response to MG infection inhibited attachment of the organism to tracheal epithelial cells (22), which may be one important mechanism of immune-mediated protection. The presence of maternal antibodies to MG in embryonated eggs reduced the *in ovo* pathogenicity of infection and increased the probability of survival of infected embryos (42, 239, 254). Considerable effort has been made to identify MG antigens, especially those with cytadhesion properties, which may play key roles in the pathogenesis of, and immune response to, infection. See "Antigenic Structure and Toxins," "Virulence Factors", and "Vaccination."

Mycoplasmas may affect the cell-mediated immune system by inducing either suppression or stimulation of B and T lymphocytes, and inducing cytokines (76, 132, 139, 231, 328, 329). Lymphoproliferation, interferon, and nitric oxide were detected *in vitro* in antigen-stimulated peripheral blood leukocytes from MG-infected chickens (329). Gaunson *et al.* (139, 141) examined the numbers and distribution of lymphocytes in the tracheas of chickens exposed to virulent and vaccine strains of MG and found specific stimulation of CD8+ cells particularly in the acute phase of disease. They observed a primary role for local antibody mediated responses in controlling MG infection, but also presented evidence for significant natural killer and cytotoxic T cell responses to infection (141).

Studies on variable expression of MG immunodominant surface proteins demonstrating high frequency variation, switching, and immune modulation suggest that this variability may function as a crucial adaptive mechanism enabling the organism to escape from the host immune defenses (immune evasion), adapt to the changing host environment at different stages of a natural infection, and allow for chronic infection despite a strong immune response (39, 40, 133, 147, 240, 241, 401). Additionally, it may be possible for MG to hide from host defenses by entering eukaryotic cells (cell invasion) and spreading systemically, contributing to its survival and persistence of infection (228, 230, 294, 402).

Diagnosis

Isolation and Identification of Causative Agent

The gold standard for MG diagnosis is isolation and identification of the organism. To culture MG, suspensions of tracheal or air sac exudates, turbinates, lungs, or fluid sinus exudate should be inoculated directly to mycoplasma broth or agar medium (217). Swabs can also be taken from the trachea or choanal cleft (palatine fissure) for MG culture (57, 421, 422). *M. gallisepticum* may also be present in oviducts (100, 308), and has been isolated from the cloaca of turkeys and chickens (9, 264, 390). For culture medium and isolation methods, see "Growth Requirements" and Kleven (217).

During the acute stages of infection (generally in the first 4–8 weeks postinfection), the population numbers of MG in the upper respirator tract and the prevalence of infection in the flock are high (223, 238, 406). Therefore, swabbing tracheas or choanal clefts of 10–20 live birds is usually sufficient to recover the organism, whereas 30–100 cultures may be required at later stages (223). Tracheal or choanal numbers of organisms in chronically infected birds, such as commercial egg layers or backyard poultry, may be so low that MG organism may not be detected by usual sampling and culture methods (240). To optimize the possibility of isolation, flocks should be sampled for MG culture prior to initiation of antimicrobial therapy (285). Ammonium chloride (54) and perhaps other drinking water treatments may hinder the isolation of MG from infected birds.

The following recommendations are for specimens that must be stored and/or shipped to a laboratory for culture (223). Ideally, mycoplasma broth media should be inoculated directly from the bird (swab, exudate, or small tissue sample) and incubated (37°C) immediately. If short-term storage and/or shipment are necessary, keep inoculated broths at 4°C or on cold packs (not longer than 24 hours) and use an overnight carrier. Alternatively, tracheas, fluids, or tissues can be collected and frozen on dry ice but must remain on dry ice until arrival at the laboratory.

Samples of growing broth cultures are transferred to mycoplasma agar medium to allow for colony formation followed by immunofluorescence tests for *Mycoplasma* spp. identification. Direct or indirect immunofluorescence of mycoplasma colonies or colony imprints (138) are commonly used to identify MG field isolates, even with cultures of mixed *Mycoplasma* spp. (217, 223, 292, 371, 372). Immunoperoxidase procedures, either alone or in combination with immunofluorescence, may also be used for rapid identification of mycoplasma cultures (38). Growth inhibition has also been used for *Mycoplasma* spp. identification (79, 217). Mycoplasma species-specific hyperimmune sera, usually produced by research laboratories in rabbits or avian species, are essential reagents for these diagnostic tests (217, 223).

Inoculation of 7-day-old embryonated chicken eggs via the yolk sac with exudates or suspensions from suspect lesions may be used as another means of isolating MG, but the inocula must be free from bacterial and fungal contamination (49, 104, 333). Death of embryos should occur within 5–8 days, but one or more serial passages of harvested yolk material might be required before embryo deaths and typical lesions are noted.

Detection of MG using DNA and ribosomal RNA gene probes has been described (99, 124, 135, 143, 176, 205, 345), but for most applications these methods have been superseded by various polymerase chain reaction (PCR) based procedures that are relatively less complex and more rapid, sensitive, and specific (115, 136, 161, 196, 300, 343, 344, 352, 355, 392). Multiplex PCR protocols have been described which allow for the simultaneous detection of different organisms (267, 317, 392). A test based on PCR of the 16S rRNA gene with *Mycoplasma*-specific primers and separation of the PCR product according to primary sequence using denaturing gradient gel electrophoresis has been described (278). Rapid detection by real-time PCR has also been described (67, 283).

Detection of MG-specific DNA by PCR has become widely available at diagnostic and institutional laboratories using commercial PCR kits or established protocols (134, 235). Detection of MG DNA by PCR compared to isolation of the organism in culture provides a negative or positive result in hours instead of days, does not rely on the presence of viable organisms, and is much less susceptible to microbial contaminants. However, culture and isolation of MG organisms remains essential for most further studies such as experimental infections, pathogenicity studies, and intra-species (strain) identification (see "Strain Classification"). An inoculated mycoplasma broth can be divided and processed for both culture and PCR. When culture and isolation of viable organisms is not necessary or possible, FTA® filter paper may be used for the inactivation and storage of MG suspensions or field specimens prior to PCR or other DNA-dependent assays (293).

Serology

Serologic procedures are useful for flock monitoring in MG control programs (14) and to aid in diagnosis when infection is suspected. A positive serologic test together with history and clinical signs typical of MG disease allows a presumptive diagnosis pending isolation and/or identification of the organisms.

The tube agglutination test was a common procedure, especially during the MG control program for turkeys in the 1960s and 1970s but is now rarely used. Serum plate agglutination (SPA) antigen, for the detection of antibodies to MG, is commercially available. Because the SPA test is quick, relatively inexpensive, and sensitive, it has been widely used as an initial screening test for flock monitoring and serodiagnosis (14, 217, 223).

However, nonspecific reactors occur in some flocks infected with *M. synoviae* due to cross-reactive antigens (18, 36), or in flocks recently vaccinated with oil-emulsion vaccines and/or vaccines of tissue-culture origin against various agents (5, 150, 341, 414). Certain nonspecific SPA reactions may be reduced by diluting the test serum (341). Some laboratories determine agglutination end points by preparing 2-fold (1:2) dilutions of sera in saline. Sera that react at 1:8 or greater are considered positive, which may also be useful in differentiating between specific and non-specific reactions (217). The SPA test is highly efficient in detecting IgM antibody, which is the first class of immunoglobulins produced in response to infection (211).

The hemagglutination-inhibition (HI) test has been commonly used to confirm reactors detected by SPA or, more recently, enzyme-linked immunosorbent assays (ELISA). However, the HI test is time consuming, the reagents are not commercially available, and the test may lack sensitivity (97, 217, 223, 224).

Enzyme-linked immunosorbent assays were developed to increase testing efficiency, and improve sensitivity and specificity of results relative to the SPA and HI tests (19, 88, 89, 166, 266, 290, 362, 374). Commercial ELISA test kits are now commonly used for flock monitoring and serodiagnosis. In general, ELISA tests may be slightly less sensitive but more specific than SPA tests and less specific but more sensitive than HI tests (19, 111, 192, 197, 200). In many production company and diagnostic laboratories, ELISA is the test of choice for MG serology. Efforts continue to improve MG ELISA sensitivity and specificity by identifying and purifying specific immunodominant MG proteins for use as ELISA antigens (20, 88, 108, 305, 313, 357). ELISAs have also been used to detect MG antibodies in respiratory tract washings (22, 406) and egg yolk samples (197, 289). Studies comparing egg yolk and serum for the detection of MG antibodies by ELISA or HI found comparable results, indicating that egg yolk samples could be used instead of serum samples for flock screening (60, 197, 289). Dot immunobinding assays for the detection of MG antibodies have also been described (17, 85, 86, 370).

Positive MG serologic test results have been encountered in some chicken breeding flocks with histories of being MG-free. The usually normal-appearing flocks began to have a small percentage of MG SPA test reactors at 28–36 weeks of age. Hemagglutination-inhibition titers rarely exceeded 1:80, and the percent of SPA reactors often did not exceed 20–40% of the flock during several months of study (265, 412). Low virulence MG strains, which were difficult to isolate and apparently egg transmitted, were considered responsible (383, 412). Turkeys have also been infected with MG isolates of low virulence, low transmissibility, and poor immunogenicity (97). Antigenic variation of MG isolates demonstrated by immunoblots (20, 23, 353) and agglutination (316) or HI assays (97, 224, 270) is at least partly responsible for "atypical" reactors.

The use of certain antimicrobics, especially early in the course of infection, may effect the development of a detectable antibody response (240, 360). In experimental infection trials, fewer serological responses were found in MG-infected chickens or turkeys treated with antibiotics than in the MG-infected nonmedicated groups (184, 187, 189, 285).

The performance of culture, PCR, plate agglutination, HI, and ELISA tests were compared for the detection of MG infection using samples from SPF layer chickens infected at 66 weeks of age, and the authors concluded that it was not advisable to rely completely on only one test system (118).

Differential Diagnosis

M. gallisepticum infections of poultry must be differentiated from other respiratory diseases and may be clinically obvious only when present in conjunction with complicating respiratory infections such as Newcastle disease or infectious bronchitis and *E. coli* (216, 217).

In chickens care must be taken to differentiate MG infection from other common respiratory diseases. Newcastle disease and infectious bronchitis or their antibodies may be present as separate entities or as part of the complicated CRD syndrome. Infectious coryza (*Avibacterium paragallinarum*) and fowl cholera (*Pasteurella multocida*) usually can be identified by bacterial culture. *M. synoviae* infection may be present alone or in addition to MG. Application of both serologic and organism identification test procedures may be necessary in some cases.

In turkeys respiratory disease including sinusitis may be due to avian influenza, aspergillosis, pasteurellosis, chlamydiosis, respiratory cryptosporidiosis, Newcastle disease, MS infection, or vitamin A deficiency as well as MG (217). Avian pneumoviruses (APV) and *Ornithobacterium rhinotracheale* (ORT) should also be considered in the differential diagnosis (180, 387). Specific organism identification and/or serologic procedures are needed to differentiate MG from other microbial causes of turkey respiratory disease.

In songbirds with conjunctivitis, *M. sturni* (127, 128, 246, 323, 394) (isolated from European starling, northern mockingbird, blue jay, crows, blackbird, magpie, American robin) should be considered as well as MG (125, 163, 164, 244, 286) (isolated from house finch, American goldfinch, purple finch, blue jay, evening grosbeak, and pine grosbeak). Chlamydiosis, other bacterial infections, and poxvirus should also be considered.

A mycoplasma strain designated 4229T, isolated in 1984 from the turbinate of a duck in France, and similar isolates from geese in France and from a partridge in England, were originally identified as MG by immunofluorescence and growth inhibition tests (48). Subsequent serologic and molecular studies indicated only a partial relationship to MG, and DNA-DNA hybridization studies revealed only approximately 40–46% genetic homology (48). A new species name, *Mycoplasma imitans*, was proposed for this organism that cross-reacts serologically with MG (48, 339) but can be differentiated by molecular techniques (134, 161, 195, 343). *M. imitans* has not been identified in the United States.

Intervention Strategies

Management Procedures

Because MG can be egg transmitted, maintaining chicken and turkey flocks free of MG infection is only possible by starting with breeding stocks that are known to be free of the infection and then rearing them with adequate biosecurity to avoid intro-

duction of the organism. Establishing the MG-clean status of breeder flocks and maintaining that status can be accomplished by participation in control programs. In the United States, turkey and chicken primary and multiplier breeders and hatcheries generally have adopted the various MG control programs of the National Poultry Improvement Plan (14) with great success. However, multiple-age production complexes, usually for commercial table egg production, but also for breeders and meat flocks, have become more common worldwide (240). Poultry population densities have increased, sometimes involving multiple companies and different poultry types (breeders, meat birds, layers), in close proximity to each other and backyard flocks. Perhaps because of these risk factors and lapses in biosecurity, maintaining MG-free poultry flocks may be difficult or impossible (240). Therefore, appropriate antimicrobial therapy may be used to reduce morbidity and mortality, losses at processing, or egg transmission. Vaccination may also be an option in some situations.

Vaccination

Types of Vaccines

Nonliving M. gallisepticum Vaccines. Interest in MG vaccines originated in the late 1970s as it became apparent that MG infection was endemic in some multiple-age, egg-laying complexes. *M. gallisepticum* bacterins (killed organisms) with oil-emulsion adjuvant protected young chickens from intra-sinus challenge with virulent MG and commercial egg layers from MG-induced drops in egg production (167). Some investigators found that bacterins could protect broilers from airsacculitis (191, 417) or layers from reductions in egg production (416), and others did not detect much efficacy in commercial egg layers with endemic MG infections (207). Bacterins have been shown to reduce, but usually not eliminate, colonization by MG following challenge (214, 373, 404, 416, 417) and generally are felt to be of minimal value in long-term control of infection on multiple-age production sites (240). A study on the effect of bacterin vaccination on the horizontal transmission of MG in a model system found that there was some reduction in shedding, but concluded that bacterin vaccination would not reduce horizontal transmission of MG between laying hens (120).

Because bacterins are nonliving, they do not engender the safety concerns of live vaccines; however, they are disadvantaged by the need for more than one application (for optimal protection) and the cost of individual bird administration. To enhance the performance of nonliving MG vaccines, various adjuvants and antigen delivery systems, including liposomes and iota carrageenan, have been investigated (27, 28, 30, 106, 107, 405). *M gallisepticum* bacterins have been produced commercially.

Development of subunit vaccines using MG surface proteins has been investigated (90, 280, 342, 364, 420) and may be gaining interest as an additional alternative to bacterins and live vaccines.

Live M. gallisepticum Vaccines. Live F strain MG vaccine is a relatively mild strain that apparently originated from the Connecticut F strain (386), and has been used in pullet immu-

nization programs (68, 151, 338). However, the original F strain isolate was described as a typical pathogenic strain (407). That strain was used in Connecticut for live culture vaccination of young broiler breeder replacement flocks to reduce possible egg transmission of MG in subsequent breeder flocks (257). Studies using the Connecticut F strain in young replacement pullets prior to housing in multiple-age egg-laying complexes have also been reported (68, 386). Numerous reports exist on the use of live F strain MG vaccine, which has been produced commercially and used extensively in multiple-age laying complexes to reduce MG-caused egg production losses (1, 53, 55, 68, 83, 87, 151, 152, 212). In broilers, vaccination with F strain provided some protection from airsacculitis following aerosol challenge with virulent R strain (238, 337, 338). The biologic mechanism underlying protection by F strain did not involve competition for adherence sites or blockage by prior colonization, and F strain vaccination did not prevent colonization by the challenge strain of MG (238). F strain can be transmitted through the egg (252) and among pen-mates (109, 212). However, pullets given F strain by the eye-drop route did not transmit the infection to broilers in pens in the same house when separated by an aisle or empty pen (212). F strain vaccinated laying hens produced more eggs than unvaccinated hens in flocks with endemic MG but not as many as MG-clean flocks (68, 288). Vaccination of pullets in isolation facilities at twelve weeks of age resulted in delayed onset of lay and decreased total egg production (62). A series of trials using this model system followed possible physiological mechanisms involved in the effects of F strain vaccination on reproductive performance (63, 64, 65, 66, 322). F strain vaccinated flocks maintain the organism in the upper respiratory tract for the life of the flock (212). In laboratory studies F strain vaccination reduced the population of a challenge strain in the upper respiratory tract (83, 238); in pen trials F strain vaccination effectively displaced infection with a challenge strain (220). Field-strain MG was displaced from a multiple-age layer complex following 2 years continuous use of F strain vaccine in replacement pullets (222). Following experimental infection F strain was found to be pathogenic in turkeys (253), and it has been associated with MG outbreaks in breeder and meat turkeys under field conditions (243). F strain vaccine can be administered by several routes including eye-drop, intranasal, and coarse spray (240). Vaccine generally is administered at 8–14 weeks of age but can be administered as early as 2 weeks or less if chicks are at risk of exposure to wild-type infection before 8 weeks (240).

The 6/85 strain of MG originated in the United States, and its development and vaccine characteristics have been described (52, 109, 110). Studies using MG 6/85 vaccine found minimal virulence in chickens and turkeys, little or no transmissibility from bird to bird, and resistance against challenge with virulent MG (1, 109, 221, 247, 423). The 6/85 vaccine is administered by spray, results in little or no detectable serologic response, and can be detected in the upper respiratory tract for 4–8 weeks after vaccination (1, 109, 247). In the United Sates, MG 6/85 vaccine has been used primarily for the prevention of egg production losses in commercial table-egg layers. This vaccine is formulated as a freeze-dried pellet and administered as a single dose to pullets 6

weeks of age or older. To be fully effective, the vaccine must be administered by the aerosol route.

Development and characterization of the ts-11 MG vaccine have been described (398, 399). The ts-11 vaccine originated from an Australian MG field isolate (strain 80083) that was subjected to chemical mutagenesis and selected for temperature-sensitivity (growth at 33°C) (399). The ts-11 MG vaccine has minimal or no virulence for chickens and turkeys, is weakly transmissible from bird to bird, stimulates a slow to develop response and low levels of detectable circulating antibody, and induces protection to MG experimental and field challenge (1, 26, 45, 140, 247, 306, 396, 398, 399). Detection of antibody response to ts-11 vaccination may be improved by using an ELISA test with autologous antigen (305). In vaccinated flocks ts-11 persists for the life of the flock in the upper respiratory tract and induces long-lived immunity (396). In experimental studies vaccination of pullets had no impact on egg production, egg and eggshell quality parameters, and egg size distribution (56). Experimental vaccination of broiler breeders showed resistance to infection by field MG in the breeders and their embryos, and better production performance in their broilers (26). Floor pen studies used to evaluate the serological response of broiler breeders after vaccination with ts-11 (81) showed a pattern of seroconversion that was different from results obtained with layer chickens (1, 247, 398) (there were other experimental differences as well). Lateral spread of ts-ll to commingled pen-mates occurred rapidly, causing seroconversion patterns to mimic those of vaccinated pen-mates (81). In the United Sates, MG ts-11 vaccine has been used primarily for prevention of egg production losses in commercial table egg layers. The vaccine is formulated as a frozen (–40°C) suspension and administered by the eye-drop route as a single dose to growing pullets 9 weeks of age or older, at least 3 weeks before expected exposure to field challenge. However, Gauson *et al.* (140) reported that ts-11 vaccine was safe in birds between 1 and 4 weeks of age and effective in preventing development of severe disease in them after challenge, even though birds of the same age were more susceptible to development of disease when infected with virulent MG.

Comparative studies and reviews on experimental and field uses of MG vaccines in poultry are available and should be consulted for more details relative to the summaries that follow. Because of their superior safety characteristics (relative avirulence and low potential for unintended transmission to non-target e.g. unvaccinated flocks), both 6/85 and ts-11 vaccines may be considered preferable to F strain when MG vaccination is necessary in situations where susceptible poultry are nearby (240). An important characteristic of MG vaccines is the ability to induce resistance to infection from wild-type challenge, resulting in displacement of wild-type strains with the vaccine strain on multiple-age production sites (218, 240). This characteristic could be used as a tool for MG eradication from such sites. F strain vaccine had greater ability to displace challenge strains in pen trials than did 6/85 or ts-11, and displaced a field strain of MG on a multiple-age commercial egg production site (218, 222). However, when vaccination on this farm was stopped, F strain continued to cycle from flock to flock, and

eradication of MG was not achieved (222, 240). The ts-11 vaccine was used to vaccinate replacement pullets on a site previously populated with F strain, and displacement of F strain by ts-11 occurred in the vaccinated flocks. After vaccination with ts-11 was discontinued, MG was no longer detected on the farm (240, 384). Similar data for the 6/85 vaccine are not available, but there are reports of complexes that have used 6/85 and became seronegative, suggesting that displacement of wild-type MG strains may have occurred (218, 240). If wild-type MG strains are highly virulent, it may be necessary to vaccinate with F strain for one or more production cycles prior to switching to either 6/85 or ts-11 (218, 240).

Because they are live vaccines, there are concerns for the safety of F, 6/85, and ts-11 strains relative to non-target flocks that relate mainly to virulence, persistence, transmissibility, and the stability of these vaccine properties. The known biological characteristics of F strain vaccine are compatible with examples of "escaped" F strain vaccine associated with MG infection and/or disease in nontarget flocks (218, 243, 253). The 6/85 vaccine has generally been very safe for chickens. However, there have been several instances of 6/85-like isolates (based primarily on RAPD genotyping) made from turkeys showing clinical disease and associated in most cases with a history of chickens vaccinated nearby (218, 221). A genotypically 6/85-like isolate was made from unvaccinated table-egg layers with swollen sinuses (379). The isolate had some phenotypic properties unlike 6/85 vaccine, and the origin and role of the 6/85-like isolate was not established (379). However, it was recommended that live MG vaccines be properly administered so that all birds in the target flock are properly immunized; and that unvaccinated, susceptible flocks should not be allowed to remain in close proximity to vaccinated flocks (379). Isolates that were ts-11-like have been detected on at least two occasions in unvaccinated chicken flocks (218). In both instances, there was a history of possible inadvertent vaccination, and in one there was subsequent spread to neighboring broiler breeders (218). These experiences suggest that even though these vaccines are generally very safe, they may have the potential for infecting non-target flocks (218). Live MG vaccines should be used only in jurisdictions where they are approved, administered with strict adherence to the manufacturers' instructions, and with careful consideration for the safety of non-target flocks.

Currently available MG vaccines have shown little potential for use in turkeys (6, 73, 218, 240). The F strain vaccine is too pathogenic (243, 253), and the ts-11 vaccine appears to have little or no ability to colonize turkeys (6, 218, 396, 399). A vaccination trial in turkeys using 6/85 vaccine resulted in little or no protection against airsacculitis after heavy aerosol challenge, but there was some protection detected against development of lesions in the upper respiratory tract (218).

Efforts continue to development new and improved MG vaccines. A modified live MG vaccine (strain GT5) was constructed by reconstitution of the avirulent high passage R strain (R_{high}) with the gene encoding the major cytadhesin GapA (179, 320). A naturally low virulent MG isolate (K5054) from turkeys, genotypically similar to the house finch strain, has shown potential for

use as a vaccine in chickens and turkeys (122, 123). A recombinant fowlpox-MG vaccine has been introduced (44).

Treatment

M. gallisepticum has shown sensitivity *in vitro* and *in vivo* to several antimicrobics including macrolides, tetracyclines, fluoroquinolones, and others but is resistant to penicillins or other antibiotics which act by inhibiting cell wall biosynthesis (50, 183, 188, 203, 236, 250, 360, 381, 391). *M. gallisepticum* may develop resistance, and demonstrate cross-resistance, to commonly used antibiotics (50, 142, 285, 332, 403, 425). Techniques for *in vitro* antimicrobial susceptibility and minimum inhibitory concentration (MIC) testing have been described (50, 160, 376). Antimicrobics have been used to treat MG respiratory diseases (149, 183, 184), and to reduce egg production losses (315) and transmission (301, 314, 348, 360, 415). Antimicrobics may reduce the severity of clinical signs and lesions, and significantly reduce populations of MG in the respiratory tract (84, 189).

Attempts to treat CRD with various antimicrobics during the 1960s produced variable results. In many cases, it was doubtful if small increases in weight gain or egg production, and moderate reduction of carcass condemnations, were sufficient to cover medication costs. However, some more commonly employed treatments that tended to provide favorable results included use of oxytetracycline or chlortetracycline at 200 g/ton feed for at least several days. Tylosin has been injected subcutaneously at 3–5 mg/lb body weight or administered at 2–3 g/gal drinking water for 3–5 days. Administration of very low levels of tylosin in feed to MG-exposed layers in multiple-age complexes was found to lessen egg production losses (315). Tiamulin and tiamulin plus salinomycin were reported to be effective treatments in chickens or turkeys (15, 35, 361). Attempts to eliminate egg transmission of MG by medication of breeder flocks or their progeny with streptomycin, dihydrostreptomycin, oxytetracycline, chlortetracycline, erythromycin, or tylosin generally were able to produce considerable reduction in rates of MG infection but generally were not adequate to obtain entirely infection-free flocks. Tylosin and gentamicin injection of chicken breeder hen eggs, and spectinomycin and lincomycin treatment of chicks showed efficacy (301). Efficacy has been shown with: spiramycin in layer chickens (15); fluoroquinolones in broilers (25, 184, 186, 199, 202, 285, 375), breeder chickens (360), and layers (314); and tilmicosin in chickens (71, 185, 201, 351) and turkeys (187).

Regulations on the use of antimicrobials in poultry are rapidly evolving, vary considerably among jurisdictions (e.g., European Union, United States, etc.) and should be consulted just prior to treatment for verification and currency. In the United States, see the AVMA Judicious Therapeutic Use of Antimicrobials in Poultry, American Association of Avian Pathologists Guidelines to Judicious Therapeutic Use of Antimicrobials in Poultry (10); AVMA Judicious Use of Antimicrobials for Poultry Veterinarians (13); Animal Medicinal Drug Use Clarification Act (11); and the FDA Approved Animal Drug List (Green Book) (12).

Egg injection or dipping with a temperature or pressure differential has been used to introduce antimicrobials into hatching eggs to control MG *in ovo* transmission (8, 145, 159, 301, 312, 363). In general, these methods greatly reduced, but sometimes did not completely eliminate, the possibility of egg transmission. Effects on hatchability were not consistently favorable, and bacterial contamination was troublesome at times. However, the use of antimicrobials for egg injection or dipping made it possible to obtain sufficient MG-free birds to provide the poultry industry with a nucleus for producing clean progeny for large flocks, resulting in MG-free chicken and turkey breeder flocks in the United Sates. An alternative approach for reducing *in ovo* transmission of MG involved heating eggs in a forced-air incubator during a 12–14-hour period to reach an internal temperature of 46.1°C (411). Hatchability was sometimes reduced (2–3% to 8–12%), but field studies demonstrated adequate success in many cases (154, 284, 348). Complete elimination of MG from all birds in an infected flock by mass antimicrobial therapy is an unrealistic expectation, and treatment should be regarded as a method for short-term amelioration of disease and economic effects, rather than as a long-term solution to the problem (240, 331, 395).

Mycoplasma meleagridis Infection
R. P. Chin, G. Yan Ghazikhanian, and Isabelle Kempf

Introduction

Definition and Synonyms
Mycoplasma meleagridis (MM) (N strain PPLO, H serotype) is a specific pathogen of turkeys. It is the cause of an egg-transmitted disease in which the primary lesion is an airsacculitis in the progeny. Other manifestations include decreased hatchability, skeletal abnormalities, and poor growth performance.

Economic Significance
Economic losses caused by MM in turkeys have been associated primarily with egg-borne infections. During the early 1980s when the prevalence of MM was very high, the monetary cost to the U.S. turkey industry resulting from MM-related hatchability losses and the cost of egg treatment to control egg-borne infections was estimated at 9.4 million dollars per year (26). Currently, the economic losses due to MM infection in turkeys have been reduced significantly with the availability of MM-free eggs and poults supplied by major turkey breeders.

Public Health Significance
M. meleagridis infections in turkeys have no public health significance.

History

In 1958, Adler *et al.* (4) were the first investigators to show that airsacculitis in poults hatched from infected eggs could be associated with a mycoplasma other than *M. gallisepticum*. The mycoplasma, later named *M. meleagridis*, was isolated from the air sac lesions of poults originating from 8 breeding flocks from 4 states. The clinical syndrome of airsacculitis and/or associated skeletal abnormalities has been called day-old type airsacculitis (81), airsacculitis deficiency syndrome (113), and turkey syndrome-65 (TS-65) (143).

Etiology

Classification
M. meleagridis (153) was designated as the N strain by Adler *et al.* (4) and placed in the H serotype by Kleckner (73), Yoder and Hofstad (169), and Dierks *et al.* (35).

Morphology and Staining
Giemsa-stained smears of broth cultures of MM show coccoid bodies approximately 0.4 μm in diameter, similar to those of *M. gallisepticum* (153, 169). They appear singly, in pairs, or in small clusters. Ultrastructure studies (140) showed that MM did not possess bleb structures typical of *M. gallisepticum*, but had thicker fibrils in the central nuclear area. In both species, ribosomes were distributed in uniform rings around the cell peripheries. Similar studies by others (60) revealed that the predominant morphotype of MM was a spherical form ranging from 200–700 nm in diameter. Other forms (chains of *Streptococcus*-like cells) suggested replication by binary fission. Similar forms, including short filaments, have been observed by scanning electron microscopy (68). An acidic mucopolysaccharide capsule was demonstrated. The DNA of type strain 17529 has a guanine and cytosine (GC) base composition of 27.0–28.1% and a genome size of $4.2 \pm 0.5 \times 10^8$ daltons, both figures being at the lower range exhibited by mycoplasma (5).

Growth Requirements
M. meleagridis is a facultative anaerobe. Growth is optimal at 37–38°C and slight at 40–42°C. Most isolates do not adapt readily to broth media (44, 148). Serum or serum fraction (Difco) is an essential ingredient for growth. Swine and horse sera are satisfactory, but chicken and turkey sera are not (148).

A number of media have been described for cultivation of MM (148). A satisfactory broth consists of mycoplasma broth powder (2.1%), yeast autolysate (1%), and heat-inactivated (56°C for 30 minutes) horse serum (15%) (98, 118, 153). For solid medium, Bacto agar (1.2%) is added to the formulation. The pH of the final medium is 7.5–7.8. Fresh yeast extract (48) may be substituted for the dehydrated product. Another commonly used medium is modified Frey's medium (49) described under "*Mycoplasma synoviae* Infection". A broth medium designated SP-4, containing cell culture medium components, also supports excellent growth of MM (44).

The fastidious nature of this organism is exemplified in the observation that from time to time, certain batches of media do not support growth of the organism. In such cases, the source of the problem often can be traced to any one of the ingredients, including the water, used in the medium.

Colonial Morphology
Colonies on agar medium after 2–3 days incubation appear small and flat (0.04–0.2 mm in diameter), with rough-appearing

centers of ill-defined nipples. Nippling of the colonies is more prominent in laboratory-adapted strains than in fresh isolates (153).

Biochemical Properties

The organism does not ferment dextrose or other carbohydrates or reduce tetrazolium salts (153, 169) but uses arginine (67), and has phosphatase activity (70). Horse erythrocytes incorporated into turkey meat infusion agar are hemolyzed by MM (169).

Susceptibility to Chemical and Physical Agents

Very little is known about susceptibility of MM to chemical and physical agents. It is assumed, however, that most chemical disinfectants would be effective against it (23).

In broth at pH 8.4–8.7, MM may survive up to 25–30 days at high titers, 10^7 colony-forming units (CFU)/ml (34). Freshly seeded cultures on agar will survive for at least 6 days at room temperature (72, 153). The organism survives for at least 6 hours in the air (9). *In vitro* inactivation of four strains of MM at 45°C varied from 6–24 hours, although at 47°C inactivation of two strains occurred between 40–120 minutes (89).

Isolates of MM may be maintained for at least 2 months by mincing colonies on agar in 3% sucrose and freezing at –20 to –70°C. Yoder and Hofstad (169) found broth-overlaid agar slant cultures to be viable after at least 2 years storage at –30°C. Lyophilized cultures remain viable indefinitely (149). The organism does not decline in substantial numbers in turkey semen during cryopreservation and subsequent thawing (46).

Antigenic Structure

M. meleagridis is antigenically unrelated to all other avian mycoplasmas. Use of hyperimmune polyclonal rabbit antiserum as well as monoclonal antibodies raised against MM shows antigen heterogeneity among strains. Moreover, analysis of epitopes with monoclonal antibodies reveals that, as for other mycoplasma species, some epitopes are not expressed in all strains (2, 36). The agglutination (4, 169), fluorescent antibody (FA) (31), antiglobulin (3), growth and metabolic inhibition (35, 44, 90, 108), and complement fixation (50, 106) tests have been used to identify MM.

A few isolates possess hemagglutination activity (119, 139, 153). When hemagglutinating and nonhemagglutinating strains of MM were compared by polyacrylamide gel electrophoresis and simple and two-dimensional immunoelectrophoresis, minor antigenic differences were observed in the latter test only (44). Rhoades (123) showed that the determinant group(s) responsible for hemagglutination differed from that of agglutination.

The organism possesses a heat-stable lipid or polysaccharide toxin that causes an increase in ceruloplasmin activity when injected intravenously into chickens (33). The relationship of this toxin to the capsular material described by Green and Hanson (60) and to hemagglutinating activity is not known. However, hemagglutinating activity is not an essential component for virulence, because strains lacking this activity may be highly pathogenic (153, 164).

Strain Classification

Pathogenic and nonpathogenic strains of MM were described by Ghazikhanian and Yamamoto (54, 55). Of three strains studied, one failed to multiply *in vivo*, another multiplied but failed to produce lesions, although the third multiplied and produced airsacculitis. Zhao *et al.* (172) showed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) that these strains differed in their cell protein profiles. Strain variations may account for the variability in clinical manifestations attributed to this organism (42).

Experimental infection of turkey embryos and tracheal explants with MM results in deciliation and sloughing of epithelial cells (83). When inoculated into the allantoic cavity of 17-day-old turkey embryos, MM induced curved toes and histological studies including scanning electron microscopy, immunohistochemistry, laser capture microdissection and PCR revealed fissures in the cartilage, cellular infiltration within the bones and the presence of MM in tarsometatarsal affected joints (85). MM was also found to cause alterations to the cellular surface topology and necrosis on the surface of the eggshell membranes (84).

Pathobiology and Epidemiology

Incidence and Distribution

Early studies showed that MM was a common pathogen of turkeys with a worldwide distribution (4, 10, 61, 91, 116, 127, 135, 142, 143). These prevalence studies, together with the knowledge that MM was transmitted through the egg, led major primary breeders in the mid-1970s to initiate programs to eradicate the agent from their stocks (60). With the success of these programs, the prevalence of MM has been reduced significantly within the past 20 years in the major turkey-producing areas in the world (see "Eradication").

Natural and Experimental Hosts

M. meleagridis is a specific pathogen of turkeys. When injected into turkey embryos by the yolk sac route, the organism produces a high incidence of airsacculitis but causes minimal mortality (150). The high infectivity and low mortality caused by MM in turkey embryos under experimental and natural conditions indicates that it has attained an ideal host-parasite relationship.

When inoculated into the yolk sac of chicken embryos, MM multiplies to high titers without causing high mortality (158, 169), but abnormally shaped toes and severely denuded tracheae may be observed (82). Turkeys of all ages are susceptible to air sac infection with MM when inoculated via the air sac or trachea (79, 99, 152). Chickens are refractory to infection with MM (2, 151). MM was reported to have been isolated from free-ranging birds of prey in Germany (88) and found to infect peafowl, pigeons and quails (66). Antibodies were also detected in lesser prairie-chickens (62).

Transmission

Vertical Transmission

M. meleagridis is perpetuated primarily through egg transmission. Infection of the female reproductive tract occurs as an endogenous infection during embryonic development (93), as an

ascending infection from foci in the cloaca or bursa of Fabricius after the occluding plate is perforated at sexual maturity (92), or by insemination of hens with MM-containing semen (79, 98, 100, 155, 161). Infection rates of 19–57% have been found in flocks in which cultures were taken from the vagina of virgin females. Although such hens contribute to the overall egg-transmission rate, particularly when the incidence is high, insemination with mycoplasma-contaminated semen plays a major role in sustaining the egg-transmission rate during the laying season (75, 79, 162). The egg-transmission rate among individual hens may vary from 10–60% (155). Apparently, however, no regular pattern exists as to the sequence of infected eggs laid (98). Transmission starts out at a low rate during the first 2–3 weeks of lay, reaches a maximum at midseason, and gradually declines toward the end of the laying season (14, 79). There seems to be some intracyclic fluctuation in the transmission pattern during the laying season (79, 162), but it has not been possible to relate such changes to the insemination schedule.

Egg transmission does not occur in hens in which the organism is found only in the upper respiratory tract (sinus) (79, 98, 147) and is minimal in hens infected via air sac and subsequently inseminated with clean semen (79).

A comparative study of persistence of MM, *M. synoviae*, and *M. gallisepticum* in the genitalia of adult turkeys indicated that MM favored this environment more than the others (147).

Although the exact site in the reproductive system where the organism infects the developing egg is not known, it appears not to be in the ovary; several studies have generally failed to yield the organism from the ova of hens known to be transmitting the organism through their eggs (98, 147, 155). Furthermore, egg transmission occurs at a high rate in the absence of active abdominal airsacculitis.

The organism has been recovered from various sites of the oviduct, with the greatest frequency from the vagina and uterus (100, 155). In hens repeatedly inseminated with MM-contaminated semen, high levels of infection in the uterovaginal region were not sustained, although such hens did transmit the organism through their eggs (149). In hens inseminated with contaminated semen, the organism was found as high as the magnum (79). The organism has been isolated from the shell membrane and vitelline membrane-yolk of preincubated eggs from naturally infected turkeys, but at higher rates from the latter (10–12%) than former (2–4%) sites (57). Mycoplasma counts of 10^3 to 10^5 CFU/vitelline membrane have been obtained (149). Thus, although the organism has the potential to infect the developing egg at various sites in the oviduct, the critical site appears to be in the area of the fimbria or magnum.

As is the case with the female, cloacal infection detected in the male at the time of hatch can persist through sexual maturity; semen taken from such males will contain the organism (147, 167). The organism remains localized in the cloaca and phallus and does not ascend the vas deferens or testes (118, 147). Isolation rates of MM from the phallus or semen of naturally infected male flocks have ranged from 13–32%. Histologic study of the phallus and accessory organs suggests that a possible site of localization is the region of the submucosal gland (52).

Horizontal Transmission

Direct and indirect transmission of MM may occur at any stage of the bird's life. Direct transmission by the airborne route may occur within a hatchery (79) or flock (160), or on occasion between flocks separated by 1/4 mile (57). Airborne transmission in mature turkeys usually results in a high infection rate (up to 100%), which remains localized in the sinus and trachea (79, 98). In young birds during the brooding and growing periods, however, the organism may localize in the genitalia of approximately 5% of the birds infected by the respiratory route (160).

Indirect transmission results from management practices including sexing, vaginal palpation, artificial insemination, and vaccination whereby mycoplasmas are carried manually from infected to noninfected turkeys via contaminated hands, clothing, and equipment (57, 98).

Airborne transmission apparently is of little significance after a bird has reached sexual maturity. Thus, egg transmission does not occur in noninfected females that have been placed in cages adjacent to infected females. Similarly, clean males held in the same room with phallus-infected males produce MM-free semen throughout the production period (147, 149).

Clinical Signs

Despite a high rate of airsacculitis in poults originating from infected dams, respiratory signs are rarely observed. Lateral transmission that may occur by direct or indirect means in adult birds may lead to a high infection rate, but rarely to clinical disease. Thus, *M. meleagridis* commonly occurs as a silent infection in adult birds.

Although not a consistent feature of the disease, the syndrome called TS-65 (also called airsacculitis deficiency syndrome) may be associated with MM egg-borne infection (59). The syndrome, which includes signs of bowing, twisting, and shortening of the tarsometatarsal bone and hock joint swelling, has been reproduced experimentally in MM-free poults (15, 105, 145, 146, 156). Deformation of cervical vertebrae (24, 101), stunting, and abnormal feathering (15) are additional features of the disease.

M. meleagridis acts synergistically in producing severe airsacculitis with *M. iowae* (126) and sinusitis with *M. synoviae* (117). In a flock naturally infected with MM and *M. synoviae*, sinusitis was estimated to be 2.1% in males and 0.13% in females (117). Although it is generally believed that neither agent alone is capable of producing sinusitis, field cases have been encountered in which only MM has been isolated from sinus exudate.

Morbidity and Mortality

Reproductive Performance. M. meleagridis does not adversely affect egg production or fertility and does not cause early incubation mortality (30, 159). It causes late incubation (25–28 days) mortality in artificially (26, 159) and naturally (38) infected turkey embryos. It has been estimated that MM causes a loss in hatchability of 5–6% of fertile eggs set under commercial conditions (41). Edson (38), using risk analysis, determined the mortality rates of embryos naturally infected with MM and/or an unidentified mycoplasma. The analysis showed that embryos infected with MM, unidentified mycoplasma, and both agents were

5, 7, and 25 times more likely to die than the mycoplasma-free embryos. The unidentified mycoplasma was later identified as *M. iowae* (149), a common mycoplasma of turkeys known to reduce hatchability (125).

Air Sac Lesions and Condemnations. During the mid-1960s, MM-associated airsacculitis was reported to be one of the major causes of condemnation of fryer-roaster turkeys in the United States (6, 78). Air sac lesion rates of 10–25% in first-run poults from MM-infected flocks over a season's production were reported under experimental and commercial conditions (47, 79, 98, 155).

Because air sac lesions caused by uncomplicated MM infection regress within 15–16 weeks (10, 167), it appears that other agents or factors may be involved in the overall picture. Anderson *et al.* (6) observed a twofold or greater increase in incidence of air sac lesions caused by MM in turkeys raised to 12 weeks of age in a high-dust environment.

Brown and Nestor (22) suggested that turkeys selected for low plasma ACTH following cold stress were more resistant to MM infection than those selected for high ACTH levels. Saif *et al.* (131) reproduced complicated airsacculitis with MM and *Escherichia coli* in poults. Mixed infections of MM and *M. iowae* also accentuate the severity of air sac lesions (126). Therefore, a number of interacting factors may aggravate MM-induced air sac lesions in young turkeys.

Skeletal Abnormalities and Growth Performance. In affected flocks, MM-associated skeletal abnormalities (i.e., TS-65 syndrome) may be observed in poults between 1–6 weeks of age (143). Five to 10% of the poults may show clinical signs, but on occasion the percentage may reach higher levels. Not all cases progress to an irreversible state (143). Incidence of the disease seems to increase with progression of the laying season. Mortality is due primarily to cannibalism of affected birds. The problem is not associated with a particular strain of bird, but the male seems to be more susceptible.

Peterson (112) found a positive association of skeletal lesions, airsacculitis, and high agglutination titers to MM in poults with the TS-65 syndrome, which supports the view that the syndrome is initiated by a generalized egg-borne infection (146). It was further hypothesized, based on *in vitro* and *in vivo* studies, that the organism may deprive the embryo of biotin, resulting in abnormal bone development (15, 17). Others have postulated that the organism may compete for arginine, an essential amino acid for proper bone development (156). *In vitro* studies indicated, however, that MM strains of varying virulence did not differ in their arginine requirement; also, significant differences in plasma arginine concentration between noninfected and infected poults with leg abnormalities were not observed (67).

Nelson *et al.* (105) distributed MM-free and MM-infected eggs in large numbers to 11 cooperators in 8 states to study the leg weakness syndrome under commercial conditions. The results indicated that the total daily mortality, number of cull poults, and skeletal deformity were much lower in poults hatched from MM-free eggs. A significant advantage in weight gain was also observed with MM-free vs. infected poults (13, 107, 143).
21.5.   Airsacculitis in a 4-week-old turkey caused by eggborne *Mycoplasma meleagridis* infection.

Conversely, others (25, 28, 29) were unable to demonstrate any economic advantage of MM-free over MM-infected turkeys. Possible reasons for the divergent results are not clear, but factors such as differences in the genetic makeup of the bird, virulence of MM strains, environmental stresses, and secondary infections may influence the picture.

Pathology
Gross
Although gross lesions, if any, in poults at time of hatch from infected dams are limited to the air sacs, the organism may be widely distributed in various tissues including feathers, skin, sinus, trachea, lungs, air sacs, bursa of Fabricius, intestine, cloaca (12, 115, 121), and hock joints (149). The air sac lesions are characterized by thickening of the air sac walls with adherence of a yellow exudate to the tissue and, occasionally, presence of variously sized flecks of caseous material free in the lumen (4). Extension of such lesions to the abdominal air sacs is a common occurrence by 3–4 weeks of age. It is also possible for the organism to be present in air sacs of day-old poults exhibiting no lesions; in such cases, air sac lesions may develop in 3–5 weeks (10). Lesions produced by MM when not mixed with *M. iowae* are not as extensive or fulminating as those described for *M. gallisepticum* (35, 81). Figure 21.5 shows a poult, hatched from an MM-infected egg, with caseopurulent airsacculitis.

Skeletal lesions, when present, usually are associated with severe airsacculitis (112). Sternal bursitis (152), synovitis (131), and ascites (145) are additional lesions observed in experimental infections. The sinusitis produced by MM and *M. synoviae* in mixed infections contains clear mucous to caseous exudate (117). Leg abnormalities in poults hatched from MM-infected eggs are shown in Figure 21.6.

21.6. Bowing of tarsometatarsal bones of a 3-week-old turkey hatched from a *Mycoplasma meleagridis*-infected egg.

Microscopic

In embryonic infection with MM, exudative airsacculitis and pneumonia were the only inflammatory lesions seen. Lesions that developed at 25–28 days of age were related to maturation of inflammatory cells. Air sac lesions consisted predominantly of heterophils with some mononuclear cells, including lymphocytes and varying amounts of fibrin and cellular debris. Epithelial necrosis was seen in severely affected air sacs. Mononuclear cells and fibrin were the prominent features of lung lesions (55, 121). Significant or marked microscopic changes in other organs in embryos or poults were not observed despite invasion of the organism into many of these sites (55).

In 7-week-old poults infected with MM by the air sac route, lymphocytic perivascular infiltration and fibrinoheterophilic exudate were observed in 2 days. Some areas of the air sac epithelium became hyperplastic and others underwent necrosis at about 4–8 days. Lymphoid follicles were observed in 16 days. When examined by electron microscopy, the follicles were found to be surrounded by encapsulated collagen bundles and composed of hemocytoblasts of bursal origin presumed to be involved in antibody formation (120). Others observed similar sequential changes in poults infected as embryos or at 1–3 days of age (7, 55, 102).

Wise *et al.* (143) indicated that gross and microscopic long-bone lesions of TS-65 were similar to those observed in perosis of dietetic origin. The main lesions were seen in proximal ends of the long bones. Cartilage farthest from blood vessels descending into the proliferative zone from the cartilaginous epiphysis lacked cell density and contained abnormal-appearing chondrocytes. In long-standing cases of 6–8 weeks or longer, growth plates often were normal, suggestive of repair, even though the bones were grossly deformed. These cellular changes in the proliferative zone of the growth plates were seen in all long bones examined, suggestive of

a generalized response. It was postulated that MM causes a secondary block of nutrients to the growth plates.

A secondary lesion in the medial side of the proximal end of the tarsometatarsal bone of chronic cases with varus deformity was described as a dyschondroplasia or chondrodystrophy resulting from partial failure of the metaphyseal blood supply at the growth plates (143).

Mild mononuclear cell infiltration was observed in the periarticular region of the hock joint in 2-week-old poults inoculated with MM intravenously (114).

The most prominent lesion in hens infected by the vaginal route was focal encapsulated accumulation of lymphocytes present most frequently in the fimbria, uterus, and vagina. Plasma cells and heterophils were also present in significant numbers in the lamina propria of the reproductive tract. The encapsulated follicles were believed to be active in antibody formation (122). Similar lesions in the reproductive tract of turkeys infected with MM were described by Ball *et al.* (8).

Gerlach *et al.* (52) examined histologically the phallus and accessory structures of males experimentally infected with MM. The only significant change was an extensive lymphofollicular formation in the region of the mucous-type glands in the submucosa of the lymphfold.

Immunity

Active

Turkeys inoculated intravenously or by the respiratory route with MM were resistant to reinfection when challenged by the same routes 21 weeks later. There was no correlation, however, between antibody titer and resistance (99). Repeated injections of 20-week-old hens with live organisms failed to induce protective immunity or reduce egg transmission (141).

When hens that had been vaginally infected artificially with MM culture or with contaminated semen were subsequently inseminated with clean semen, the organism was eliminated from the vagina within 4–14 weeks, although hens continuously inseminated with contaminated semen maintained a high incidence of infection (75, 79). However, insemination with clean semen of virgin hens known to be vaginal carriers of MM resulted in a high egg-transmission rate and persistence of oviduct infection (38, 162). In the first-mentioned studies, it appears that an active immune mechanism was functioning to eliminate the organism after removal of the source of infection, i.e., contaminated semen. Persistence of infection in the latter study may be an expression of immune tolerance in hens infected by egg transmission.

Yamamoto *et al.* (166) found that hens infected with MM via the oviduct during one breeding season were free of MM at the start of the second laying season; among five adult males infected via the phallus, the organism persisted for 55–344 days. These findings are consistent with the observation that the decline in the egg-transmission rate during the latter part of the laying season may be related to an active immune response. A study by Ortiz *et al.* (109) suggested that MM infection of the bursa of Fabricius during embryonic development causes an impairment of the secondary antibody response to innate or inactivated antigens.

Passive

Maternal antibodies (agglutinins) may be detected in a high percentage of poults from infected dams, and persist for approximately 2 weeks post-hatching. Such antibodies are not protective against the development of air sac lesions in infected embryos (99, 155). Conversely, purified IgM and IgG antibodies when injected into the yolk sac of infected embryos significantly reduced embryo mortality and the incidence of leg deformities in hatched poults, but they did not reduce air sac lesions or isolation rates when compared with the controls (18).

Diagnosis

Isolation and Identification of Causative Agent

Bacterial Isolation and Identification

M. meleagridis may be isolated readily on several commercially available and laboratory-prepared media (see "Growth Requirements"). Thallium acetate (1:4000) and penicillin (1000 units/ml) are inhibitors added to agar plates, slants, and broth. Polymyxin B (100 units/ml) may be added to the broth portion of the overlay to facilitate isolation of MM from highly contaminated sources such as the cloaca and phallus. Mycostatin (50 units/ml) may be added to the agar and broth to inhibit fungi (100). *M. meleagridis* may be selectively isolated from specimens containing mixed cultures by adding to the medium immune serum against the undesired mycoplasma (20). The organism may be isolated from vitelline membrane, air sacs, intestine, and many other sites of infected embryos (see "Pathology, Gross"). It may also be isolated from the kidneys of poults infected by the air sac route (145).

For large sampling studies in the field (e.g., cultures from the trachea, palatine cleft, vagina, or phallus), placing swab specimens in overlay broth (4) facilitates transport to the laboratory; the broth also serves as an initial enrichment (110). At necropsy, the organism may be isolated from various sites of the respiratory (including sinus) and reproductive systems.

When growth is apparent in the original isolation medium, usually after 4–6 days of incubation, agar plates are streaked and placed in a sealed container with added moisture. Plates are incubated at 37°C for 5–7 days before being examined for colonies under the dissecting microscope, and are incubated at least 10 days before being discarded as negative.

M. meleagridis may be differentiated from other chicken and turkey mycoplasmas by its inability to utilize glucose and its ability to metabolize arginine and phosphate (67, 70, 135, 169). Definitive identification, however, must be based on serologic methods. The direct (31) and indirect (20) FA, growth inhibition (35), and immunoperoxidase (69, 134) tests are commonly used for this purpose. In addition, an antigen-capture ELISA has been developed for detection of mycoplasma antigen directly in broth culture (1).

Antigen Detection

DNA-based tests have recently been developed for the direct detection of the organism in clinical specimens (19, 45, 51, 86, 96, 97, 170, 171). Main advantages of PCR-based methods are their rapidity and their ability to detect MM within a high background flora as in the case of cloacal swabs or from samples collected on antibiotic-treated birds.

Serology

The rapid plate (RP) and tube agglutination (TA) tests are effective in detecting MM infections. Antibodies are detected in poults hatched from infected eggs in 3 weeks and in turkeys infected by contact in 4–5 weeks. Birds with active air sac lesions may have high agglutinin titers, and those with localized infections in the sinus or phallus may be negative or show low titers (2, 99, 167). The RP test may be quantified by performing it on serially diluted serums. A reaction at a dilution of 1:5 is significant (164, 167), but for flock diagnosis, some samples should react at 1:10 or higher. Each lot of antigen should be pretested with a standard positive serum for its reactive quality at higher serum dilutions.

The hemagglutination-inhibition (HI) test (119, 139) is another useful test for detecting antibodies to MM infections. Although nonhemagglutinating laboratory strains of MM do not elicit high HI antibody responses in turkeys, the HI test is very effective in detecting such antibodies in naturally infected birds (123). Apparently, field infections with MM occur with strains possessing hemagglutinating activity, but this characteristic is quickly lost for most strains when they are cultivated on laboratory media (123). Furthermore, because the antigenic determinant(s) responsible for hemagglutination differs from that of agglutination (123), it is possible to find individual turkeys in an infected flock whose serum will be positive in the HI and negative in the TA tests; the reverse situation may also occur (164).

Yamamoto *et al.* (164) adapted the HI test to the microtest system. Using four units of antigen, titers of 1:40 were considered suspects and 1:80 or greater as reactors. When used as a confirmatory test to the RP test, a positive HI signifies infection, although a negative HI requires a more conservative interpretation and may involve use of other confirmatory tests or follow-up testing for final diagnosis (165). The micro-HI test has been used to identify false-positive RP reactions (149) in flocks recently vaccinated with *Erysipelothrix* vaccine (16).

Kleven and Pomeroy (74) found that the RP test detected IgM; the TA test detected both IgM and IgG; and the HI test detected IgG most efficiently. However, the early HI antibody response of turkeys to high doses of MM given intravenously was of the IgM class (124).

Other tests developed for mass screening are the microagglutination (157), indirect or blocking enzyme-linked immunosorbent assay (ELISA) (37, 111), and avidin-biotin enhanced dot-immunobinding assay (32).

Differential Diagnosis

Air sac lesions caused by MM must be differentiated from those caused by *M. gallisepticum*, other Mycoplasma serotypes, and possibly other agents. The possibility of a mixed infection of MM with *M. synoviae* or *M. iowae* should be considered if embryo mortality, sinusitis, or airsacculitis is observed. *M. meleagridis*-associated skeletal abnormalities must be differentiated from similar lesions caused by *M. iowae* or of dietetic origin.

Intervention Strategies

Management Procedures

Although early studies placed much emphasis on the control of MM infections in turkeys by use of various antibiotic treatment regimens (see "Treatment"), the goal of primary breeder organizations was to eradicate the agent from their stocks. Because virtually all breeding stocks were infected, a program of test and slaughter—which had been so effective in the control of *M. gallisepticum*—was not a practical approach for eradicating MM (163). Experimental studies demonstrated that the administration of antibiotics into eggs either by dipping or by inoculation into the air cell (65) or the small end (43, 94, 95) were useful methods to reduce the egg-transmission rate. Heat treatment of eggs (168) was not effective in eliminating MM from turkey eggs (61, 71, 143). Tylosin (76) or gentamicin (129) was not effective, but spectinomycin (0.6 mg/ml of diluent) (128) was effective in eliminating MM from turkey semen. These studies laid the foundation for effective eradication programs that followed.

Eradication

The basic principles and procedures for producing MM-free breeders include: 1) reduction of genital infection to minimal levels by serology and culture. The egg-transmission rate can be reduced significantly by using males that are not genital carriers. Males that yield three consecutive negative cultures from the phallus or semen are usually free of infection. Eliminating vaginal carriers can reduce the infection rate even further. Even a single sampling will identify most carriers. Cultures from males are taken a few weeks before their use as breeders, and those from females are taken from the cloaca before or from the vagina during egg production. Special care must be taken to prevent cross-contamination when specimens are taken for culture or during insemination (39). 2) Treatment of eggs with an effective antibiotic(s) by dipping and/or injection. Because these procedures may reduce hatchability by 10% or more, pretrials should be conducted before embarking on a large program. The possibility of developing antibiotic resistant strains of MM should be kept in mind, particularly at the primary breeder level where treated birds must be recycled in the operation (53, 95, 146). 3) Hatching of eggs in MM-free hatchers and isolation rearing of the turkeys. Because MM can be introduced onto a farm in a number of ways (see "Transmission") and usually occurs as an unapparent infection, it is essential that a high level of biosecurity be maintained. 4) Serologic and cultural monitoring of the treated flock at 16 weeks of age and periodic intervals thereafter, and elimination of infected groups.

Using the principles just outlined, MM-free turkeys have been produced experimentally (147) and commercially (56, 57, 80, 107, 144). A treatment regimen that was used to eradicate MM from a primary breeder organization consisted of dipping eggs in a solution of gentamicin sulfate (750–900 ppm) followed by injection with a solution containing 0.6 mg gentamicin and 2.4 mg tylosin/dose into the small end of the egg (57).

Edson *et al.* (40) developed an equation based on the Poisson distribution to predict the chance of success of eradicating MM:

$p(0) = e^{-na\beta h}$, where the probability of success $p(0)$ was described by n, the number of eggs treated; a, the pretreatment infection rate of the eggs; β, the treatment failure rate; and h, the hatchability of treated eggs. Decreasing the size of any or all of the four parameters increases the likelihood of eradication. This predictive equation is a useful quantitative tool for management decision-making. Currently, the primary breeder organizations that are the major genetic source for commercial turkeys worldwide are free of MM.

An economic decision analysis was described by Carpenter *et al.* (27) to assist commercial multiplier breeders to determine the economic advantage of eradicating MM.

A program for certifying freedom from MM infection of turkey breeding stocks under the National Poultry Improvement Plan (NPIP) was initiated on January 1, 1983 (133). According to the 2005 NPIP testing summary, 98.3% of 579 multiplier breeder flocks representing 4.5 million breeders qualified as "U.S. MM Clean" (103). These data and an industry-based survey conducted in 1994 suggest that significant progress has been made in reducing the prevalence of MM in the turkey industry because MM-free stock first became available in the early 1980s (57, 58, 77). Similarly, a very low prevalence of MM infections is observed in European breeder and meat flocks. In the European Community, disease surveillance programs provided in the Council Directive 90/539/EEC on health conditions governing intra-Community trade in, and imports from, third world countries of poultry and hatching eggs, include MM in turkeys.

Vaccination

Vaccines are not available for prevention of MM infection in turkeys.

Treatment

Antibiotics having *in vitro* activity against MM include gentamicin (130), tylosin, tetracycline (154), spectinomycin-lincomycin (63), tiamulin, spectinomycin and spiramycin (87), doxycycline and the fluoroquinolones (138), and josamycin (136). In trials conducted with turkey embryos, tylosin was the most active; tetracycline, chlortetracycline, and streptomycin were variable; and erythromycin showed no activity against two isolates of MM (154).

A combination of lincomycin and spectinomycin administered at 2 g/gal of water for 5 days (64) or tiamulin at a concentration of 0.025% in the drinking water for 3 days (137) had therapeutic activity against MM infections. Enrofloxacin was effective in reducing mortality of poults having complicated MM infections (21). Parenteral injections or water medication with tylosin of turkeys in production did not reduce egg transmission (14, 78). Dipping of hatching eggs in antibiotic solution, however, significantly reduced the incidence of air sac infection (11, 78, 112, 132) concomitant with improved hatchability (78, 132), improved performance (11, 104), reduced incidence of skeletal deformities (104, 112), and reduced condemnation at processing (78, 104).

During the late 1960s to early 1980s, before MM-free eggs and poults were available, it was a common practice for multiplier breeders to dip their eggs in antibiotic solution. Tylosin (3000

ppm) or gentamicin (500 ppm) along with a disinfectant such as quaternary ammonium compound (250 ppm) were used in dip solutions. However, repeated hatching egg dipping in antibiotics to reduce the incidence of MM infection could lead to induction of antibiotic-resistant organisms (53). Eradication of MM from major primary breeding companies has reduced the practice of hatching egg dipping in antibiotics by the commercial industry and currently, most major U.S. multiplier breeder companies dip their eggs only when faced with a potential MM outbreak.

Mycoplasma synoviae Infection

Stanley H. Kleven and Naola Ferguson-Noel

Introduction

Mycoplasma synoviae (MS) infection most frequently occurs as a subclinical upper respiratory infection. It may cause air sac lesions when combined with Newcastle disease (ND), infectious bronchitis (IB), or both. At other times, MS becomes systemic and results in infectious synovitis, an acute to chronic infectious disease of chickens and turkeys, involving primarily the synovial membranes of joints and tendon sheaths producing an exudative synovitis, tenovaginitis, or bursitis.

History

Infectious synovitis was first described and associated with a mycoplasma by Olson *et al.* (114, 115). A respiratory form of *M. synoviae* infection occurs (117) and air sac infection results with some isolates of MS when combined with ND and IB vaccination (77). See Jordan (64, 66) and Timms (143) for reviews of the MS literature.

Etiology

Classification

Mycoplasma colonies were observed as satellites adjacent to *Micrococcus* colonies by Chalquest and Fabricant (27), who identified the requirement for nicotinamide adenine dinucleotide (NAD). It was designated as serotype S by Dierks *et al.* (33). Olson *et al.* (118) studied several isolates and proposed the name *M. synoviae,* which was subsequently confirmed as a separate species (67).

Identification is based on typical colony and cell morphology,

biochemical characteristics, special requirements for growth, and serologic reactions. Immunofluorescence of mycoplasma colonies is the most rapid and reliable method for identification of field isolates. DNA sequence analysis of the 16S rRNA gene has proven to be useful for mycoplasma identification and in phylogenetic studies (153). The complete genome sequence of a strain of *M. synoviae* has been published (150).

Morphology and Staining

In Giemsa-stained preparations, *M. synoviae* cells appear as pleomorphic coccoid bodies approximately 0.2 μm in diameter. Ultrastructural studies of avian synovium reveal MS in endocytotic vesicles. The mycoplasma cells are round or pear shaped with granular ribosomes. They are 300–500 nm in diameter, lack a cell wall, and are bounded by a triple-layered unit membrane (151). An extracellular surface layer has been demonstrated by electron microscopy by ruthenium red and negative staining (1).

Growth Requirements

Nicotinamide adenine dinucleotide is required for growth (27); however, it may be possible to substitute nicotinamide for the more expensive NAD for production of antigens (32). Serum is essential for growth, and swine serum is preferred (28). Growth on agar is accomplished by incubation of plates in a closed container to prevent dehydration of the agar. The optimum temperature is 37°C.

Excellent growth is obtained using a modification of Frey's medium (44) (Table 21.2) or a medium described by Bradbury (20). For agar plates, use 1% of a purified agar such as ionagar #2, Noble agar, or Difco purified agar. All components except cysteine, NAD, serum, and penicillin may be sterilized by auto-

Table 21.2.   Modified Frey's medium.

Mycoplasma broth base (BBL)	22.5 g
Glucose	3 g
Swine serum	120 ml
Nicotinamide adenine dinucleotide (NAD)	0.1 g
Cysteine hydrochloride	0.1 g
Phenol red (1%)	2.5 ml
Thallium acetate (10%)*	5 ml
Potassium penicillin G*	1,000,000 units
Distilled H$_2$O	1000 ml
Adjust pH to 7.8 with 20% NaOH and filter sterilize.	

*For potentially contaminated specimens, an extra 20 ml of 1% thallium acetate and 2,000,000 units of penicillin per liter may be added. Ampicillin (200 mg/l to 1 g/l) may be substituted for penicillin.

claving at 121°C for 15 min. Cool to 50 C and aseptically add the above components, which have been sterilized by filtration and warmed to 50°C. Pour plates to a depth of approximately 5 mm. Phenol red may be eliminated from agar plates.

On primary isolation, tissue antigens, toxins, and antibodies may be present; therefore, a small inoculum, transferred within 24 hr, or making dilutions of the inoculum in broth may improve results. Transfers are made with a pipette using a 10% inoculum. Inoculation of broth medium with a cotton swab from the trachea, choanal cleft, or synovial or air sac lesion is satisfactory. Plain or charcoal cotton swabs are more effective than rayon swabs, and retaining the swab in the broth medium was more effective than discarding the swab (161), but leaving the swab in the growth medium may lead to increased bacterial contamination of cultures. Direct plating onto agar plates may result in colonies at 3–5 days of incubation, but isolation in broth is more sensitive. Broth cultures should be incubated until a color change of the phenol red indicator from red to orange or yellow is noted (usually after 3–7 days); the culture should then be transferred to an agar plate and subcultured into another broth culture. *M. synoviae* is sensitive to low pH; therefore, cultures incubated for more than a few hr after the phenol red indicator has changed to yellow (pH <6.8) may no longer be viable. Plates are observed for the presence of mycoplasma colonies after 3–5 days using a microscope with indirect or low-intensity lighting at a magnification of approximately ×30.

Colony Morphology

Colonies on solid media are best observed with a dissecting microscope at ×30 using indirect lighting; they appear as raised, round, slightly latticed colonies with or without centers. Colonies range from less than 1 to 3 mm in diameter, depending on number of colonies present, suitability of medium, and age of culture. Growth is seen on solid medium in 3–5 days.

Biochemical Properties

Biochemical characteristics of *M. synoviae* have been described (27, 33). *M. synoviae* ferments glucose and maltose with production of acid but not gas in suitably enriched media. It does not ferment lactose, dulcitol, salicin, or trehalose. *M. synoviae* is phosphatase negative and produces film and spots (67). Most isolates are capable of hemagglutinating chicken and turkey erythrocytes. Its ability to reduce tetrazolium salts is very limited.

Susceptibility to Chemical and Physical Agents

Resistance to disinfectants has not been determined but is probably similar to other mycoplasmas. Day-old chicks placed in contaminated chicken houses which had been cleaned and disinfected and maintained empty for 1 wk did not become infected (45). *M. synoviae* is not stable at pH 6.8 or lower. It is sensitive to temperatures above 39°C. It will withstand freezing; however, the titer is reduced. End points have not been reached, but in yolk material *M. synoviae* is viable at least 7 yr at –63°C and after 2 yr at –20°C. Broth cultures maintained frozen at –70°C or lyophilized cultures maintained at 4°C are viable for several years. Survival occurred up to 3 days at room temperature on feathers and up to 12 hr in the nasal cavity of a volunteer, while survival was less than 1 day on most other materials (30). MS was also detected in environmental samples, including feathers, dust, feed, drinking water, and droppings by culture and by PCR (97). A reverse transcriptase PCR detecting 16srDNA was correlated with viable MS organisms in the environment of infected birds. Positive RT-PCR and culturable MS organisms were found in the environment of a depopulated isolator unit for 3–5 days after depopulation of MS-infected chickens (99).

Antigenic Structure

Serum plate agglutination (SPA) (116), tube agglutination (TA) (147), hemagglutination (16, 146), agar gel precipitin (AGP) (134), and enzyme-linked immunosorbent assay (ELISA) (55, 123, 126) antigens have been studied. Studies utilizing Western blots have characterized the major immunogenic membrane antigens of MS (4, 5). A major immunogenic protein, p41, showed promise as an antigen in a dot ELISA, while p53 and p22 did not perform well (4). The molecular size of the major membrane proteins varied among MS strains (5).

Serum from chickens infected with MS occasionally agglutinates *M. gallisepticum* plate antigen (118, 119). Roberts and Olesiuk (133) suggested that the cross-reactions were related to presence of rheumatoid factor and could be stimulated by tissue reactions. Cross-reactions are minimal when the hemagglutination inhibition (HI) or TA test is used. There are also epitopes shared by *M. gallisepticum* and MS (3, 160). Species-specific monoclonal antibodies against MS have been produced (59). Immunoglobulin G Fc receptors have been identified (85).

A cluster of 45–50 kDa surface proteins is immunodominant in strain WVU-1853 (108); they are size and expression variable and fall into two groups, MSPA and MSPB, which are both associated with hemadsorption, which is also variably expressed. MSPA was shown to be a hemagglutinin. These proteins are coded by a single gene, *vlhA* (14, 109), the product of which is then cleaved to form MSPB and MSPA. This gene has a high degree of identity with the *pMGA*1.7 gene of *M. gallisepticum* and hybridizes with other areas of the genome, suggesting that it is

part of a multi-gene family. Variability in expression of *vlhA* is controlled by homologous recombination events with pseudogenes located in other parts of the genome (2, 15, 61, 111). Cultures of the hemagglutinin negative phenotype expressed truncated versions of PMSB and were less pathogenic than hemagglutination positive cultures (105).

Strain Classification

Available information indicates a single serotype of *M. synoviae* (33, 118), and DNA-DNA hybridization techniques show little heterogeneity among MS strains (159, 160). *M. synoviae* strains can be differentiated using restriction endonuclease analysis of DNA (88, 102). A simpler more rapid procedure for differentiation of MS strains is the random amplified polymorphic DNA (RAPD) technique (37, 38), but results may be inconsistent. Pulsed field gel electrophoresis and amplified polymorphic DNA analysis have also been shown to be a valuable tool for discriminating among strains of *M. synoviae* (34, 38, 98). Sequencing of a portion of the *vlhA* gene, either from cultures or tissue samples, has been useful for partial characterization of *M. synoviae* strains (15, 57).

Virulence Factors

Little is known about virulence factors for MS. Differences in virulence could not be explained by potential virulence factors such as hemagglutination and hemadsorption, attachment to cells, or ciliostasis (91). However, the hemagglutination positive phenotype of MS induces infectious synovitis lesions more frequently than does the hemagglutinin negative phenotype (105).

Pathobiology and Epidemiology

Incidence and Distribution

Infectious synovitis was observed primarily in growing birds 4–12 wk of age in broiler-growing regions of the United States during the 1950s and 1960s. Since 1970s the synovitis form has been infrequently observed in chickens in the United States, but the respiratory form has been seen more frequently. Infection without apparent clinical signs is not unusual. *M. synoviae* infection occurs frequently in multi-age commercial layers (100, 122). Infectious synovitis usually appears in turkeys when they are 10–20 wk old. Breeding stock from all major commercial breeds of chickens and turkeys is largely free of infection. *M. synoviae* is worldwide in distribution.

Natural and Experimental Hosts

Chickens and turkeys are the natural hosts of *M. synoviae.* Ducks (10, 144), geese (9), guinea fowl (125), pigeons (8, 128), Japanese quail (8), pheasants (22), and red-legged partridge (127) have been found to be naturally infected. Pheasants and geese (22, 139), ducks (155), and budgerigars (18) are susceptible by artificial inoculation. *M. synoviae* was isolated from house sparrows (*Passer domesticus*) in Spain (127); Kleven and Fletcher (79) found that sparrows could be artificially infected, but were quite resistant. Rabbits, rats, guinea pigs, mice, pigs, and lambs are not susceptible to experimental inoculation (115).

Natural infection in chickens has been observed as early as 1 wk, but acute infection is generally seen when chickens are 4–16 wk old and turkeys are 10–24 wk old. Acute infection occasionally occurs in adult chickens. Chronic infection follows the acute phase and may persist for the life of the flock. The chronic stage may be seen at any age and in some flocks may not be preceded by an acute infection.

Airsacculitis occurs in day-old and older turkeys in MS-infected flocks. Air sac inoculation of mycoplasma-free turkeys results in airsacculitis (48, 131). Inoculation of 18-day-old chicken embryos via the yolk sac resulted in synovitis and airsacculitis in the chicks (19). *M. synoviae* may be isolated from lesions during the acute phase of the disease, but infection of the upper respiratory tract is permanent (77).

Transmission

Lateral transmission occurs readily by direct contact. *M. synoviae* has been demonstrated in the respiratory tract of contact control chickens 1–4 wk following infection of the principals (117). Spread between batteries in the same room occurs. In many respects, the spread appears to be similar to that of *M. gallisepticum* (120) except that it is more rapid. However, slow-spreading infections have been reported (152). Transmission occurs via the respiratory tract, and usually 100% of the birds become infected, although none or only a few develop joint lesions.

Infection has not been thought to occur as a result of environmental contamination after depopulation of infected premises, but in a recent study day-old chicks became infected after placing them in a contaminated environment, but evidence of infection was not seen until 33 to 54 days of age (99). Birds are infected for life and remain carriers.

Vertical transmission occurs in naturally and artificially infected chickens (25); however, many flocks hatched from infected dams remain free of infection. Vertical transmission plays a major role in spread of MS in chickens and turkeys. Thus, all eggs used for live virus vaccine production should be obtained from MS-free flocks. Experimental infection of broiler breeders resulted in MS infection in the trachea of day-old progeny, infertile eggs, and dead-in-shell embryos 6–31 days postinoculation (149). When commercial breeder flocks become infected during egg production, the egg-transmission rate appears to be highest during the first 4–6 wk after infection; transmission thereafter may cease, but infected flocks may shed at any time.

Incubation Period

Infectious synovitis has been seen in 6-day-old chicks, suggesting that the incubation period can be relatively short in birds infected by egg transmission. The incubation period following contact exposure is generally 11–21 days. Antibodies may be detected before clinical disease becomes evident. In birds experimentally infected by inoculation at 3–6 wk of age with joint exudate from infected birds or yolk from infected embryos, the order of susceptibility and incubation period is as follows: foot pad, 2–10 days; intravenous, 7–10 days; intracranial, 7–10 days; intraperitoneal, 7–14 days; intrasinus, 14–20 days; and conjunctival instillation, 20 days. Birds are also susceptible to intramus-

cular inoculation. Intratracheal inoculation results in infection of the trachea and sinus as early as 4 days and readily spreads to contact birds. Air sac lesions are at a maximum 17–21 days after aerosol challenge (77). The incubation period varies with titer and pathogenicity of the inoculum.

Clinical Signs
Chickens
The first observable signs in a flock affected with infectious synovitis are pale comb, lameness, and retarded growth. As the disease progresses, feathers become ruffled and the comb shrinks. In some cases, the comb is bluish red. Swellings usually occur around joints, and breast blisters are common. Hock joints and foot pads are principally involved, but in some birds most joints are affected; however, birds are occasionally found with a generalized infection but not with apparent swelling of the joints. Birds become listless, dehydrated, and emaciated. Although birds are severely affected, many continue to eat and drink if placed near feed and water. A greenish discoloration of droppings, which contain large amounts of uric acid or urates, is frequently seen. Acute signs described above are followed by slow recovery; however, synovitis may persist for the life of the flock. In other instances, the acute phase is absent or not noticed and only a few chronically infected birds are seen in a flock. Chickens infected via the respiratory tract may show slight rales in 4–6 days or may be asymptomatic. Chondrodystrophy was noted in the opposite leg of chickens inoculated via the foot pad. This may have been due to increased weight bearing stress on the leg opposite the affected leg (103).

Recent outbreaks of MS in brown egg layers in the Netherlands were associated with amyloid arthropathy, which was reproduced experimentally (82, 83, 84).

Air sac infection may occur at any age, but is most often observed as a cause of condemnation in broilers (75). Under field conditions, most air sac lesions resulting from *M. synoviae* infection occur in winter. Progeny of MS-infected breeders may have increased air sac condemnations, reduced weight gains, and reduced feed efficiency.

Experimental aerosol inoculation of hens with MS resulted in a detectable drop in egg production in 1 wk postchallenge; by 2 wk production dropped 18%, and by 4 wk production returned to normal (92). Challenge of commercial layers at 10 weeks of age did not result in egg production losses (24). With naturally occurring infection of adults, however, there is ordinarily little or no effect on egg production or egg quality (101, 122), although instances of egg production losses in commercial layers have been observed. However, challenged layer chickens were characterized by transient heterophilia, lymphopenia, monocytosis, eosinopenia, and basopenia (23).

Turkeys
M. synoviae generally causes the same type of signs in turkeys as in chickens. Lameness is the most prominent sign. Warm fluctuating swellings of one or more joints of lame birds are usually found. Occasionally, there is enlargement of the sternal bursa. Severely affected birds lose weight, but many less severely af-

fected make satisfactory weight gains when separated from the flock. In experimentally infected turkeys (115), the first noticeable sign is failure to grow.

Respiratory signs are not usually observed in turkeys, but MS has been isolated from sinus exudates obtained from turkey flocks exhibiting a very low incidence of sinusitis. Rhoades (130) described a synergistic effect of MS and *M. meleagridis* in producing sinusitis in turkeys. Foot pad inoculation of turkeys may result in total cessation of egg production. Challenge with field isolates of MS indicated that current strains are capable of reproducing synovitis in turkeys (69).

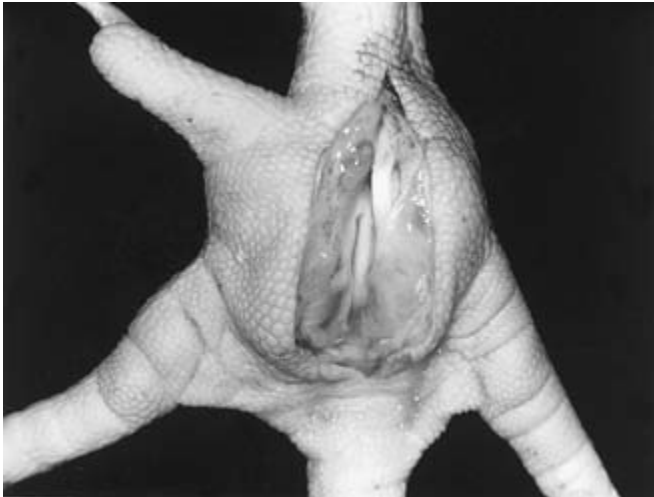
Morbidity and Mortality
Chickens. Morbidity in flocks with clinical synovitis varies from 2 to 75%, with 5–15% being most usual. Respiratory involvement is generally asymptomatic, but 90–100% of the birds may be infected. Mortality is usually less than 1%, ranging up to 10%. In experimentally infected chickens, mortality may vary from 0 to 100%, depending on route of inoculation and dose of inoculum.

Turkeys. Morbidity in infected flocks is usually low (1–20%), but mortality from trampling and cannibalism may be significant.

Pathology
Gross
Chickens. In early stages of the infectious synovitis form of the disease, chickens frequently have a viscous creamy to gray exudate involving synovial membranes of the tendon sheaths, joints, and keel bursa, and hepatosplenomegaly (Fig. 21.7). Kidneys are usually swollen, mottled, and pale. As the disease progresses caseous exudate may be found involving tendon sheaths, joints, and extending into muscle and air sacs. Articular surfaces, particularly of the hock and shoulder joints, become variably thinned to pitted over time (Fig. 21.8). Generally no gross lesions are seen in the upper respiratory tract. In the respiratory form of the disease, airsacculitis may be present.

Turkeys. Swellings of the joints may not be as prominent as in chickens, but fibrinopurulent exudate is frequently present when the joints are opened. Lesions in the respiratory tract are variable.

Microscopic
The histopathology of infectious synovitis (70, 73, 139) in chickens and respiratory disease caused by *M. synoviae* in chickens (43) and turkeys (48, 132) has been described.

The joints, particularly of the foot and hock, have an infiltrate of heterophils and fibrin into joint spaces and along tendon sheaths. The synovial membranes are hyperplastic with villous formation and a diffuse to nodular subsynovial infiltrate of lymphocytes and macrophages (Fig. 21.9). Cartilage surfaces, over time, become discolored, thinned, or pitted. Air sacs may have a mild lesion consisting of edema, capillary proliferation, and the accumulation of heterophils and necrotic debris on the surface, to more severe lesions with hyperplasia of epithelial cells, a diffuse infiltrate of mononuclear cells and caseous necrosis. Other lesions reported to be associated with infectious synovitis are hy-


21.7. Incised swollen foot pad of 8-week-old turkey with granulation tissue and purulent exudate surrounding digital flexors. Similar lesions can be seen in chickens.

21.8. Ulceration of articular surface of distal tibiotarsus from a chicken with infectious synovitis.

perplasia of the macrophage-monocyte system associated with the sheathed arteries of the spleen; lymphoid infiltrates in the heart, liver, and gizzard; and thymic and bursal atrophy. Cardiac pathology has been described in detail (72).

Pathogenesis of the Infectious Process

There is considerable variation among isolates in their ability to produce disease; many isolates cause little or no clinical disease. Although most recent isolates from the U.S. appear to be of relatively low virulence, clinical infectious synovitis has recently been reported in broilers in California (138). There have been numerous field reports of MS strains of high virulence in Mexico, Argentina, The Netherlands, and Eastern Europe. The pathogenicity and virulence of field isolates have been compared experimentally (56, 89, 103). Significant variability in virulence among strains was found, but no evidence was found for selective tropism for epithelial membranes of the lower respiratory tract to those of the joints, tendon sheaths,and bursae (56). These strains also showed differences in pathogenicity for chick embryos (90), but this did not correlate with virulence for chickens. Potential virulence factors such as hemagglutination and hemadsorption, attachment to cells, and ciliostasis were also studied. Previously found differences in virulence for chickens could not be explained by these factors (91). They concluded that pathogenicity involves attachment and colonization of the upper respiratory tract plus additional unidentified factors associated with systemic invasion and lesion production. Passage in embryos, tissue culture, or broth reduces its ability to produce typical infection. Embryo passage appears to have less effect on pathogenicity than broth passage.

M. synoviae isolated from air sac lesions are more apt to cause airsacculitis, while those isolated from synovia are more apt to produce synovitis (78). Airsacculitis is exacerbated by ND-IB vaccination (77, 140) or any respiratory infection. The severity of
21.9. Hyperplastic synovial membrane with multiple subsynovial lymphoid aggregates from a 7-week-old turkey with infectious synovitis.

the airsacculitis depends on the virulence of the infectious bronchitis virus used in conjunction with MS (58). Air sac lesions are greatly enhanced by cold environmental temperatures (157). Infectious bursal disease causes immunosuppression in chickens, and dual infection with MS results in more severe air sac lesions (49). However, no synergistic effects were seen with dual infections with avian pneumovirus (74) or with *Ornithobacterium rhinotracheale* (164). Nervous signs with lesions of meningeal vasculitis have been seen in MS-infected turkeys displaying severe synovitis (29).

Immunity

Chickens exposed intranasally to *M. synoviae* were resistant to subsequent foot pad challenge (117). Chickens immunized intranasally with a temperature-sensitive mutant of MS were protected against airsacculitis for at least 21 wk (107). Prior expo-

sure to MS-H, a temperature-sensitive mutant strain, protected against subsequent challenge with a virulent synovitis-producing field strain (137). Parenteral inoculation of MS frequently overwhelms the bird before adequate resistance can develop. Resistance to lesions induced by MS is bursa dependent (81, 148), while thymus-dependent lymphocytes may be needed for the development of macroscopic synovial lesions (81).

Diagnosis

Isolation and Identification

Positive diagnosis may be made by isolation and identification of *M. synoviae.* Isolation from lesions in acutely infected birds is not difficult, but in the chronic stages of infection viable organisms may be no longer present in lesions. Isolation from the upper respiratory tract is more reliable in chronically infected birds. (For medium and isolation methods, see Growth Requirements.) The fluorescent antibody technique using colony imprints (31) or intact colonies (142) may be used for the identification.

Direct detection of MS DNA in tissues or culture medium utilizing DNA probes has been described (7, 40, 60, 71, 162). It is a simple, rapid method of detection, but sensitivity may not be adequate. Polymerase chain reaction is a simple, rapid, and highly sensitive method of detection of MS DNA in tissues or culture medium (46, 86, 136, 163), and PCR kits (145) are commercially available. The PCR procedures are comparable in sensitivity to isolation and identification (135).

Serology

Antigen is available commercially for the serum plate agglutination (SPA) test. Adequate directions for use are given with each package. Generally 0.02 ml serum is mixed with an equal amount of antigen on a glass plate, which is gently rotated and observed for agglutination. Antigen should be tested with known positive and negative serums each day. Approximately 2–4 wk are required for antibodies to develop in infected birds (116). The SPA test may be insensitive in some instances; Ewing *et al.* (35) reported that the SPA test missed infected commercial layer and breeder flocks that were detected by ELISA.

Nonspecific reactors occur in some flocks when using the SPA test (50, 158), especially in flocks that have been vaccinated with oil emulsion vaccines against various agents. *M. gallisepticum* antigen may be agglutinated on occasion, but reaction is somewhat delayed and usually lower in titer (119). To confirm specificity of the reaction, the HI test is used (146). In a comparison of diagnostic tests for MS, all serological procedures studied exhibited some false-positive activity (39). They concluded that it is not advisable to rely completely on any single serological procedure. In another comparison of diagnostic procedures, PCR was found to be more sensitive than either serology or culture (41).

An indirect immunoperoxidase test utilizing intact *Mycoplasma* colonies as substrate has been utilized to detect antibodies in serum, respiratory secretions, synovial fluids, bile, Harderian gland, oviduct, and yolk (11, 12, 13).

Enzyme-linked immunosorbent assay (ELISA) (55, 123, 126)

is commonly used as a diagnostic test and for routine testing of flocks, and may replace serum plate agglutination as the primary serologic test. ELISA kits are available commercially. A semi-purified preparation containing antigens in the p46–52 region showed promise as an ELISA antigen (51). A recombinant antigen containing a highly antigenic domain of MSPB (108) has potential as a serodiagnostic reagent (110). The recombinant MSPB antigen from vaccine strain MS-H was more efficient in detecting antibodies in vaccinated chickens than was a similar antigen prepared from strain WVU 1853, suggesting some antigenic variability in that region (112). ELISA has also been used to detect antibodies in the yolk of eggs from commercial layers (52).

Specific antibodies of the IgG, IgM, and IgA classes have been detected in the oviduct and albumen of chickens naturally infected by MS, as well is in their developing embryos (17).

Further confirmation of serologic results may be made by isolation and identification of *M. synoviae* from the upper respiratory tract (134) or by PCR.

Turkeys produce a low level of antibody following respiratory infection; therefore, agglutination may not be effective in determining the *M. synoviae* status of a flock. Significant antibodies develop following foot pad inoculation only (48, 129). Various commercial agglutination antigens vary in their ability to detect agglutinins in turkeys. Under some situations there may be a delayed antibody response in chickens that were proved to be infected by PCR (36). Individual infected turkeys may not develop detectable antibodies(124). Turkeys that were infected systemically developed a strong antibody response; whereas, those birds infected via the upper respiratory tract did not develop circulating antibody, or antibody production was delayed (80). Culture, PCR, and HI testing may be required in some cases to detect infection.

Differential Diagnosis

A presumptive diagnosis may be made on the basis of pale comb, droopiness, emaciation, leg weakness, breast blisters, enlarged foot pads or hock joints, splenomegaly, and enlarged liver or kidneys. Bacteria as causes of synovitis or arthritis must be eliminated by bacteriologic procedures. *Staphylococcus aureus, Escherichia coli,* pasteurellae, and salmonellae may also be present as primary causes of synovitis. *M. gallisepticum* may also be a cause of breast blisters and joint lesions (115, 118).

Fibrosis of metatarsal extensor or digital flexor tendons and lymphocytic infiltration of the myocardium associated with the viral arthritis agent help to differentiate it from *M. synoviae* (93). Serum from viral tenosynovitis-infected chickens does not agglutinate MS antigen, but one must bear in mind that MS agglutinins may be present without obvious joint involvement.

In cases with respiratory involvement, *M. gallisepticum* and other causes of respiratory disease should be eliminated.

Intervention Strategies

Management Procedures

M. synoviae is egg transmitted, and the only effective method of control is to select chickens or turkeys from MS-free flocks.

Most primary breeding stocks are free of infection, and MS-free sources of replacement breeding stocks should be available. Effective biosecurity measures should be used to prevent introduction of the infection.

Outbreaks of MS infection in broilers can often be traced to a specific breeder flock. By the time the infected breeder flock is found, egg transmission may be low or no longer of clinical significance. The decision to slaughter infected parent breeder flocks is often made on an economic basis. If such flocks are kept for egg production, progeny should be hatched separately and isolated from MS-free flocks. Antibiotic treatment of breeders is not effective in eliminating MS, although the level of egg transmission may be reduced.

M. synoviae is susceptible *in vitro* to several antibiotics, including chlortetracycline, danofloxacin, enrofloxacin, lincomycin, oxytetracycline, spectinomycin, spiromycin, tetracycline, tiamulin, tilmicosin, aivlosin, and tylosin (21, 26, 54, 65, 68, 76, 154). In contrast to *M. gallisepticum,* MS isolates appear to be resistant to erythromycin (21, 154). High level resistance to erythromycin and tylosin developed rapidly after low level exposure *in vitro*, but enrofloxacin resistance developed more gradually. No resistance to tiamulin or oxytetracycline was shown (47). Earlier isolates seem to respond more poorly to chlortetracycline than later isolates (121). Generally, suitable medication is of value in preventing airsacculitis or synovitis, but treatment of existing lesions is less effective. Antibiotic medication is not thought to eliminate MS infection from the flock, but in a field study a flock naturally infected with MS was medicated with three treatments of enrofloxacin and later continuous medication with 600 ppm oxytetracycline in the feed. This flock subsequently became MS negative by PCR, suggesting possible clearance of MS from the flock as a result of medication (42). In another study (141), treatment with enrofloxacin at 10 mg/kg in the drinking water for 14 days did not eliminate detection of MS by PCR. In another study, two treatments with enrofloxacin at recommended dose levels did not affect recovery of MS from tracheal swabs, and isolates from the medicated birds exhibited an increased resistance to enrofloxacin as well as substitutions in the topoisomerase IV gene (87).

A summary of data obtained from field and experimental studies indicates that chlortetracycline (50–100 g/ton of feed) given continuously will provide satisfactory control of infectious synovitis in chickens. Higher concentrations (approximately 200 g/ton) are required to control synovitis after infection has occurred. In turkeys, prophylactic levels of 200 g/ton are required. Effectiveness of chlortetracycline may be related to the MS isolate involved (121).

Soluble lincomycin-spectinomycin (2 g/gal of drinking water) is of value in preventing airsacculitis in broilers (53). Tiamulin in the drinking water (0.006–0.025%) has been shown to be effective in preventing airsacculitis and synovitis in chickens (6). Other products have been used, but their value in treatment of MS has not been adequately studied.

Treatment of eggs with antibiotics such as tylosin by egg dipping, or egg inoculation with tylosin and gentamycin (106), or heat treatment (156) of hatching eggs has been used in breeding flocks to prevent egg transmission of MS. Exposure of breeders before the onset of egg production with virulent MS will reduce egg transmission. This should only be used in flocks in which infection will almost certainly occur.

Vaccination

An inactivated, oil emulsion bacterin is commercially available, but its role in the control of MS has not been adequately studied. A live temperature-sensitive MS vaccine strain, MS-H, was selected by mutagenesis of a field isolate from Australia (104). Its safety and efficacy have been established under laboratory (94, 95) and field (96) conditions. Vaccine doses of 4.8×105 ccu/ml were protective (63); immunity was detected after 3–4 weeks postvaccination (62). Factors other than the temperature-sensitive phenotype appear to be involved in the attenuation of the MS-H vaccine strain (113). This vaccine has received wide use in Australia, but it is not licensed in many countries, including the United States.

Mycoplasma iowae Infection

Janet M. Bradbury and Stanley H. Kleven

Introduction

Mycoplasma iowae has been associated with reduced hatchability and embryo mortality in turkeys. It has also been shown experimentally to induce mortality in turkey and chicken embryos and mild to moderate airsacculitis and leg abnormalities in chickens and turkeys. There have been occasional reports of leg problems in young turkeys associated with natural infection of *M. iowae*.

Economic Significance

Poult hatchability can be reduced by 2–5%.

History

The Iowa 695 strain of avian mycoplasma was isolated in 1955 and characterized by Yoder and Hofstad (75) and was subsequently designated avian serotype I (76). Avian mycoplasma serotypes I, J, K, N, Q, and R were classified into separate groups by Dierks *et al.* (25) and were subsequently characterized as a single, related group (4, 5, 30). The organism was later named *Mycoplasma iowae* (40) and 695 was designated as type strain. Type 8 strains isolated from turkeys in the United Kingdom (70) and North America (10) were also subsequently identified as *M. iowae* (1).

Etiology

Classification

M. iowae is a typical member of the family Mycoplasmataceae, class *Mollicutes*, having characteristic colonial morphology, no cell wall, and a growth requirement for sterol. Its lack of urease distinguishes it from the genus *Ureaplasma* and places it within the genus *Mycoplasma*. Identification at species level is based on serologic reactions. Immunofluorescence of mycoplasma colonies (68) is a rapid and reliable method for identification. Phylogenetic analysis of the 16S rRNA of *M. iowae* places it in the Pneumoniae group along with *M. gallisepticum* and the human pathogen *M. pneumoniae* (73).

Morphology and Staining

As with other mycoplasmas, Giemsa staining or dark-field examination reveals *M. iowae* organisms as coccobacillary but showing some pleomorphism. Ultrathin sections demonstrate that the cells are bound by a plasma membrane and lack a cell wall (40). Some studies suggest the possible presence of an attachment organelle (1) which would be consistent with its phylogenetic placement, since several phylogenetically related organisms possess this feature.

Growth Requirements

Like other mycoplasmas, *M. iowae* has complex growth demands including a requirement for cholesterol. Incubation is usually at 37°C, although some strains grow best at 41° to 43°C (35) and growth occurs either aerobically or with added CO_2 (40). Recovery of *M. iowae* from tissues appears to be more successful by direct plating on agar than by inoculation of broth (3). Although several formulations of mycoplasma medium have been used successfully, the formulation described by Bradbury (13) works well. The presence and quality of yeast extract are im-

portant, and some field isolates of *M. iowae* may be intolerant of certain media components. It is advisable to perform quality control checks on batches of yeast extract and serum using low passage field isolates of the organism.

Colony Morphology

Colonies on agar are characteristic of mycoplasmas with typical fried egg morphology and a diameter of 0.1–0.3 mm (75).

Biochemical Properties

M. iowae ferments glucose, hydrolyses arginine, does not possess urease or phosphatase, and does not produce films and spots or reduce tetrazolium chloride (40). Glucose metabolism is accompanied by oxygen uptake and thereby distinguishes *M. iowae* from some other avian species (69). Unusually for a mycoplasma, it can grow in the presence of 0.5–1.0% bile salts (62). Some strains are reported to hemagglutinate avian red blood cells (25, 75, 76), but the property is not stable. Although *M. iowae* hemagglutinins are variably expressed, the relevant proteins and genes have not yet been characterized (9).

Susceptibility to Chemical and Physical Agents

Resistance of *M. iowae* to disinfectants has not been determined, but it is probably similar to that of other mycoplasmas. *M. iowae* appears to be hardier than *M. gallisepticum* or *M. synoviae* (24). Under experimental conditions strains survived for 5 days or more on feathers and at least 6 days on human hair and several other materials. This may have implications for terminal site disinfection, especially with the existence of an oral/fecal mode of transmission. Practically, however, the organisms appear to be inactivated by proper cleaning and disinfection.

Antigenic Structure and Toxins

The antigenic structure of *M. iowae* is not well characterized, and there appears to be significant antigenic variation among strains (15, 35, 56, 77). Although few differences were seen between SDS-PAGE profiles (56, 77), immunoblotting using monoclonal antibodies revealed considerable diversity between different strains (56). Colony immunoblots probed with a monoclonal antibody demonstrated phenotypic variation of surface antigen in *M. iowae* (28, 60). A surface-exposed protein of 41 kD was identified in *M. iowae*, *M. gallisepticum,* and *M. imitans* giving the first evidence of an antigenic relationship between *M. iowae* and these other two species (59).

Toxins have not been reported for *M. iowae*.

Strain Classification

Antigenicity

In the past, *M. iowae* strains have been loosely classified into one of several serovars (25). *M. iowae* strains give a poor antigenic response in chickens and turkeys in terms of antibodies and little is known about the cellular immune response. When antibodies were raised in chickens to 12 different avian mycoplasma species, it proved to be more difficult with *M. iowae* than any of the others (14). Furthermore, no single antiserum, even from hy-

perimmunized rabbits, could detect all members of the group by immunofluorescence (23).

Immunogenicity or Protective Characteristics

Little is known about the immunogenicity of *M. iowae*, and it may even be slightly immunosuppressive because experimental infection of day old turkeys resulted in a decreased bursa to body weight ratio and a slightly delayed antibody response to sheep erythrocytes (16). A monoclonal antibody that reacts with a 65 kD polypeptide in *M. iowae* may play a role in cytadhesion (27).

Genetic or Molecular Characteristics

The genome size of *M. iowae* is reported as 1280–1315 kbp, making it one of the largest within the genus. Heterogeneity in the DNA of *M. iowae* strains was reported (23, 77) using restriction enzyme analysis and by restriction fragment length polymorphism using Southern hybridization with 16S rRNA probes (51). Neither of these methods provided clear cut classification of strains.

Pathogenicity

Variability exists in the pathogenicity and virulence of *M. iowae* strains (45, 58, 75). Experimental infection with *M. iowae* causes dose-related mortality in chicken and turkey embryos (20, 34, 54, 58, 75). Under field conditions, it is responsible for embryo mortality and reduced hatchability in turkeys, but some field strains appear to be more embryo lethal than others. The hatchability loss is widely variable and dependent on the extent of vertical transmission. Hatchability losses are not always apparent in eggs from infected turkey breeder flocks. On other occasions, however, the losses can be quite severe and prolonged. The reasons for these differences are unknown but could include the differences in virulence of strains, the incubation conditions, and the susceptibility of breeds of turkeys.

Artificial challenge with *M. iowae* induces mild to moderate airsacculitis in turkeys (25, 58, 75), as well as leg lesions in both chickens and turkeys (17, 19, 22, 75). The severity of lesions appears to vary with the strain. Artificial inoculation of 1-day-old broiler breeder chickens resulted in stunting and poor feathering in addition to leg lesions (18). Few clinical reports, however, describe airsacculitis or leg problems in chickens or turkeys, or embryo mortality in chickens under field circumstances. An outbreak associated with *M. iowae* in commercial turkey poults exhibiting leg weakness and dehydration has been described (71).

Virulence Factors

Virulence factors have not been studied for *M. iowae*.

Pathobiology and Epidemiology

Incidence and Distribution

In addition to North America, *M. iowae* has been reported in Western Europe (39), Eastern Europe (8), India (57), Japan (66), and Taiwan (53). It is presumed to be almost worldwide in distribution, although it has not been detected in Australia.

Natural and Experimental Hosts

The natural host appears to be the turkey, but isolation of *M. iowae* from chickens is not uncommon (8, 75), and it has also been reported in geese (53). In addition, *M. iowae* has been isolated from yellow-naped Amazon parrots (12) and from wild and exotic birds in the United Kingdom (2).

Age of Host Commonly Affected

Turkey embryos in the later stages of incubation are most commonly affected, although any age of live turkey may be infected. Little is known about other hosts, although the mycoplasma was isolated from natural infections of adult chickens (20) and adult geese (53).

Transmission, Carriers, and Vectors

Only avian species are known to be infected with *M. iowae*, although there is one report of its isolation from an apple seed in France (35). Egg transmission occurs in turkeys (54, 75), and it is possible that lateral transmission could occur in the hatchery because the organism is present in the meconium. This is because, unlike other avian mycoplasmas, *M. iowae* exhibits a predilection for the digestive tract (55).

Horizontal transmission may occur, but the organism does not spread rapidly in young flocks. Before achieving reproductive maturity, very few birds may be identified as culture-positive within a flock.

Infection may be spread venereally, and under modern methods of insemination, infected semen may play a role in dissemination (46, 61). After laying begins, following artificial insemination and for a few weeks thereafter, a high percentage of birds may become culture-positive. The organism can be recovered from both cloacal and vaginal sites. Although the infected male may play a role in lateral spread, vaginal contamination following hand contact at artificial insemination may be more important (6). The patterns of vertical transmission have been well characterized (34). Within any infected flock, it is possible to identify individuals that do not lay any infected eggs. Other birds lay only one or a few infected eggs, and the remainder lay many infected eggs. It is the latter group that is important in determining the extent of vertical transmission.

Incubation Period

Embryos infected via the dam usually die from about 18 days of incubation.

Clinical Signs

No clinical signs are usually observed in live turkeys, although one report (71) associates *M. iowae* with leg weakness in young poults, as do occasional further reports from the field. Eggs from infected turkey breeders may have reduced hatchability (usually 2–5%). Affected embryos usually die during the last 10 days of incubation, typically from days 18–24, although death may occur later. Experimentally infected embryos showed a significantly reduced embryo to egg weight ratio (55).

Pathology

Gross

Lesions in affected embryos consist primarily of stunting and congestion, with various degrees of hepatitis, edema, and splenomegaly (54, 55, 75). Sometimes affected embryos exhibit a down abnormality, "swollen down plumule," particularly in severe cases. The chorioallantoic membranes of inoculated turkey embryos are edematous and sometimes hemorrhagic (55). Airsacculitis in inoculated chickens and turkeys is ordinarily mild to moderate and similar to lesions caused by other mycoplasmas (25, 58, 75). Inoculation of day-old poults results in stunting, poor feathering, tenosynovitis, and leg abnormalities including chondrodystrophy, rotated tibia, toe deviations, and sometimes erosion of the articular cartilage of the hock joint and rupture of the digital flexor tendon (22, 75). Similar leg lesions may be observed in experimentally infected chicks, including rupture of the digital flexor tendon (18, 21). Inoculation of turkey poults with *M. iowae* may result in bursal atrophy (16). Lesions are not usually reported under field conditions, perhaps because many infected embryos do not hatch.

Microscopic

The chorioallantoic membranes of inoculated turkey embryos show edema and infiltration with heterophils and mononuclear cells, and the parenchymatous organs show a granulocytopoietic response (55).

After inoculation of day-old poults, lesions of the spleen consist of reticular cells with macrophages, plasma cells, and heterophils in the parenchyma. The bursa of Fabricius has localized congestion with infiltration of plasma cells, heterophils, and reticular cells. Macrophages, lymphocytes, heterophils, and plasma cells are seen in the lamina propria of the duodenum, ileum, and cecal tonsils. Little obvious change is observed in cartilage and tendon except for edema in the tendon sheaths (22). After air sac inoculation of turkey poults, lesions consist of thickened air sacs that contain large numbers of inflammatory cells, primarily lymphocytes. In some areas, lymphoid follicles are observed. Exudate on the mucosal surface contains fibrin and inflammatory cells (58). In experimentally infected broiler breeders, affected joints show acute tenosynovitis, hemorrhage, and tendon fiber degeneration, which is followed later by chronic lymphocyte/plasma cell reaction and tendinous and peritendinous fibrosis (18).

Ultrastructural

Adherence of *M. iowae* to embryo intestinal mucosa was demonstrated in artificial infection (55). Most organisms adhered to the microvilli, which often appeared swollen.

M. iowae organisms have been demonstrated in the crypts of the cloaca and in the secondary mucosal folds of the vagina of the turkey hen by electron microscopy (65).

Pathogenesis of the Infectious Process

Very little is known about the pathogenesis of *M. iowae*. The first step in the invasive process may be attachment to the embryo in-

testinal epithelial surface (55, 65). A 65-kD polypeptide in *M. iowae* may be involved in attachment (27).

In strains that proliferate in the embryo, death probably results from an acute nonspecific inflammation of the chorioallantoic membrane and a granulocytopoetic reaction in the parenchymatous organs (55). Western blots of *M. iowae* reacted positively with antibodies to a 48-kD mycoplasma protein, which has been shown to have immunomodulatory and hematopoietic differentiation activities (36).

Phenotypic variation may play a role in the infectious process by allowing the mycoplasmas to persist despite an immune response. As mentioned previously, there is also a possibility that *M. iowae* may be mildly immunosuppressive (16).

Immunity
Active
A paucity of information on active immunity to *M. iowae* exists, although antibody responses have been observed (75). Equally, very little information on the age susceptibility of turkeys is available. It is difficult or impossible to infect some individuals within a flock of adult breeder turkeys (7). Breeders that become infected and vertically transmit the organism to their eggs usually resolve the infection. This may occur in a few weeks or sometimes can take 2–3 months. Embryo mortality usually subsides immediately before resolution of the infection. That an immune response is involved is suggested by the finding of growth-inhibiting and metabolism-inhibiting antibodies in the serum of these hens (7).

Passive
There appears to be no information on the effects of passive antibodies, including maternally derived antibodies, on *M. iowae.*

Diagnosis
Isolation and Identification of Causative Agent
M. iowae may be present in high numbers in dead embryos (20, 54). After inoculation of turkey poults, it can be isolated from a variety of tissues, especially from the gastrointestinal tract and cloacal swabs, but isolations become less frequent with age, and organisms could not be recovered after 12 weeks (22, 63). Isolation of *M. iowae* from oviduct, semen, and phallus of adult chickens and turkeys has been reported (57, 61, 75). A combined oviduct/cloacal swab was found to be a useful method of detection during the final stages of an eradication program (74). Cotton swabs from the appropriate tissue are streaked on agar plates and incubated for 4–5 days or longer at 37°C. Typical *Mycoplasma* colonies can be identified by immunofluorescence (68), although the use of polyclonal antisera to several different serovars may be needed to cover for antigenic variation (23). Fluorescein-conjugated rabbit antiserum prepared against a cocktail of all the six serovars (I, J, K, N, Q, and R) was used successfully to detect field and laboratory strains (50). Although the reactions of some monoclonal antibodies might be too specific to detect all isolates, antibodies to a 45-kD antigen reacted with all

of 22 field isolates tested and showed no evidence of phenotypic variation in immunoblots (67).

Polymerase chain reaction has been developed for direct detection of *M. iowae* DNA (11, 31, 32, 45, 48, 49, 72, 78). One procedure at least (49) has been used successfully to amplify *M. iowae* from swab samples in the field.

A further refinement of the use of PCR, amplified fragment length polymorphism, has been used to differentiate between avian *Mycoplasma* species and has confirmed that high genetic homogeneity exists amongst *M. iowae* strains examined by this method (38).

Arbitrarily primed PCR may be a useful molecular tool for the epidemiological tracing of field strains (26).

Serology
Although agglutination, metabolism inhibition, indirect hemagglutination, and ELISA tests have all been used for experimental infections (45, 64, 75) the serologic response is weak (21, 22), and nonspecific reactions have been a problem with ELISA (44). Thus, there is no reliable serologic test available for use in the field. Growth-inhibiting and metabolism-inhibiting antibodies have been found in the serum of naturally infected breeding turkey hens (7).

Differential Diagnosis
M. iowae infection should be considered in cases of low hatchability in turkeys, especially when there is evidence of late embryo mortality. However, *M. meleagridis* will also be a consideration in this case. None of the lesions seen in embryos can be considered pathognomonic because there can be similar gross lesions in certain nutritional deficiencies, and the down abnormalities may be very similar to those observed when embryos are overheated in the incubator (29). Although it is not recognized as a significant cause of clinical tenosynovitis, *M. iowae* should be considered as a possibility in cases where there is no apparent explanation for leg problems including tenosynovitis, especially in young turkeys.

Intervention Strategies
Management Procedures
M. iowae was eradicated by certain primary turkey breeders in Europe and the United States by a pre-incubation treatment of hatching eggs with enrofloxacin, backed up by cultural monitoring (1).

There is no reliable serologic testing procedure for *M. iowae* to screen commercial flocks. Screening by culture may also be impractical before birds begin production because of the difficulties involved in isolating the organism and the poor horizontal spread. It is often possible, however, to detect infection in toms and hens before the onset of reproduction.

Clean flocks can be maintained free of *M. iowae* infection by preventing fomite transmission. Special attention should be given when birds reach reproductive age, especially during artificial insemination. It should be noted, however, that *M. iowae* does not always appear to be associated with hatchability losses.

Residual site infection is not known to be a problem where effective terminal cleaning and disinfection procedures are employed. The possibility of contaminated fomites should be borne in mind, however, if adequate cleaning is not achieved between successive flocks.

Vaccination

There is no demand for vaccines against *M. iowae*.

Treatment

Treatment of clinical disease in turkeys associated with *M. iowae* has not been an issue because it is not typically associated with clinical disease. Jordan (41, 42) did show the effectiveness of different antibiotics in reducing levels of infection. Attempts have been made, however, to reduce vertical transmission in commercial flocks to alleviate hatchability losses.

M. iowae appears to be more resistant than the other avian mycoplasma pathogens to some of the commonly used antimicrobials, especially tylosin tartrate (37, 47, 52). The quinolone class of antibiotics, particularly enrofloxacin (Bayer), have sometimes been effective when administered to laying hens in the drinking water, early during production. Eggs from medicated turkeys have been shown to be resistant to *in ovo* challenge with *M. iowae* (42). Egg treatment with enrofloxacin has, however, been more commonly employed. Hatching eggs from affected flocks are vacuum dipped in a solution of the antibiotic. This product is not generally available for food animal use in some countries.

Production of a challenge model that induces persistent infection for the purpose of evaluating antimicrobials has been difficult; a procedure involving inoculation of the lung of day-old poults has been recommended for such purposes (43).

Although little is known about development of resistance to antibiotics *in vivo*, *M. iowae* was shown to develop resistance rapidly during culture in subinhibitory amounts of erythromycin and tylosin (33). Some resistance was also found after culture with enrofloxacin, tiamulin or oxytetracycline and resistant mutants occurred more readily and more rapidly with *M. iowae* and all these antibiotics than it did with either *M. gallisepticum* or *M. synoviae*.

Other Mycoplasmal Infections
Stanley H. Kleven and Naola Ferguson-Noel

Mycoplasma imitans

Mycoplasma imitans is of interest because of its close relationship to *M. gallisepticum.* It has been isolated from ducks and geese in France and from a partridge in England. *M. imitans* strains share many phenotypic properties with *M. gallisepticum,* including biochemical reactions, hemadsorption, hemagglutination, and presence of an attachment organelle. The original isolates were initially identified as *M. gallisepticum* on the basis of immunofluorescence and growth-inhibition tests. Further serologic studies indicated only a partial relationship to *M. gallisepticum,* and DNA hybridization studies with the type strains of *M. gallisepticum* showed a DNA homology of 40–46% (5, 10). *M. imitans* contains a gene family closely related to the *pMGA* (now *vlhA*) family of *M. gallisepticum* (29), and shares epitopes with *M. gallisepticum* hemagglutinin *vlhA*, pyruvate dehydrogenase *pdhA*, lactate dehydrogenase, and elongation factor Tu (26).

Polymerase chain reaction (PCR) procedures for *M. gallisepticum* which are based on the 16S rRNA gene (16) do not differentiate between *M. gallisepticum* and *M. imitans.* A commercially available PCR kit for *M. gallisepticum* (IDEXX, Westbrook, Maine), however, does differentiate between the two species, as do PCR reactions based on genes for *mgc2, gapA,* and LP (17).

M. imitans causes ciliostasis in chicken and duck tracheal organ cultures and has an adherence structure similar to that seen in *M. gallisepticum* (1). It reproduced respiratory disease similar to but somewhat milder than *M. gallisepticum* in red-legged partridges (13). An isolate of *M. imitans* gained virulence on back-passage in turkeys, and reproduced a respiratory disease which was more severe when it was present in a dual infection with rhinotracheitis virus (14). *M. imitans* did not produce signs or lesions when inoculated into chickens, but in a dual infection with infectious bronchitis virus a synergistic effect was seen (15).

Although *M. imitans* has not yet been reported in the United States, and it has not been found in commercial poultry flocks, there is concern about possible misidentification of isolates as *M. gallisepticum* and possible serologic cross-reactions in testing of field flocks.

Mycoplasma gallinarum

M. gallinarum has not been considered to be one of the pathogenic avian mycoplasma species, but there is one report of consistent isolation from air sacs and tracheas from a series of broiler flocks that were having higher than normal condemnations due to airsacculitis. One of those isolates had the ability to induce airsacculitis when given in conjunction with Newcastle disease-infectious bronchitis vaccine (23). It has also been suggested that *M. gallinarum* infection delays the onset of fatty liver syndrome in commercial layers (6). *M. gallinarum* and *M. gallinaceum* are often isolated as contaminants during attempts to isolate pathogenic avian mycoplasmas.

It was originally classified as avian serotype B (8) and was named *Mycoplasma gallinarum* (11). It grows well on all commonly used avian mycoplasma media, and has characteristics common to all mycoplasmas, including cell and colony morphology, absence of a cell wall, and a requirement for cholesterol. It does not ferment glucose, but reduces tetrazolium, is positive for arginine decarboxylase, and exhibits film and spots (2). There is genetic heterogeneity among various strains (9) as measured by RFLP analysis of genomic DNA.

M. gallinarum is ordinarily isolated primarily from chickens, but it may also been found in turkeys (3, 19). It has been isolated from jungle fowl (33), ducks (12), and pigeons (32). It is considered to be worldwide in distribution. *M. gallinarum* is commonly isolated as a contaminant during attempts to isolate *M. gallisepticum* or *M. synoviae,* especially from adult chickens. Isolation of *M. gallinarum* from chicken embryos (3) and demonstration of the organism in oviducts (7, 45) suggest the possibility of egg

transmission. It is readily identified by immunofluorescence of colonies on agar (43). No serologic test is available.

Mycoplasma pullorum

M. pullorum was classified as avian serotype C (8) and was later named *Mycoplasma pullorum* (21). It has been isolated from chickens, quail, partridge, pheasants, and turkeys (30). *M. pullorum* has been isolated from turkey embryos from flocks in France which were experiencing low hatchability and was shown to be pathogenic for chicken and turkey embryos (30). Like other mycoplasmas, *M. pullorum* isolates demonstrate genetic heterogeneity (27).

Avian Ureaplasmas

Ureaplasmas differ from mycoplasmas primarily in their ability to hydrolyze urea (25). There are several reports of isolation of avian ureaplasmas (18, 24). These organisms subsequently received the name *Ureaplasma gallorale* (25). There are no reports of avian ureaplasma isolation in North America.

Very little is known about the pathogenicity. Artificial challenge of chickens produced no clinical signs or macroscopic lesions (24). Turkeys and chickens challenged with a turkey ureaplasma isolated in Hungary developed fibrinous airsacculitis and serologic responses (35). Ureaplasmas were also isolated in Eastern Europe from turkeys that were experiencing problems with reduced fertility (36).

Mycoplasma Infections of Geese

Three serologically and biochemically distinct *Mycoplasma* species were isolated from geese in Europe (38). One of these has been further characterized and named *Mycoplasma anseris* (4); it has been associated with airsacculitis, peritonitis, and embryo mortality (42). Another was subsequently identified as *Mycoplasma cloacale* (39), and the third was designated strain 1220. Two other isolates, strains 1223 and 1225, also represent two additional species isolated from geese (44).

Clinically, strain 1220 has been associated with reductions in egg production and egg transmission, infertility, inflammation of the cloaca and phallus, and lack of weight gain in hatched goslings (37, 39, 40), but proof of etiology is unclear because mixed mycoplasma species were isolated. Strain 1220, on experimental inoculation of goose embryos and day-old goslings, resulted in embryo mortality and reduced growth of young goslings (40). Strain 1220 has also been implicated in a field syndrome of goslings with respiratory and nervous signs (41). More work needs to be done to clarify the role of these mycoplasmas in the field syndromes described.

Mycoplasma Infections of Pigeons

There are three species of *Mycoplasma* primarily associated with pigeons: *M. columbinasale* (21), *M. columborale,* and *M. columbinum* (34). One or more of these *Mycoplasma* species have been isolated from normal birds (3, 20, 31), as well as birds showing signs of respiratory disease (22, 28, 32). An isolate of *M. columborale* reproduced airsacculitis in chickens (28). Medication of pigeons infected with *M. columborale* with tylosin elicited a favorable response (28, 32). Even though there has been isolation of these organisms from birds showing respiratory signs, and there have been favorable responses to medication, there is no conclusive proof that pigeon mycoplasmas are etiologically involved in naturally occurring respiratory disease of pigeons.

Chapter 22
Clostridial Diseases

Introduction

H. John Barnes

Four clostridial diseases of poultry or game birds are reviewed in this chapter—ulcerative enteritis (UE) caused by *Clostridium colinum*, necrotic enteritis (NE) caused by *C. perfringens*, gangrenous dermatitis (GD) caused by *C. perfringens* or *C. septicum*, and botulism caused by *C. botulinum*. Societal concerns about antimicrobial resistance and perceptions of organic poultry products being of higher quality have resulted in decreased availability and use of growth promoters and coccidiostats. As a consequence, clostridial diseases, especially NE, have greatly increased in occurrence and economic importance (6, 32, 34). A mild or subclinical form of NE that causes significant production losses has been recognized. Definition and criteria for diagnosis of this form of NE are still hazy, but a serological test for determining alpha-toxin antibodies shows promise as both a diagnostic tool and method to monitor NE activity in a flock (17). Some integrated broiler companies also have experienced substantial increases in GD. Collectively NE and GD now rank among the most important causes of disease-related economic loss among many broiler producers.

The complex interactions that result in clinical NE are being unraveled, however, an incomplete understanding of the pathogenesis of NE has hampered development of alternative control methods. Toxins produced by the organisms are responsible for the pathology of most clostridial diseases. Otherwise the organisms are relatively innocuous unless cofactors exist such as dietary ingredients or changes, severe stress, other infectious agents, coccidiosis, or immunosuppressive infections such as infectious bursal disease or chicken infectious anemia. For example co-infections with *C. septicum* and *Staphylococcus aureus* produce greater mortality and more severe GD than infections with either organism alone (33).

Other clostridial species have been isolated from sporadic diseases. *C. chauvoei* was identified in lesions of the comb and livers of chickens in two flocks with complex disease conditions (25) and from intestines and livers of ostriches in a zoological collection with an unusual neuroparalytic disease (18). *C. difficile* caused high mortality in young ostriches (10, 30). Severe enteritis and enterotoxemia due to *C. difficile* occurred in 153 of 160 young ostrich chicks that died in one flock; a second flock experienced a similar disease with high mortality. The organism was isolated in culture and *C. difficile* enterotoxin was confirmed by enzyme-linked immunosorbent assay (10). Hepatitis was a prominent feature in another group of affected ostriches (30). *C. sordelli* also caused sporadic mortality in ostriches (24, 30). *C. novyi* (20) and *C. sporogenes* (21) have been isolated from diseases in chicks. Four colony types of clostridia were recovered, along with *Mycoplasma synoviae*, from inflamed joints of chickens with infectious synovitis (22). Isolated cases of Tyzzer's disease, caused by *C. piliforme* (26), and enterotoxemia associated with *C. tertium* (8) have been confirmed in psittacines and could possibly be found in poultry in the future.

The host range for clostridial diseases continues to expand. NE caused high mortality in egg-laying chickens (7), ostriches (14), and free-living avian species (2, 3, 4). Mortality in psittacines due to UE has been reported for the first time (23).

Clostridium perfringens increasingly is being recognized as a cause of hepatitis and cholangiohepatitis in chickens at processing (13, 16, 27). *C. perfringens*-associated hepatitis (CPH) is the name that has been given to this liver disease. There is an inverse correlation between CPH and flock performance (16). Subclinical NE results in a higher occurrence of CPH at processing (15). CPH also can be found in chicks at hatching (28). Additionally *C. perfringens* has been associated with cellulitis of turkeys (5, 11), gizzard erosions in young replacement layer pullets (9) and broiler chickens (19), and navel infections in neonatal chicks (12). Possible vertical transmission of *C. perfringens* has been shown (29), which is supported by the finding of CPH in newly hatched chicks (28).

Botulism is uncommon but outbreaks characterized by weakness, paralysis, and increased mortality still occur, especially in turkey flocks. The disease tends to repeat on the same farm. Improved molecular diagnostic methods, vaccines, and a model to predict and manage botulism outbreaks in waterfowl may have application for poultry flocks (1, 35, 36). Botulism typically results from ingestion of preformed toxin; however, the toxicoinfectious form of botulism that resulted from caponizing wound contamination by spores of *C. botulinum* has been identified in poultry (31).

Ulcerative Enteritis (Quail Disease)

Dennis P. Wages

Introduction

Ulcerative enteritis (UE) is an acute bacterial infection in young chickens, turkeys, and upland game birds characterized by sudden onset and rapidly increasing mortality. The disease was first seen in enzootic proportions in quail and was, therefore, named quail disease. It has since been established that many avian species other than quail are susceptible, and the earlier name has been superseded by ulcerative enteritis.

Distribution of UE is worldwide; a number of reports have originated from England (23), Japan (31), Canada (38), Germany (46), and India (26, 48, 49).

Ulcerative enteritis is an important disease problem in some concentrated poultry-raising areas (10) and is a threat to game birds either in confinement or in the wild.

Infection of humans has not been reported.

History

Quail disease was first reported in the United States in 1907 (37). Several scattered outbreaks in quail and grouse (1, 20, 32, 33, 34, 42) were reported during the next 2 decades. Subsequently, infection in wild and domestic turkeys (11, 47) was discovered. Other avian species found to be susceptible included pigeons (21), chickens (22, 47), robins (50), pheasants, blue grouse, partridges (44), California quail (12) and lories (43). Genetic differences in susceptibility to ulcerative enteritis have been described in Japanese quail (15). Chronologic events leading to isolation and precise identification of the etiologic bacterium are detailed by Bass (2, 3), Peckham (39, 40), and Berkhoff *et al*. (7).

Etiology

Classification

Ulcerative enteritis is caused by a species of *Clostridium* named *Clostridium colinum* (5, 8). On the basis of 16S rRNA sequence analyses, *C. colinum* has been placed into subcluster XIV-b with 6 other *Clostridium* spp. It is most closely related to *C. piliforme,* the noncultured causative agent of Tyzzer's disease (14).

Initially, a gram-positive, pleomorphic, aerobic, nonmotile bacterium isolated from the liver of a diseased quail was used to reproduce UE in quail. The organism originally was identified as *Corynebacterium perdicum.* It did not grow on solid media and grew poorly in fluid media. On subculture, the organism quickly lost virulence (35). Subsequently, a gram-negative, anaerobic bacillus was isolated from the intestine and liver of infected
22.1.   Blood smear from quail with UE. Note two bacteria, one of which has a subterminal spore. (M. C. Peckham)

quail. Feeding quail thioglycolate broth cultures reproduced the clinical syndrome (3).

Peckham (39, 40) reported isolation of a gram-positive, anaerobic, spore-forming rod following yolk sac inoculation of chick embryos. This organism produced UE lesions in inoculated quail. It was re-isolated from inoculated quail, fulfilling Koch's postulates. Similar anaerobes were isolated from chickens and turkeys affected with UE, and it was established that UE in chickens, turkeys, and quail was caused by the same organism (40). Berkhoff *et al*. (8) cultured the etiologic anaerobe on solid media, which allowed the study of its biochemical characteristics.

Morphology and Staining

C. colinum is a gram-positive 1×3–4 μm bacillus that occurs singly as a straight or slightly curved rod with rounded ends. Sporulation is rarely seen in artificial media, but if spores are present, they are oval and subterminal. Sporogenic cells are much longer and thicker than nonsporing cells (Fig. 22.1).

Growth Requirements

The organism is fastidious in its growth requirements, needing an enriched medium and anaerobic conditions. The best medium for isolating *C. colinum* is tryptose-phosphate agar (Difco) to which 0.2% glucose and 0.5% yeast extract are added. The pH is adjusted to 7.2, and the medium then is sterilized by autoclaving. After cooling to 56°C, 8% horse plasma is added, and the medium is poured into Petri dishes. Prereduced plates are inoculated with material from liver lesions and incubated anaerobically for 1–2 days at 35–42°C (19); colonies are 1–2 mm in

diameter, white, circular, convex, and semitranslucent and have filamentous margins. Growth in broth media, prepared as stated previously but without agar, can be detected as early as 12–16 hours postinoculation (PI). Actively growing cultures produce gas. Gas production continues for no more than 6–8 hours, after which growth settles to the bottom of the tube (5). Subcultures should be made from actively growing broth cultures still producing gas; later transfers may be unsuccessful.

Biochemical Characteristics

The following carbohydrates are fermented: glucose, mannose, raffinose, sucrose, and trehalose. Fructose and maltose are weakly fermented. Mannitol is fermented only by some strains, one of which is the type strain, ATCC 27770. Carbohydrates not fermented are arabinose, cellobiose, erythritol, glycogen, inositol, lactose, melezitose, melibiose, rhamnose, sorbitol, and xylose. Fermentation products of this organism are acetic and formic acids (5, 8).

Esculin is hydrolyzed. Starch hydrolysis is usually negative; only 2 strains have been found to cause starch hydrolysis. The type strain does not hydrolyze starch. Nitrite and indole are not produced. Milk is unchanged, and casein is not digested. Good growth occurs in chopped meat carbohydrate (CMC) broth. Pyruvate and lactate are not used. Gelatin is not liquefied. Catalase, urease, lipase, and lecithinase are not produced.

C. colinum resembles *C. difficile* most closely. These 2 organisms can be differentiated on cultural characteristics. *C. difficile* hydrolyzes gelatin and is unable to ferment raffinose, whereas *C. colinum* is inactive on gelatin and readily ferments raffinose (19).

Susceptibility to Chemical and Physical Agents

The anaerobe, by virtue of its spore-forming characteristic, is extremely resistant to chemical agents and physical changes. Spores of *C. colinum* are resistant to octanol and chloroform (8). Yolk cultures have remained viable after 16 years at –20°C and survive heating at 70°C for 3 hours, 80°C for 1 hour, and 100°C for 3 minutes (40).

Pathogenesis and Epidemiology

Incidence and Distribution

Ulcerative enteritis is worldwide in its distribution and affects a wide variety of avian species. Even though a common infection recognized in quail, chickens and turkeys can be affected worldwide.

Natural and Experimental Hosts

Ulcerative enteritis is found in a wide range of avian hosts, but quail are undoubtedly among the most susceptible species. Natural infections have been found in the following: bobwhite quail (*Colinus virginianus*), California quail (*Lophortyx californica*), Gambel quail (*L. gambelii*), mountain quail (*Oreortyx picta*), scaled quail (*Callipepla squamata*), and sharp-tailed grouse (*Pedioecetes phasianellus*) (37); ruffed grouse (*Bonasa umbellus*) (32, 33); domestic turkeys (*Meleagris gallopavo*) and chickens (*Gallus gallus*) (18, 47); European partridge (*Perdix*

perdix) and wild turkeys (*M. gallopavo*) (18); chukar partridge (*Alectoris graeca*) (44); pigeons (*Columba livia*) (21); pheasants (*Phasianus colchicus*) and blue grouse (*Dendragapus obscurus*) (12); and crested quail (*L.c. californicus*) (23). An outbreak of UE in robins (*Turdus migratorius*), confirmed by isolation of *C. colinum* from the liver, was the first evidence that UE could affect passerine birds (50). UE has also been confirmed in lories (*Trichoglossus* spp.) and *Eos* spp. (43).

Although chickens frequently are infected naturally, experimental infections are difficult and can be readily produced only in quail (9). Ulcerative enteritis is more frequently seen in young birds. It occurs in chickens 4–12 weeks (40), turkeys 3–8 weeks (11), and quail 4–12 weeks of age. An outbreak has been reported in adult quail (27).

Outbreaks in chickens often accompany or follow coccidiosis, chicken infectious anemia, infectious bursal disease, or stress conditions. The importance of coccidiosis in outbreaks of UE in chickens was confirmed by producing UE in 5-week-old chickens previously infected with *Eimeria brunetti* and *E. necatrix* but not with either one alone (16).

Age of Host Commonly Affected

Quail of all ages can be affected by UE, however, the young growing quail are more commonly observed with infection.

Transmission

Under natural conditions, UE is transmitted through droppings; birds become infected by ingesting contaminated feed, water, or litter. The organism produces spores, resulting in permanent contamination of premises after an outbreak has occurred. Oral administration of at least 10^7 viable cells of *C. colinum* is required to experimentally reproduce UE in quail (8).

The carrier status of recovered birds or survivors in a flock has not been studied critically. Chronic carriers, however, have been considered to be one of the most important factors in perpetuation of UE and a complement-fixation (CF) test to detect them has been used (36).

Incubation Period

Following experimental infection in quail, the acute form of UE results in death within 1–3 days. The course of the disease in a flock generally lasts about 3 weeks, with peak mortality occurring 5–14 days PI.

Clinical Signs

Birds dying from acute disease may exhibit no premonitory signs. They are usually well muscled and fat and have feed in the crop. Quail often exhibit watery, white droppings. As UE progresses, infected birds become listless and humped up, with eyes partly closed and feathers dull and ruffled. Extreme emaciation with atrophy of pectoral muscles is seen in birds affected 1 week or longer.

Morbidity and Mortality

Mortality in young quail may be as high as 100% in a matter of a few days. Chicken losses typically range from 2–10%.

Pathology

Gross

Acute lesions in quail are characterized by marked hemorrhagic enteritis in the duodenum. Small punctate hemorrhages may be visible through the serosa in the intestinal wall. Ulcerations may be extensive enough to erode through the intestinal wall, perforating the intestines resulting in peritonitis.

In birds that have survived infection for several days, inflammatory changes are followed by necrosis and ulceration, which may occur in any portion of the intestine and ceca. Early lesions are characterized by small yellow foci with hemorrhagic borders, which may be seen on serosal and mucosal surfaces. As ulcers increase in size, the hemorrhagic border tends to disappear. Ulcers may be lenticular or roughly circular in outline, sometimes coalescing to form large necrotic, diphtheritic patches. The lenticular shape is more common in the upper portion of the intestine. Ulcers may be deep in the mucosa; in older lesions, they may be superficial and have raised edges. Ulcers in ceca may have a central depression filled with dark-staining material that cannot be rinsed off. Perforation of ulcers frequently occurs, resulting in peritonitis and intestinal adhesions. Gross lesions in the intestine are shown in Figure 22.2A,B.

Liver lesions vary from light yellow mottling to large, irregular yellow areas along the edges. Other liver lesions are disseminated gray foci or small, yellow circumscribed foci, sometimes surrounded by a pale yellow halo (Fig. 22.2F). The spleen may be congested, enlarged, and hemorrhagic. Gross lesions are absent in other organs. Peckham (40) described an unusual lesion of UE in turkeys characterized by a necrotic, diphtheritic membrane occupying the middle third of the intestine. This combination of necrosis and sloughing of intestinal mucosa appeared similar to lesions produced by *E. brunetti* infection in chickens.

Microscopic

For a description of the histopathology of UE in quail, see reference 16. Intestinal sections from acute cases reveal desquamation of mucosal epithelium, edema of intestinal wall, vascular engorgement, and lymphocytic infiltration. The lumen of the intestine contains desquamated epithelium, blood cells, and fragments of mucosa. Early ulcers consist of small hemorrhagic, necrotic areas involving villi and extending into the submucosa. Cells adjacent to these areas exhibit coagulation necrosis with karyolysis and karyorrhexis. Lymphocytic and granulocytic infiltration occurs adjacent to necrosis. Small clumps of gram-positive bacteria are often present in necrotic tissue. Older ulcers appear as thick masses of granular, acidophilic, coagulated serum proteins mixed with cellular detritus and bacteria. Infiltrations of granulocytes and lymphocytes surround the ulcer. Microscopic pathology of the intestine is illustrated in Figure 22.2C,D,E. Small blood vessels near ulcers and in liver occasionally are occluded by thrombi and bacteria. Liver lesions consist of poorly demarcated foci of coagulative necrosis, with minimal inflammatory reaction and occasional intralesional, gram-positive bacterial colonies, scattered throughout the parenchyma (23) (Fig. 22.2F,G,H).

Pathogenisis of the Infectious Process

Pure cultures of *C. colinum* grown anaerobically were highly pathogenic for quail following oral inoculation. The experimental disease appeared either in an acute form with birds dying around 3 days PI or in a more chronic form with deaths occurring after 1–2 weeks (7).

Immunity

Active Immunity

Active immunity seems to develop in birds that recover from naturally occurring infections. When survivors of a UE outbreak were subsequently challenged, no noticeable effect was seen (28), whereas 85% of similarly challenged susceptible controls died. It has been observed, however, that survivors in groups treated with antibiotics may remain highly susceptible to infection (30, 41).

Diagnosis

Diagnosis of UE can be made on the basis of gross postmortem lesions. The presence of typical intestinal ulcerations accompanied by necrosis of the liver and an enlarged, hemorrhagic spleen suffices for clinical diagnosis. As an aid in diagnosis, necrotic liver tissue can be crushed between two slides, fixed by heat, and stained by Gram's method. Large, gram-positive rods, subterminal spores, and free spores can be seen. If necessary, *C. colinum* can be isolated from liver or spleen (see "Isolation and Identification of Causative Agent").

A fluorescent antibody (FA) has been developed and found to be highly specific for diagnosis of UE; correlation between a presumptive diagnosis based on gross lesions and the FA test was 100% (6).

Isolation and Identification of Causative Agent

A clinical diagnosis of UE can be confirmed by isolation and identification of *C. colinum.* Because the organism is often present in the liver in pure culture, isolation from liver rather than from ulcerative, intestinal lesions is recommended. *C. perfringens* may be present as a secondary invader but is easy to recognize (7, 19) (see "Growth Requirements").

Serology

An agar gel immunodiffusion test has also been used for diagnosis of UE (4). Soluble bacterial antigens that reacted with antisera prepared against *C. colinum* were found in high concentrations in intestinal contents. These antigens were identical to bacterial antigens present in culture filtrates of *C. colinum.* Antigens were not, however, species-specific, as some strains of *C. perfringens* types A and C have cross-reacting antigens. Cross-reactivity among clostridial species makes this test unreliable for diagnostic purposes.

Differential Diagnosis

Among similar diseases that must be differentiated from UE are coccidiosis, necrotic enteritis, and histomoniasis. Frequently, coccidiosis in chickens, turkeys, and pheasants precedes or occurs concurrently with UE (Fig. 22.3). Both diseases may be
22.3. Combined UE and *Eimeria brunetti* coccidial infection in the intestine of a chicken. Note small ulcers in ceca and rectum. Diphtheritic membrane is due to coccidial infection. (M. C. Peckham)

present in the same or different specimens submitted for diagnosis (11, 12, 16, 39). It is imperative that a differential diagnosis between coccidiosis and UE be made because medication for each disease is distinct. Furthermore, both diseases may occur simultaneously, necessitating use of 2 different medications.

A condition initially described as necrotic enteritis frequently occurs in broilers in densely populated areas. Although there was much controversy that UE and necrotic enteritis are the same disease, it has been conclusively demonstrated (17) that they are distinct. Gross and histopathologic differentiation of necrotic enteritis and UE has been described (24) (see "Necrotic Enteritis").

Histomoniasis produces caseous cores in ceca and necrotic areas of varying size in the liver. This combination of cecal and liver lesions seen in chickens, turkeys, and other gallinaceous birds makes it imperative that cecal ulcerations and liver necrosis of UE be distinguished from histomoniasis. An enlarged hemorrhagic spleen and intestinal ulcerations are characteristic of UE. Histologic examination of the liver or ceca will reveal histomonads (see Chapter 28).

Intervention Strategies

Management Procedures

Because the infectious organism is in the droppings and remains viable indefinitely in litter, it is recommended on problem farms to remove contaminated litter and use clean litter for each brood. In chickens, avoid stresses caused by overcrowding, keep coccidiosis under control, and use preventive measures against viral diseases, which may act as stressors and/or cause immunosuppression.

Game farm managers should exercise caution with regard to overgrazing ranges or overcrowding birds. Placing birds on 0.5-inch wire mesh is recommended on farms where the disease is a problem. Survivors of an outbreak may be carriers and should not be mixed with unexposed birds.

Treatment

Early attempts to use sulfonamides for treatment of UE were unsuccessful (13, 44). Streptomycin administered by injection or in feed or water has prophylactic and therapeutic value against UE in quail. Streptomycin at a level of 60 g/ton of feed or 1 g/gal of water gives complete protection when administered prophylactically (27, 28, 29, 30, 41). Addition of 100 g bacitracin/ton feed provides protection (41). Bacitracin methylene disalicylate can be used at 200 grams per ton for control of ulcerative enteritis in quail. Other chemotherapeutics reported to have efficacy for controlling UE in quail include furazolidone, chlortetracycline (CTC) (41), penicillin, ampicillin (31), and tylosin (25). Kondo *et al.* (31) tested the *in vitro* sensitivity of *Clostridium colinum* to 19 antimicrobial agents.

Ulcerative enteritis can be prevented and/or controlled through medication by either drinking water or feed.

Necrotic Enteritis

Kenneth Opengart

Introduction

Definition and Synonyms

Clinical necrotic enteritis (NE) can be defined as a disease of primarily young chickens, caused by infection with, and toxin production by, *Clostridium perfringens* type A and type C. The clinical infection is characterized by sudden onset, high mortality and necrosis of the mucous membrane of the small intestine. Since its first description, sub-clinical (121) and mild (69) forms of the disease have been described. The disease is also known as clostridial enteritis, enterotoxemia and rot gut.

Economic Significance

There have been very few studies that have evaluated the economic significance of the clinical manifestation of NE. The costs associated with NE prevention have been estimated to be approximately $0.05 per broiler in the U.S. (130). While it is difficult to determine the prevalence of the mild form of the infection, it has been shown to impair growth rate and feed conversion (81) and cause higher condemnation rates in broilers due to resulting hepatitis (80). Flocks with high levels of *C. perfringens*-associated hepatitis had 25–43% poorer performance than flocks with low levels of *C. perfringens*-associated hepatitis (81). In countries where the practice of using antibiotics in the feed to enhance growth has been discontinued, the incidence and, therefore, the economic significance of subclinical and clinical NE have increased (54).

Public Health Significance

Clostridium perfringens type A and type C, in addition to producing toxins which can induce NE in poultry, also produce enterotoxins at the moment of sporulation which can produce foodborne illness in humans. Two distinct diseases are induced by these subtypes; type A *C. perfringens* produces diarrhea and type C *C. perfringens* produces necrotic enteritis in humans (131). High percentages of *C. perfringens*-positive carcasses have been reported following processing (28, 92) and outbreaks of type A food poisoning traced to consumption of chicken have been reported (62, 109). Although type C food poisoning is a much more severe disease in humans and type C *C. perfringens* can be found in poultry, it is not considered to be a major foodborne concern because of the very low prevalence of the disease in humans (131). Of concern is the potential for incidence of C. *perfringens*-induced foodborne illnesses to increase with the worldwide trend of removing growth enhancing antibiotics from poultry rations. The removal of these compounds, most of which have anti-clostridial activity, has led to an increase in clinical and sub-clinical NE and hepatitis in broilers (54) and will, no doubt, also increase the carriage of *C. perfringens* on broiler carcasses throughout processing.

History

Necrotic enteritis in domestic chickens was first described by Parish in 1961 (101, 102, 103) who reproduced the disease with a strain of *Clostridium welchii* (*C. perfringens*). It subsequently has been reported from most areas of the world where poultry is produced (7, 13, 22, 23, 66, 73, 77, 94, 95, 129). *C. perfringens* has also been associated with NE in turkeys (38, 39, 50).

Etiology

Strain Classification and Toxin Production

The etiologic agent of NE is a Gram-positive, spore-forming anaerobe; *C. perfringens* type A (3, 9, 14, 72, 78, 98, 110, 128, 134) and type C (32, 72, 95, 103, 110, 112).

Both of these strains are capable of producing various toxins and enzymes which are responsible for the associated lesions and clinical signs. Specifically, alpha-toxin produced by *C. perfringens* types A and C and beta-toxin produced by *C. perfringens* type C are believed responsible for the production of the intestinal mucosal necrosis commonly associated with NE (5, 46, 98, 120).

Healthy and diseased birds may harbor *Clostridium perfringens* type A within their intestines although it is not clear whether isolates from birds with NE produce significantly larger quantities of alpha-toxin than isolates from birds that do not have NE (52, 61). Using an immunoglobulin G anti-alpha-toxin ELISA test, a significant relationship between antibody titer to alpha-toxin and sub-clinical NE as well as an association between antibody titer and the occurrence of *C. perfringens*-associated hepatitis at slaughter has been demonstrated (83).

The quantity of alpha-toxin produced by different isolates appears to be determined by the regulation of a specific gene, *cpa* (115). Expression of *cpa* is thought to be influenced by inducers within the intestinal micro-environment. The stimulus for production of these inducers, however, is unclear (107) but it has been speculated that it may be based on quorum sensing—the method through which bacteria produce, secrete, detect and respond to signaling molecules which accumulate in the extracellular environment and influence gene expression (89). Whether expression of *cpa* by *C. perfringens* is down-regulated in the healthy gut, or in response to inducers, is up-regulated to initiate enteric disease is unclear at this time (89).

Morphology and Staining

C. perfringens can be isolated readily on blood agar plates incubated anaerobically at 37°C overnight. *C. perfringens* colonies on blood agar (with rabbit, human, or sheep blood) are surrounded by an inner zone of complete hemolysis and an outer zone of discoloration and incomplete hemolysis and are composed of short to intermediate, gram-positive rods without spores.

Growth Requirements and Biochemical Properties

Positive identification of the organism is made by inoculation of differential media (1). Most strains ferment glucose, maltose, lactose, and sucrose; do not ferment mannitol; and variably ferment salicin. Principal products of fermentation are acetic and butyric acids. Gelatin is hydrolyzed; milk is digested; and no indole production occurs. Growth on egg yolk agar demonstrates the presence of lecithinase and the absence of lipase production. Subculturing on egg yolk agar plates, one-half of which have been spread with *C. perfringens* antitoxin, and incubating anaerobically overnight will produce a zone of precipitation around colonies on control sides of the plate and little or no precipitation on sides spread with antitoxin (1).

Pathobiology and Epidemiology

Natural and Experimental Hosts

Naturally occurring outbreaks of NE have been reported in chickens from 2 weeks to 6 months of age. A majority of reports of NE have been in 2 to 5-week-old broiler chickens raised on litter (7, 13, 48, 57, 66, 77, 93, 95, 129). Cases of necrotic enteritis have also been reported in 3 to 6-month-old commercial layers raised in floor pens (22, 73), 12 to 16-week-old caged-reared commercial layer replacements (20, 45), and mature commercial layers in cages (36). Necrotic enteritis has also been reported in turkey poults (40), 7 to 12-week-old turkeys (50), and turkeys with concurrent ascarid infection (99) or coccidiosis (38).

Necrotic enteritis has been reproduced experimentally in chickens (9, 25, 51, 55, 56, 104, 105), turkeys (43), and Japanese quail (32). In broiler chickens, the incidence of the disease can be from 1.3–37.3% and as high as 62.0% in specific-pathogen-free chicks (9). Necrotic enteritis can be reproduced by rearing chickens on litter in facilities where the disease has previously occurred (55, 56, 86, 133); feeding feed contaminated with *C. perfringens* (78, 128); administering vegetative cultures of *C. perfringens* intravenously (16), orally (16), or into the crop (9); administering intraduodenally broth cultures of *C. perfringens* (3), bacteria-free crude toxins of *C. perfringens* (4), or a combination of *C. perfringens* and its toxins (5, 10); or by dosing chickens with sporulated oocysts of *Eimeria* spp. and feeding vegetative cultures of *C. perfringens* or *C. perfringens*-contaminated feed (2, 8, 9, 10). Others have combined several predisposing factors (dietary inclusion of wheat and fishmeal along with a coccidial and clostridial challenge) to reproduce the disease (136). Immunosuppression due to IBDV challenge has been shown to make the disease more severe (90).

Transmission, Carriers, and Vectors

C. perfringens can be found in feces, soil, dust, contaminated feed and litter, or intestinal contents (26, 28, 29, 72, 74). In various outbreaks of NE, contaminated feed (23, 45, 134) and contaminated litter (133) have been incriminated as sources of infection. Domestic flies have been shown to be a mechanical vector, and perhaps a biological vector as well, in a cage-layer facility that experienced a necrotic enteritis outbreak (36).

C. perfringens can be disseminated through commercial hatcheries to broiler farms (26, 27, 28, 29) and has been isolated from eggshells, hatchery fluff and chick box pads (27)**.** Other studies, using ribotyping, have confirmed the vertical dissemination of *C. perfringens* from commercial breeder farms to the hatchery, broiler farms and, ultimately, the processing plant (29).

Clinical Signs

Clinical signs in naturally occurring outbreaks include marked to severe depression, decreased appetite, reluctance to move, diarrhea, and ruffled feathers (7, 15, 57, 77, 95, 101, 129). Clinical illness is very short; often birds are just found acutely dead without any outward signs of disease.

Pathology

Gross

Gross lesions in naturally occurring outbreaks usually are confined to the small intestine, primarily the jejunum and ileum (Fig. 22.4A) (7, 15, 57, 95, 129); however, cecal lesions have been described (79). Intestines are often friable and distended with gas. The mucosa is lined by a loosely to tightly adherent yellow to green pseudomembrane that is often described as having a "Turkish towel" appearance (Fig. 22.4C). Flecks of blood have been reported, but hemorrhage is not a prominent feature. Experimentally, gross lesions characterized by a gray, thickened mucosa in the duodenum and jejunum may be observed as early as 3 hours following inoculation of *C. perfringens* (3). By 5 hours, there is necrosis of the intestinal mucosa, which progresses over time to a severe fibrinonecrotic enteritis with formation of a diphtheritic membrane (9, 112). Hepatitis, characterized by swollen, tan colored livers with necrotic foci (40) in addition to cholecystitis (100) has been reported in association with classical and subclinical NE infections (80, 81).

A more mild form of the disease has been described characterized by focal areas of intestinal mucosal necrosis, hepatic necrosis and impaired performance with or without clinical signs of the infection (68, 80, 81).

Microscopic

Microscopic changes in natural outbreaks are characterized primarily by severe necrosis of the intestinal mucosa with an abundance of fibrin admixed with cellular debris adherent to the necrotic mucosa (Figs. 22.4B,D) (15, 57, 79, 95, 129). Initial lesions develop at the apices of villi and are characterized by sloughing of epithelium and colonization of the exposed lamina propria with bacilli, accompanied by coagulation necrosis. Areas of necrosis are surrounded by heterophils. Progression of lesions usually occurs from villi apices to crypts. Necrosis may extend into the submucosa and muscular layers of the intestine. Numerous large bacilli often are observed attached to cellular debris. In birds that survive, regenerative changes consist of crypt epithelial cell proliferation with a corresponding increase in mitotic figures. Epithelial cells are primarily cuboidal, with a relative decrease in goblet and columnar epithelial cells. Villi are relatively short and flat. In many outbreaks, various sexual and asexual stages of coccidia are also found in the intestine (57, 79, 95).

Microscopic changes after experimental inoculation of *C. perfringens* occur as early as 1 hour following challenge and consist of slight edema and dilation of vessels in the lamina propria, sloughed epithelial cells in the intestinal lumen, and occasional heterophils and mononuclear cells in the lamina propria (3). By 3 hours, marked edema, resulting in the detachment of the epithelial cell layer from the lamina propria, mostly at the apex of villi, has occurred. Mononuclear cell infiltration of the lamina propria is more marked than earlier. At 5 hours, there is marked coagulation necrosis of the epithelial cell layer and lamina propria at villous tips, resulting in villus shortening. Colonization of organisms may be prominent on necrotic tissues and apices of exposed lamina propria. Blood vessels are very congested, occasionally occluded by hyaline thrombi. By 8–12 hours, there is massive necrosis of villi, in some instances reaching to the crypts, characterized by areas of amorphous eosinophilic-staining material and cell nuclei. Fibrin and cellular debris are present in the lumen. Ultramicroscopically, the most prominent changes of the luminal cell membrane are loss of vesiculation and complete loss of microvilli (67). These changes occur most prominently in necrotic parts of the intestinal mucosa in close proximity to individual *C. perfringens* bacterium and further suggests that hydrolysis of epithelial cell membranes by bacterial toxins is important in the pathogenesis of NE.

Histopathologic lesions of the liver include bile duct hyperplasia, fibrinoid necrosis, cholangitis and focal granulomatous inflammation (80, 100, 108).

Pathogenesis of the Infectious Process

The pathology associated with NE is a result of the alpha- and beta-toxins produced and released by *C. perfringens* within the mid-intestine (4). There continues to be debate over the specific events that initiate toxin production and the importance of relative numbers of clostridia within the intestine in healthy and diseased birds. Some studies have found *C. perfringens* to be the principal obligate anaerobic bacterium in the intestinal tract of healthy chickens (65, 113); whereas others have reported it only sporadically and in low numbers from the small intestine of normal chickens ranging in age from recently hatched to 5 months of age (11, 12, 111, 117, 126). It appears that the make-up of the intestinal population of *Clostridium perfringens* is determined by the health status of the bird. In flocks experiencing necrotic enteritis, isolates tend to be clonal within a flock with different diseased flocks having different clonal populations. Healthy flocks, on the other hand, have more diverse populations of *C. perfringens* isolates (42, 52, 96).

Although the events that lead up to the production of toxin remain unclear, what is clear is the ability of the toxins to induce the lesions and clinical signs characteristic of NE. Alpha-toxin is a phospholipase C sphingomyelinase that hydrolyzes phospholipids and promotes mucous membrane disorganization (97, 131) which then stimulates the arachadonic acid cascade to induce the production of inflammatory mediators like leukotrienes, prostacyclin, platelet-agglutinating factor and thromboxane (21, 127). These mediators lead to contraction of blood vessels, aggregation of platelets and myocardial dysfunction, leading to acute death

(131). Beta-toxin induces hemorrhagic necrosis of the intestinal mucosa characteristic of the disease (53, 76)**.**

Contributing Factors

Infection with mid-intestinal species of coccidia is a major predisposing factor for NE (2, 6, 8, 9, 10, 57, 112). Colonization of the small intestine by *Eimeria* sp. may lead to intestinal mucosal damage which may then, in turn, provide natural substrates (plasma proteins) required for *C. perfringens* proliferation (131).

Management factors which may influence the development of NE include the use of high fiber litter (128), bird stocking density and programmed feed changes (moving from starter rations to grower rations, for example) which may create intestinal stress (89). It has also been reported that the occurrence of NE may result from a complex relationship between cereal grain ration (wheat/barley/maize), dietary animal protein level, and seasonal effects (70).

Manipulating the diet can affect the population of *C. perfringens* in the intestinal tract (118) and may also increase the rate of fecal shedding of *C. perfringens* (26), suggesting that *C. perfringens* numbers within the intestinal tract and the onset of intestinal clostridial disease in chickens may be precipitated by the nature of the ration (95, 106). Inclusion of cereal grains in the ration like wheat (18), barley (68) or rye (70, 123) that are rich in water-soluble non-starch polysaccharides can predispose or exacerbate outbreaks of NE. In chickens fed wheat diets, the severity of NE lesions was reduced with the addition of dietary fiber and complex carbohydrates (17).

Additionally, rations containing high levels of protein, specifically protein derived from animal sources, may predispose birds to necrotic enteritis (37, 66, 70, 128). More specifically, it appears that the higher relative glycine content in animal-derived proteins relative to plant-derived proteins may trigger the proliferation of *C. perfringens* and the up-regulation of the genes controlling toxin production (34, 37, 135).

The mechanisms through which these predisposing factors enhance the growth of *C. perfringens* and the incidence of NE are unclear. These factors create conditions which stimulate the secretion of intestinal mucus which then induce the proliferation of mucolytic bacteria within the intestinal lumen (24). Mucolytic bacteria provide substrates favorable for the proliferation of *C. perfringens*.

Genetic resistance to NE influenced by major histocompatibility genotype and background genome has also been suggested (116).

In turkeys, NE has been reported in association with coccidiosis (38), ascaridiasis (99), and clinical hemorrhagic enteritis (39). Gender also appears to be a risk factor for NE, as significantly more male turkey flocks than female flocks were diagnosed (39).

Diagnosis

Isolation and Identification of Causative Agent

Diagnosis of NE can be made based on typical gross and microscopic lesions and isolation of the causative agent. In field cases of NE, *C. perfringens* can be isolated readily from intestinal con-

tents, the scrapings of intestinal wall, or hemorrhagic lymphoid nodules by anaerobic incubation overnight at 37°C on blood agar plates (44). Identification of *C. perfringens* can be done as described under "Etiology." Some commercially available media may not be formulated adequately for selective cultivation and enumeration of *C. perfringens* unless used in combination with other tests for specific identification (33).

Using a sandwich ELISA technique for screening, a difference in the number of *C. perfringens* and the amount of toxin present when comparing sick and healthy birds was demonstrated (87). A polymerase chain reaction (PCR) method for quantification of *C. perfringens* (138) and for the detection of the alpha-toxin gene within *C. perfringens* isolated from the gastrointestinal tract of chickens has also been reported (71).

Differential Diagnosis

Diseases that must be differentiated from NE are ulcerative enteritis (UE), *Eimeria brunetti* or *Eimeria maxima* infection. Ulcerative enteritis is caused by *C. colinum* (see "Ulcerative Enteritis"). Characteristic gross lesions are multiple areas of focal necrosis and ulceration in the distal small intestine and ceca and areas of necrosis in the liver. As described previously, lesions of NE usually are confined to jejunum and ileum with little or no involvement of ceca. These distinguishing characteristics should allow differentiation of NE and UE. Isolation and identification of the causative agent will confirm the diagnosis. *E. brunetti* infection (see "Coccidiosis," in Chapter 28) causes gross lesions similar to those produced by *C. perfringens*; however, microscopic examination of fecal smears, impressions, or intestinal sections should demonstrate the presence or absence of coccidia. Finally, NE and coccidiosis often occur concurrently in a flock. Therefore, demonstration of one or both agents is necessary for an accurate diagnosis.

Intervention Strategies

Because the sub-clinical and mild forms of NE are so detrimental to efficient performance, management of the disease should focus on controlling those factors which most put flocks at risk: coccidiosis, dietary factors and litter condition. In cases of clinical NE, early detection and treatment are necessary to prevent "seeding down" of the environment.

Management Procedures

Where a high environmental challenge exists (high soil spore counts) and repeat outbreaks occur, the addition of NaCl to poultry house dirt floors (60–75#/1000 ft^2) following a thorough clean out may prevent recurrence of the disease. Others have reported that placing birds on acidified litter aids in reducing horizontal spread of *C. perfringens* in chickens (49). Cleaning and disinfection of live haul containers with either 5% sodium hypochlorite solution or 0.4% quaternary ammonia solution have been shown to significantly reduce *C. perfringens* recovery (88).

Vaccination

Active and passive immunity through vaccination against *C. perfringens* and its toxins appears to offer good protection against infection. Immunization of chickens with a virulent strain of *C. perfringens* followed by an antibiotic treatment protected birds against a challenge infection with *C. perfringens*. Protection was also induced through oral vaccination with a live alpha-toxin-deficient isolate of *C. perfringens* (125).

The C-terminal of the alpha-toxin protein derived from avian *C. perfringens* isolates has been shown to be highly conserved (114). Antibody produced against this highly conserved region of the protein has been shown to provide protection in other species (137), and it is speculated that it may have the same effect in poultry (46, 114). Others have shown that immunization of broiler breeders with alpha-toxin vaccines produces an antibody response that appears to be protective in progeny against sub-clinical *C. perfringens*-associated NE and hepatitis (82).

Vaccination against coccidiosis may indirectly prevent the development of NE since the presence of *Eimeria* species is a predisposing factor (131, 136).

Competitive Exclusion, Probiotics, and Prebiotics

Experimentally, competitive exclusion treatments have been shown to be effective in lowering numbers of *C. perfringens* in the intestinal tract (75) while also reducing the number of gross lesions, mortality and performance losses associated with NE infections (30, 41, 58, 59, 60). The addition of mannan-oligosaccharide in addition to administration of a lactic acid-producing bacterial culture also was effective in reducing NE-associated mortality and its sub-clinical effects on performance (58). Others have shown that administration of probiotics, such as *Lactobacillus acidophilus* and *Streptococcus faecium*, reduce the severity of NE (47). *Bacillus subtilis* strains have been shown to produce bacteriocins which inhibit the growth of *C. perfringens in vitro* (124). Dietary lactose supplementation has also been shown to reduce cecal carriage of *C. perfringens* in chickens (123).

Under field conditions, treatment with a commercial competitive exclusion product was associated with improvement in intestinal health, delayed proliferation of *C. perfringens* within the intestine and delayed appearance of *C. perfringens*-associated lesions (69).

Other compounds have been investigated as potential preventive or therapeutic agents for NE. The administration of ß-mannanase to experimentally infected chicks significantly reduced the severity of the NE infection (63). Essential oil blends derived from plants have also been shown to control *C. perfringens* colonization and proliferation in the intestine of chickens (91).

Antibiotics and Anticoccidials

A number of antibiotics placed in the feed have been shown to reduce the numbers of *C. perfringens* shed in feces of chickens (119, 121, 122). These include virginiamycin, tylosin, penicillin, ampicillin, bacitracin, and furazolidone. *In vitro* antimicrobial susceptibility has also been documented for *C. perfringens* isolates from commercial turkeys and broilers (132).

Outbreaks of NE have been effectively treated with the administration of lincomycin (55, 56), bacitracin (105), oxytetracycline (7), penicillin (73, 78), and tylosin tartrate (73) in the water.

Bacitracin (104, 133), lincomycin (86), virginiamycin (35, 51), penicillin (95), avoparcin (68, 93, 104), nitrovin (94) and tylosin (19, 24) have been shown to be effective in preventing and controlling NE when placed in the feed. One survey of field isolates from clinical NE outbreaks, however, found resistance to bacitracin and lincomycin but sensitivity to virginiamycin and penicillin (31). In studies done following the removal of growth enhancing antibiotics in Scandinavia, isolates were found to be sensitive to the antibiotics ampicillin, avilamycin, erythromycin, tylosin, vancomycin, bacitracin and virginiamycin and the ionophore anticoccidials, lasalocid, maduramycin, monensin, narasin and salinomycin (64, 85). Monensin has been shown to provide a protective effect against infection through altering the microbial ecology of the ileum; reducing ileal lactobacilli populations and increasing *C. lituseburense* and *C. irregularis* populations (84). In this case it was suggested that the non-*C. perfringens* clostridia actually competitively exclude *C. perfringens*.

Botulism
John E. Dohms

Introduction

Botulism is an intoxication caused by exotoxins of *Clostridium botulinum.* Synonyms are "limberneck" and "Western duck sick-

ness." Free-ranging and confinement-reared poultry and feral birds can be affected. Most avian cases are caused by *C. botulinum* type C, although outbreaks due to other toxin types have been described (5, 42).

The public health significance of avian type C outbreaks is considered minimal (5, 33). Four human type C botulism intoxi-

cations have been reported but are not well documented (29, 33). No human cases of type C botulism have been associated with concurrent outbreaks of avian botulism (33, 63). Nonhuman primates, however, have succumbed to type C botulism after toxin inoculation (65) and captive monkeys died after eating chicken contaminated with type C toxin (60).

History

Botulism was first reported in chickens in 1917 (13). Both chickens and humans developed the disease after ingestion of home-canned vegetables. Western duck sickness, first recognized in the United States in the early 1900s, was later found to be caused by *C. botulinum* type C toxin (23, 34). Botulism in chickens following ingestion of *Lucilia* fly larvae was reported in 1923. The first *C. botulinum* type C strains also were isolated from these invertebrates (4). For additional historic information, see (9, 15, 40, 55).

Incidence and Distribution

The disease has affected poultry and waterfowl worldwide (33). Although many early cases occurred in free-ranging poultry, and modern methods of poultry husbandry were thought to have reduced the incidence of botulism by preventing access to toxin-contaminated food, severe cases have been reported in confined broiler flocks (5, 15, 28, 49, 50, 52, 53, 61). All types of wild birds and both avian and mammalian predators and scavengers have been affected during type C botulism outbreaks in wild birds (33). In these outbreaks, ducks have been most often affected (55). Botulism has been reported in pheasants reared on game farms (55). Botulism in ducks, broiler chickens, and pheasants occurs more frequently and with greater severity during warmer months. However, outbreaks in broiler chickens also have been reported in winter (17, 51).

Etiology

C. botulinum is a gram-positive, spore-forming bacterium capable of elaborating potent exotoxins under appropriate environmental conditions (42).The species consists of a diverse group of anaerobic bacteria including 4 cultural (1–IV) and 8 antigenically different toxigenic groupings (A, B, C alpha, C beta, D, E, F and G). Human disease has been associated mainly with types A, B, E, and F, while A, C, and E have caused disease in birds (62). Cases of botulism in chickens, ducks, pheasants, and turkeys in natural or commercial settings have been caused primarily by type C toxigenic group (15, 55, 61).

Morphology and Staining

The gram-positive cells of *C. botulinum* type C measure 4–6 $\times$ 1.0 um, often occurring singly or in short chains. The vegetative cell is motile. Subterminal or occasional terminal endospores are present in aging cultures (42). A cell-wall lysin is responsible for rapid autolysis of the organism and causes gram-variable staining in older cultures. Toxin is released during autolysis (7). Type C spores are more easily heat inactivated than type A and B spores

(42) but are more resistant to heat than type E spores (58). The time required to cause a 10-fold reduction in spore viability at 101°C (D value) was 2.44 min for a terrestrial type C strain (58).

Culture group III contains nonproteolytic or weakly proteolytic type C and D toxigenic types (30, 63). *C botulinum* requires available water content (a_w) of 0.92 for growth and toxin production (52). The type C toxigenic group is further subdivided into C alpha and C beta subtypes based on their toxigenic properties (42).

Toxins

Botulism exotoxins are among the most potent toxins known (39). Type C toxin is produced under anaerobic conditions at temperatures between 10° and 47°C with optimal toxin production between 35 and 37°C (42). The neurotoxins action occurs at the peripheral cholinergic nerve terminus. The neurons action occurs at the peripheral cholinergic nerve terminus.

Type C alpha cultures produce three toxins; C1, C2, and small amounts of type D toxin (20). C1 and D toxin production is mediated by bacteriophage. Type C strains, cured of their prophage, can be converted to type D organisms by infection with phage purified from type D strains. The reciprocal is also true (20). Type C beta strains, lacking bacteriophage encoding C1 and D toxins, produce only C2 toxin; genes encoding C2 toxin are not phage associated (20). Because of the interconverabilty of C and C beta strains, the relevance of C alpha and C beta toxigenic grouping has been questioned (20).

C1 and D, together with A, B, E, and F toxins, are synthesized as single nontoxic progenitor polypeptides that are later cleaved by proteases to produce 150-kD dichain neurotoxins (44, 59, 64). The progenitor type C toxin is associated with a nontoxic non-hemagglutinin and hemagglutating proteins which increase resistance to acid and protease degradation. However, at the mildly alkaline pH of the small intestine, a protease-sensitive loop is cleaved, producing a 100-kD heavy chain and a 50-kD light (L) chain, held together by an interchain disulfide bond. The active domains include H_N, a membrane translocation domain, H_C, a neurospecific binding domain, and L, a Zn^{+2} -dependent metalloproteinase (44). After binding to a specific receptor in the presynaptic membrane, the molecule is captured within an endocytic vesicle and acidified by a vacuolar ATPase proton pump which permits translocation into the cytosol. Reduction inside the cytosol produces the active metalloproteininase specific for two components of the presynaptic neuromuscular junction, syntaxin and SNAP-25. The outcome is persistent loss of acetylcholine release, and because acetylcholine receptors are not stimulated, muscle paralysis occurs (44).

Binary C2 toxin, although not neurotoxic, requires trypsin activation causing increased membrane permeability in a variety of cultured tissues (46, 59). The active toxin contains 2 distinct proteins, a binding and translocation protein (C2II) and an actin-ADP-ribosylating enzyme (C2I). The C2I enzyme ADP-ribosylates G actin at Arg-177, which inhibits actin polymerization and actin ATPase activity and converts actin into a capping protein that binds to actin filaments and prevents fast polymerization (1, 21, 66). It also complexes with gelsolin, altering its in-

teraction with actin (6). The C2 toxin is cytolytic in cultured cells and causes changes in the actin cytoskeleton, depolymerization of actin filaments, and cell rounding (6). Toxicity requires C2II attachment to asparagines-linked complex carbohydrate receptors after the trypsin dependent cleavage of an N terminal 20-kDa fragment (46). The trypsinized component forms heptomers that produce channels in artificial membranes. The complex is endocytosed, and the C2I enzyme translocates into the cytosol disrupting actin. Nucleic acid sequence of C2 toxin shows sequence similarity with other actin-ADP-ribosylating toxins from other *Clostridium* and *Bacillus* species (6). *C. botulinum* C2 toxin shows homology to the *Bacillus anthracis* protective antigen, which translocates edema factor, adenyl cyclase, and lethal factor into the cytosol (6).

Ducks and geese inoculated intravenously with C2 toxin showed cardiopulmonary symptoms (32, 46). In mice, C2 toxin has enterotoxic properties (46). The role of C2 toxin in natural botulism outbreaks is presently unclear.

Chickens, turkeys, pheasants, and peafowl are susceptible to types A, B, C, and E but not D or F toxin (25). Chickens are most sensitive to types A and E given intravenously but relatively resistant to type C1 intoxication (16, 25, 43, 52, 53). In contrast, ducks and pheasants are more susceptible to C1 toxin (25, 27). Compared with other toxins, C1 and C2 are more readily absorbed by chickens when given orally (25). As broiler chickens age, they become less susceptible to C1 toxin. At hatching the chicken lethal dose-50% (LD$_{50}$) was $10^{3.0}$ mouse-LD$_{50}$ per kg body weight compared with $10^{6.3}$ mouse-LD$_{50}$ per kg body weight at 8 wk of age (16).

Pathogenesis and Epidemiology

Natural and Experimental Hosts

Type C botulism has occurred in many species of birds including chickens, turkeys, ducks, pheasants, and ostriches (2). In wildlife outbreaks, 117 avian species in 22 families have been affected (32). Outbreaks in aviaries have occurred (61, 63). Mammalian species affected by type C toxin include mink, ferrets, cattle, pigs, dogs, horses, and a variety of zoo mammals (42). Fish succumbed to type C botulism during outbreaks on fish farms (63). Type C botulism in ruminants fed poultry manure has caused serious economic loss (19). Laboratory rodents are fully susceptible to type C toxin; mice are useful in the bioassay for toxin detection and typing.

In a study of 27 outbreaks in broiler chickens, ages ranged from 2 to 8 wk with a mean of 6.2 ± 1.7 wk (17). Outbreaks in older broiler chickens have been reported (5). Paradoxically, at these ages broiler chickens are relatively resistant to C1 toxin (16).

Incubation Period

Experimental subcutaneous, intravenous or oral inoculation of type C toxin in chickens and ducks produced clinical signs identical to those observed in field outbreaks. Morbidity and mortality were dose related. With high levels of toxin, disease appears within hours. With low toxin doses, onset of paralysis occurs within 1–2 days (16, 25, 27, 31).

22.5.   Botulism in chickens showing paralysis of wing and lower eyelid, difficult breathing caused by partial paralysis of respiratory muscles, and ruffled hackle feathers.

Transmission

C. botulinum type C is distributed worldwide wherever large populations of wild and domestic birds are found. Type C organisms readily grow in the gastrointestinal tract of birds and are considered obligate parasites (63). Type C spores are commonly found in and around poultry and pheasant farms (17, 38, 61, 62). Presence of organisms in the gastrointestinal tract of wild and domestic birds and resistance of spores to inactivation favor spread of this organism (17, 33).

Signs

Clinical signs of botulism in chickens, turkeys, pheasants, and ducks are similar (9, 15, 31, 55).In chickens, flaccid paralysis of legs, wings, neck, and eyelids are predominant features of the disease. Paralytic signs progress cranially from the legs to include wings, neck, and eyelids. Initially, affected birds are found sitting and are reluctant to move. If coaxed to walk, they appear lame. Wings droop when paralyzed. Limberneck, the original and common name for botulism, precisely describes the paralysis of the neck (Fig. 22.5). Because of eyelid paralysis, birds appear comatose and may seem dead. Gasping has been reported when birds are handled. Death results from cardiac and respiratory failure (63).

Affected chickens have ruffled feathers, which may fall out with handling. Quivering of certain feather tracts has been ob-

served. Broiler chickens showing signs of botulism may have diarrhea with excess urates in the loose droppings.

Morbidity and Mortality

Morbidity and mortality are related to the amount of acquired toxin. Low levels of intoxication produce little mortality and morbidity, which can confuse diagnosis. In severe cases, up to 40% mortality has been observed in broiler flocks (15, 51).

Western duck sickness is one of the most devastating diseases of waterfowl. Mortality, although difficult to estimate in wild birds, was reportedly greater than 100,000 birds on separate occasions (9, 33). Such losses have major impact on wildlife populations (33). In other cases, outbreaks in small lakes have been limited to the relatively few waterfowl in these habitats (3, 61). Mortality of pheasants reared on game farms has been as high as 40,000 birds (55).

Pathology

Birds with type C botulism lack gross or microscopic lesions. Occasionally, maggots or feathers can be found in the crop or affected birds.

Pathogenesis

Type C botulism can be caused by ingestion of preformed toxin. Because the organism is widely distributed in the gut, dead birds provide conditions for *C. botulinum* growth and toxin production. Greater than 2000 minimum lethal doses (MLD) of type C toxin per gram of carcass tissue have been found (5). Birds scavenging such carcasses can readily obtain enough toxin to become affected. Fly-blown carcasses may have maggots containing varying levels of botulism toxin. Maggots have been found to contain from 10^4–10^5 MLD of toxin (61). Maggots are readily devoured by chickens, pheasants, or ducks, which can lead to explosive botulism outbreaks. In aquatic environments, small crustaceans and insect larvae may contain *C. botulinum* in their gut. If large numbers die due to oxygen depletion, toxin can be produced within these invertebrates. Ingestion of toxin laden invertebrates has been proposed as the cause of type C botulism in ducks (55, 68). Lakes with shallow sloping banks that experience dramatic fluctuations in water level are most commonly associated with botulism outbreaks (33, 68).

Botulism caused by A and E occurs rarely and generally has been associated with consumption of spoiled human food products fed to backyard chicken flocks (40). Botulism in sea gulls, loons, and grebes was caused by eating dead or dying fish contaminated with type E toxin (42). A case of type A botulism in broiler chickens was due to a contaminated feed source (12).

The pathogenesis of botulism was once exclusively thought to be due to ingestion of preformed toxin. There is growing evidence that *C. botulinum* type C elaborates toxin *in vivo* to cause disease (61). The term *toxico-infection,* originally used by Russian researchers, was adapted to describe this form of the disease in broiler chickens (51, 63). In two cases of type C botulism in broiler chickens, carcasses were implicated as the source (5, 28). In the majority of broiler chicken outbreaks however despite comprehensive searches, no toxin sources have been identified

(17, 26, 49, 57, 61). The disease pattern in many of these outbreaks was inconsistent with food or water as toxin sources. Dead carcasses could not account for intoxications.

Type C botulism was reproduced in leghorn chickens and pheasants fed botulinal spores. Chickens and pheasants with their ceca ligated had a lower incidence of disease following spore challenge (38, 43) suggesting the cecum as the site of toxin production. In pheasants, the crop supported toxin production (14). Attempts to reproduce the toxicoinfectious form of botulism in broiler chickens have in the past been unsuccessful (15, 38). Toxin has been produced in the cecum of broiler chickens, but not at levels sufficient to kill the host (38). Chickens treated with the immunosuppressive drug cyclophosphamide before *C. botulinum* type C spore inoculation showed cecal colonization and reproduction of clinical botulism, perhaps suggesting that stress or viral induced immunosuppression might predispose chickens to the disease (48). An environmental, bacterial, phage, and/or host interaction may be required for toxicoinfections botulism to occur in broilers.

Immunity

Because the toxigenic dose is lower than the immunogenic dose, chickens and ducks recovering from botulism do not develop immunity (8, 25). However, carrion-eating crows and turkey vultures possessed antibodies to botulinal toxin (39, 47). This may partly explain why vultures were resistant to experimental inoculations of toxin (35).

Diagnosis

The differential diagnosis of botulism is based on clinical signs and lack of gross or microscopic lesions. Definitive diagnosis requires detection of toxin in serum, crop, or gastrointestinal washings from morbid birds (15, 63).

Serum is the preferred diagnostic sample. Because *C. botulinum* is found in the gut of normal chickens, toxin can be produced in decaying body tissues. Therefore, finding toxin in tissues of dead birds does not confirm botulism.

The mouse bioassay is a sensitive and reliable method for confirming heat-labile toxin in serum (15). Groups of mice are inoculated with suspect serum samples. Other mice receive samples inoculated with suspect serum samples treated with type-specific antiserum. If toxin is present in the sample, signs and death of mice given untreated samples usually occur within 48 hr. Mice inoculated with antitoxin will be protected. Other *in vitro* methods of detecting toxin have been reviewed (45). An antigen-capture ELISA assay for *C. botulinum* type C toxin was able to detect 0.25ng/ml toxin compare to 0.12ng/ml detection using the mouse bioassay. However, using larger sample volumes in ELISA proved to be as sensitive to the mouse test due to the concentrating effect of the capture antibody (54).

In waterfowl and some poultry outbreaks, toxin levels in blood may be too low to produce disease in mice. Concentration of serum or repeated inoculation of mice with suspect serum may be required to demonstrate toxin in these cases (27). More recently a sensitive and specific immunoassay for type C and D was developed alleviating the use of the mouse bioassay (22).

In advanced stages of the disease, clinical signs are obvious; during mild intoxications, only leg paralysis may be observed. The mild form of the disease must be differentiated from Marek's disease, drug and chemical toxicity, or appendicular skeletal problems. In these cases, the mouse bioassay is particularly helpful in diagnosis. Eyelid paralysis is a key sign differentiating botulism from other conditions. Botulism in waterfowl must be differentiated from fowl cholera and chemical toxicities. Lead poisoning of waterfowl is commonly confused with botulism (55, 63).

Isolation of *C. botulinum* requires anaerobic culturing and is of little help in diagnosis (30). The organism is widely distributed in gut, liver, and spleen of clinically normal chickens (16). Detection of the organism, however, in feed or environmental samples may prove useful in epidemiologic studies. The organism can be demonstrated in samples inoculated into cooked-meat medium and inoculated anaerobically at 30°C (11). After 3–5 days incubation, toxin can be detected using mouse bioassay with specific typing antitoxins. Other modifications of this procedure are available (30, 63). The organism can be detected using the fluorescent antibody technique (41).

Treatment

Many sick birds, if isolated and provided with water and feed, will recover. Treatment of large numbers of morbid birds, however, is difficult, and various protocols have been used but not verified experimentally. The success of these treatments is hard to establish because of the difficulty in experimentally reproducing toxicoinfectious botulism. The patterns of disease in untreated broiler houses can rise and fall during a given outbreak (17). Therefore, it is difficult to know whether a particular treatment is effective, or, if by chance, treatment precedes a drop in mortality that would have occurred anyway. However, several treatments have been reported to be of benefit. Treatment of affected broiler flocks with sodium selenite and vitamins A, D₃, and E reduced mortality (57). Antibiotics including bacitracin (100 g/ton in feed), streptomycin (1g/L in water), or periodic chlorotetracycline treatments also reduced mortality (55). Penicillin was ineffective in controlling one outbreak (49) but has been found efficacious in other affected flocks (51). *In vitro* susceptibility of *C. botulinum* to 13 antibiotics include tetracycline, metronidazole, erythromycin, penicillin, rifampin, chloramphenicol, clindamycin, cephalothin, cefoxitin, and vancomycin (56).

Inoculation with specific antitoxin neutralizes only free and extracellular bound toxin and might be considered for treating valuable birds in zoologic collections. Ostriches showing clinical signs of botulism responded favorably within 24 hr after treatment with type C antitoxin (2). This is impractical in commercial poultry, duck, or pheasant outbreaks.

Prevention and Control

Management practices should emphasize removal of potential sources of the organism and its toxin from the environment. Prompt disposal of dead birds and culling of sick birds is very important in prevention and control. In problem areas, removal of contaminated litter and thorough disinfection using calcium hypochlorite, iodophor or formalin disinfectants may help reduce spore numbers in the environment (56). In houses with dirt floors, complete destruction of these spore formers is difficult. Disinfection of areas around poultry houses has been recommended (56). Spores may be located in soil outside of the poultry facility and can be transported back into houses. Fly control may be another means of reducing the risk of toxic maggots in the environment. During outbreaks, it has been suggested that feeding lower energy diets reduces mortality caused by toxicoinfectious botulism (57). Two cases of type C botulism were reported in commercial broilers and were associated with elevated intake of iron from water and feed sources, iron having been shown to promote the proliferation of many enteric bacteria including *C. botulinum* (50). In the first case, the outbreak took place in a house where water was drawn from a well with elevated iron levels (1.35 ppm), while an adjacent house with a different well source (iron level 0.66 ppm) was botulism-free. In the second case type C botulism outbreaks occurred on farms geographically separated but operated by the same company. Elevated iron was found in the drinking water on one farm while on the second affected farm, broiler feed contained 34,000 ppm iron. To confirm the relationship of iron and botulism, experimental reproduction of toxicoinfectious type C botulism must be demonstrated. Acidification of drinking water with citric acid has been suggested as a method of lowering gut pH which promotes more favorable growth of normal flora, inhibits *C. botulinum* growth and acts as a heavy metal chelator (10, 11, 24, 36, 50, 67).

Immunization

Active immunization with inactivated bacterin-toxoids has been successfully used in pheasant operations (37). Similarly formulated toxoids protect chickens and ducks from experimental botulism (8, 18). Vaccination of large numbers of broiler chickens is costly and vaccination of wildfowl is not practical.

Gangrenous Dermatitis
Kenneth Opengart

Introduction

Definition and Synonyms
Gangrenous dermatitis (GD) is a disease of chickens and turkeys caused by *Clostridium perfringens* type A*, C. septicum or Staphylococcus aureus*. The disease is characterized by a sudden onset of acute mortality. The primary lesion in affected birds is necrosis of the skin and subcutaneous tissue, usually involving the breast, abdomen, wing or thigh. Gangrenous dermatitis has also been referred to as necrotic dermatitis, gangrenous cellulitis, gangrenous dermatomyositis, avian malignant edema, gas edema disease, wing rot, and, in some instances, blue wing disease—a component of CIAV infection (7, 44, 53).

Economic Significance
The economic impact of GD is primarily related to the degree of GD-associated mortality that occurs within a flock. Gangrenous dermatitis usually affects mature broilers and turkeys and the economic losses due to the disease are, therefore, associated with any lost investment in production costs (chick/poult cost and feed) and the loss of income related to the reduction in marketable pounds.

Public Health Significance
Gangrenous dermatitis is a disease characterized by acute mortality, lesions which are localized rather than systemic and a relatively short incubation period. Most affected birds succumb quickly to infection and do not make it to processing age. Therefore, the public health significance of GD is thought to be minimal.

History
Severe necrosis of muscle and subcutaneous tissue following intramuscular inoculation of *Clostridium welchii* (*C. perfringens*) isolated from heart blood and liver of 2 chickens was first described in 1930 (41). The following year, *C. perfringens, C. sep-*

ticum, and *C. novyi* were isolated from a diagnostic case in which chickens were dying of wound infections following the collection of blood samples for pullorum testing (5). Death of turkey breeder hens from wound infections occurring during mating caused by *C. perfringens*, *C. septicum*, and *C. sordellii* was reported in 1939 (16). Since that time GD has been reported in chickens and turkeys throughout the world (2, 4, 6, 8, 9, 10, 11, 18, 19, 20, 27, 28, 29, 34, 38, 46, 48, 50).

Etiology

Classification

Causes of GD are *C. septicum* (18, 19, 27, 28, 34, 49), *C. perfringens* type A (4, 11, 54), and *S. aureus* (6, 9, 20, 34), either singly or in combination (19, 29, 34, 48), with combined infections generally being more severe. Frequency, severity of lesion production and resulting mortality depend upon the specific bacterial strains involved in the infection and their ability to produce toxins (55).

Morphology and Growth Requirements

Isolation and identification of *S. aureus* and *C. perfringens* have been described elsewhere (see Chapter 23, "Staphylococcosis" and "Necrotic Enteritis" in this chapter). Culture for *C. septicum* should be carried out anaerobically on blood agar plates containing 2.5% agar, which will reduce the swarming of *C. septicum* over the plate surface (17). Incubation is for 1–2 days at 37°C. Positive identification of the organism is made by inoculation of differential media (1).

Biochemical Properties

The biochemical properties of *S. aureus* and *C. perfringens* are described elsewhere (see Chapter 23, "Staphylococcosis" and "Necrotic Enteritis" in this chapter). *C. septicum* ferments glucose, maltose, lactose, and salicin but not sucrose or mannitol. Principal products of fermentation are acetic and butyric acids. Gelatin is hydrolyzed, milk is not digested and indole is not produced. Growth on egg yolk agar demonstrates an absence of lecithinase and lipase production. Clostridial spores are oval and located subterminally.

Pathobiology and Epidemiology

Incidence, Distribution, Hosts

While natural outbreaks of GD have been described in chickens from 17 days to 20 weeks of age, most have been reported in 4- to 8-week-old broiler chickens (4, 6, 9, 18, 19, 27, 28, 29, 34, 48). The disease has also been reported in 6- to 20-week-old commercial layers (19, 48), 20-week-old broiler breeders (20), and chickens following caponization (54). Subcutaneous emphysema in chickens, from which *C. perfringens* was isolated, was described in Israel in 1950 (46). Since 1963, there have been reports of gangrenous dermatitis from various parts of the world including the United States (19, 48), the United Kingdom (18), Germany (28, 34), Belgium (20), Argentina (4), New Zealand (38), Egypt (2) and India (10, 11, 50).

In turkey breeder hens, cellulitis and mortality associated with clostridia and gram-positive cocci infections have been reported (16). *Clostridium perfringens* type A has also been isolated from the tail and ventrum of market age commercial turkey flocks experiencing cellulitis and excessive mortality (8).

Experimental reproduction of GD in chickens (19, 27, 28, 34, 48) and turkeys (48) following intramuscular or subcutaneous inoculation of *C. septicum*, *C. perfringens* type A, or *S. aureus* has been reported to cause mortality and lesions similar to those that occur in naturally occurring outbreaks. Intramuscular inoculation with *C. septicum* isolated from chickens caused death in turkeys within 24 hours with circumscribed lesions at the inoculation site (48).

Transmission, Carriers, and Vectors

Clostridia are present in soil, feces, dust, contaminated litter or feed and intestinal contents (1, 33). Staphylococci are ubiquitous and common inhabitants of skin and mucous membranes of poultry and areas where poultry are hatched, reared, and processed (see Chapter 23, "Staphylococcosis").

Clinical Signs

Clinical signs in naturally occurring outbreaks of GD include varying degrees of depression, incoordination, inappetence, leg weakness, and ataxia (18, 19, 27, 28, 48). Because the period of illness is short, usually less than 24 hours, birds are often well-fleshed and hydrated. Mortality occurs acutely and can range from 1 to 60% (18).

Pathology

Gross

Gross lesions consist of dark reddish-purple, weepy areas of the skin, usually devoid of feathers. Affected areas usually include wings, breast, abdomen, or legs (see Figs. 22.4E, F) (11, 18, 19, 27, 28, 48). Extensive blood-tinged edema, with or without gas (emphysema), is present beneath the affected skin (Fig. 22.4G). Underlying musculature is discolored gray or tan and may contain edema and gas between muscle bundles. In some cases, emphysema and serosanguineous fluid are present in subcutaneous tissue, but there is no loss of integrity to the overlying skin (29). Most cases report no internal lesions; however, discrete white foci (necrosis) in the liver (9, 48) and small flaccid bursae of Fabricius (9, 29), the latter presumably due to IBD virus infection, have been reported in affected birds. In turkeys with cellulitis of the tail, edema and vesicle-like lesions were present laterally and ventrally around the tail. Tail feather shafts were soft, blood-filled, and were often broken (8).

Microscopic

Microscopic changes are characterized by edema and emphysema (Fig. 22.4H) with numerous large, basophilic bacilli or small cocci within subcutaneous tissues (9, 48). Severe congestion, hemorrhage and necrosis of underlying skeletal muscle are often present. Liver, if affected, contains small, randomly scattered, discrete areas of coagulation necrosis with intralesional bacteria. Bursal changes, in cases suspected to have concurrent

IBD, are characterized by extensive follicular necrosis and atrophy (9, 29).

Pathogenesis of the Infectious Process
Contributing Factors
In many instances, GD is believed to occur as a sequela to other diseases which produce immunosuppressive effects such as infectious bursal disease (IBD) virus, chicken infectious anemia virus (CIAV) (7, 23, 44, 53), reticuloendotheliosis virus (31), and avian adenovirus infections, including inclusion body hepatitis virus (9, 18, 29, 36, 40, 47). In addition, some outbreaks of GD have been reported to be breeder flock-associated (i.e., progeny from specific breeder flocks consistently develop GD) (21). Lack of antibody to IBD virus in broiler breeders correlates with increased susceptibility of their progeny to dermatitis (47).

Lesions characteristic of chicken infectious anemia virus-induced GD (blue wing disease) include intracutaneous, subcutaneous, and intramuscular hemorrhages and edema as well as atrophy of thymus, spleen, and bursa of Fabricius (14). Numerous avian reoviruses and CIAV have been isolated from chickens affected with blue wing disease (7, 14), and GD has been reproduced by dual infection with CIAV and a reovirus (15). Gangrenous dermatitis often occurs secondarily to the hemorrhages associated with blue wing disease. A compromised immune system is thought to be the underlying predisposing factor associated with GD in these birds (13, 25).

Environmental factors (high litter moisture due to poor litter quality, poor drinker management or poor ventilation) may also predispose flocks to GD, especially when they occur in conjunction with challenges from immunosuppressive viruses. Poor farm management, especially failing to remove dead birds from an area in a timely manner, may also predispose a flock to GD. Factors that lead to increased scratches, such as overcrowding, feed outages, meal time feeding, and bird migration in tunnel ventilated houses, can increase GD incidence (56). The incidence of GD has also been observed to be related to the season of the year with peak occurrence in the spring. In the absence of other predisposing factors such as immunosuppressive infectious agents and management factors, GD tends to be associated with certain strains or breeds, males more often than females, and flocks which perform above production standards. Affected farms tend to have repeat outbreaks.

Diagnosis

A diagnosis of GD can be confirmed with the presence of typical gross and microscopic lesions and the isolation of the causative agent(s). In field cases of GD, staphylococci and clostridia can be isolated from exudates of skin and subcutaneous tissue or underlying muscle (9, 11, 19, 28, 48). Identification of the causative agent(s) can be done as described under "Etiology." As mentioned previously, occurrence of GD often can be preceded by other infectious agents affecting the immune function of the bird. Diagnosis of an underlying etiology is often necessary to fully understand the complexity of GD infection.

Differential Diagnosis
A variety of skin conditions must be differentiated from GD. Contact or ulcerative dermatitis ("breast burn") of broiler chickens (24, 37) and plantar pododermatitis of turkeys (37) are conditions characterized by erosions and ulcers accompanied by acute inflammatory changes over the breast, hock, and plantar surface of the feet. A strong correlation between wet or poor litter and these conditions is present (37, 39). Infectious or inflammatory process (IP), a condition usually caused by *E. coli* in market age broilers involving the subcutaneous tissues of the abdomen, thigh, and leg, can also cause the dermis to appear reddened and edematous (22). However, this condition never has emphysematous lesions or mortality associated with it and is generally only a problem observed at the processing plant. Scabby hip dermatitis is a syndrome of broilers that, like contact dermatitis, is a nonspecific dermatitis with ulceration and secondary bacterial infection (26). Lesions have been correlated with high stocking densities which may cause feather breakage and scratches of the lumbar and sacral regions allowing entrance of bacteria into the dermis (26, 45). To differentiate GD from these conditions, demonstration of poor environmental conditions or overcrowding and the lack of an association with a primary immunosuppressive infectious agent must be demonstrated.

Squamous cell carcinoma (now known as avian keratocanthoma) which can lead to ulceration and infection of the epidermis may be difficult to differentiate from GD (52). Histopathology of the affected area may be necessary to differentiate the two conditions.

Additionally, a number of nutritional deficiencies and genetically slow-feathering male chickens may predispose birds to GD (12).

Dermatitis caused by mycotic agents *Rhodotorula mucilaginosa* (3), *R. glutins* (42), *Candida albicans* (35), and *Aspergillus fumigatus* (57) can be differentiated from GD by the demonstration of fungal elements in impression smears or tissue sections and by isolating and identifying the agent. Vesicular lesions involving the wattles, comb, shanks, and feet have been described in chickens (30, 43, 51) and have been suspected or proven to be due to the ingestion of the fungus *Cladosporium herbarum*, producing an ergot-like disease, or *Ammi visnaga* seeds, which lead to photosensitization. These lesions invariably occur only on unfeathered areas of the skin and should be differentiated easily.

Intervention Strategies

Management Procedures
Prevention has been accomplished by managing the placement of susceptible breeds on at-risk farms. Additionally, total clean out of farms, followed by thorough cleaning and disinfection of the house and floor, has helped resolve farms with historical problems. In these cases, large amounts of water mixed with a phenolic disinfectant (1500 gallons per 20,000 ft^2) have been used to achieve a saturation depth of 3–4 inches of the dirt floor pad. Treating the floor with salt at 60–100 pounds per 1,000 ft^2 prior to placement of bedding material also has decreased the incidence of GD on problem farms. Generally, management procedures to improve litter condition, reduce litter moisture, acidify litter pH, reduce bacterial levels in the environment and mini-

mize trauma are useful adjuncts to other prevention and control methods.

Vaccination

Administration of a mixed clostridial bacterin at 1 day of age has been shown to reduce losses in flocks due to GD (21). Similar results have been reported in 5-week-old chickens vaccinated with a mixed *E. coli*, *S. aureus* and *C. perfringens* bacterin following bacterial challenge with live cultures of the same organisms (32).

Treatment

Outbreaks of GD have been treated effectively with the administration of chlortetracycline (27), oxytetracycline (48), erythromycin (48), penicillin (9, 11, 29), or copper sulfate (2) in the water and chlortetracycline (28, 48) or furoxone (28) in the feed. However, in many instances, antibiotics used for control have proved to be of limited use (18, 20, 21, 34). Failure of antibiotic treatment can often be explained by the fact that an underlying immunosuppressive viral infection is usually a predisposing factor for GD. The birds, therefore, are unable to completely clear the bacterial infection even with the presence of an antibiotic. For this reason, modification of vaccine programs directed at immunosuppressive agents like IBD and CIAV may sometimes be used to combat widespread GD problems.

Water acidification, with citric and proprionic acid, have been used to reduce, but not eliminate, mortality in flocks where the rate of mortality does not dictate the use of an antibiotic or where antibiotics are no longer effective.

Chapter 23
Other Bacterial Diseases

Introduction
H. John Barnes

Collectively, bacterial diseases continue to be a significant cause of economic loss in the poultry industry. Those that are common, widespread, or of major public health significance are covered elsewhere in individual chapters. Diseases caused by bacteria that are sporadic or of limited occurrence are reviewed in this chapter. Significant losses from these diseases still may occur in an affected flock, or rarely an integrated company, but their impact on the entire poultry industry is not considered great. Enterococcal infections are included with streptococcal infections. Enterococci continue to increase in importance as use of growth promotants and antibiotics are being minimized (2, 8), and they have been associated with a variety of local and systemic diseases (1, 3, 5, 6, 9), while streptococcosis is rarely seen.

Bacteria that are isolated from sick or dead birds but have an unknown role, are infrequently associated with disease, or are primarily of public health significance have been grouped together in a concluding subchapter comprised of sections about each genus or disease. Readers are referred to earlier editions of *Diseases of Poultry* for information on *Bacillus anthracis* (anthrax), *Brucella, Cowdria, Coxiella, and Francisella* (tularemia). While infections of poultry and other birds with these organisms are possible, they either do not produce clinical disease or have not been reported recently. The section on turkey osteomyelitis complex has been moved to the chapter on colibacillosis to better reflect the nature of that disease and information on megabacteria, which is not a bacterium but a yeast (*Macrorhabdus*), and can be found in the chapter on fungal infections.

Improved methods of taxonomic classification based on genomics have resulted in removal of some bacteria from an existing genus and placement into a new one (e.g., *Actinobacillus salpingitidis,* avian *Pasteurella haemolytica*-like, or *P. anatis* placed into a new genus *Gallibacterium*) or creation of new genera or species for previously unnamed organisms (e.g., *Coenonia, Pelistega, Suttonella*). *Arcobacter* and *Helicobacter* are composed of bacteria that were formerly considered atypical campylobacters or campylobacter-like organisms. They have the same capacity as *Campylobacter* to cause food-borne illness in people but appear to be relatively innocuous for poultry (7). Knowledge concerning the host and geographic distribution, public health significance, disease associations, and species of helicobacters continues to expand. *Listeria* is another bacterium of considerable importance as a cause of human disease, but in poultry, it rarely causes clinical disease.

Some diseases such as beak necrosis, venereal disease of geese, and liver granulomas appear to have a bacterial cause, but because of their multifactorial nature, specific organisms have not been identified. Similarly, a microorganism consistent with a spore-forming bacterium has been seen in lesions in Muscovy ducks, but its identity remains unknown.

Bacteria can be primary pathogens, but this is infrequent compared to the roles they play as opportunists or co-pathogens. Often Koch's postulates cannot be fulfilled, even though a specific bacterium is associated with a lesion or disease. When many factors, in addition to an infectious agent, contribute to the cause of a disease, it may be impossible to duplicate the required conditions to reproduce it experimentally. In such situations, it may be possible to use Evans' postulates to document the role of a bacterium in such a disease (4).

Staphylococcosis

Claire B. Andreasen

Introduction

Staphylococcus infections are common in poultry. These infections are mainly caused by *Staphylococcus aureus*, although other species are occasionally involved (8, 19, 102, 112). The symptoms vary with the site of entry. The most frequent sites are the bones, tendon sheaths, and joints, especially the tibiotarsal and stifle joints (Table 23.1). Staphylococcal infections occur less frequently in other locations including skin (43, 56, 100, 102, 127), sternal bursa (121), yolk sac (131), heart (13), vertebrae (17), eyelid (19), and as granulomas in the liver and lungs (7, 77, 87). Infections are usually characterized by increased heterophil counts and marked heterophilic infiltration of tendons, synovial membranes, and other affected organs (4). Staphylococcal septicemia, causing acute deaths in laying birds (14), seems to be most prevalent in hot weather and resembles fowl cholera. The route of entry, pathogenesis, and host response are not completely defined. Staphylococcal disease is usually chronic and responds poorly to antimicrobial therapy or immunization.

Economic Significance

Staphylococcal infections are a worldwide problem in chickens and turkeys and cause economic losses due to decreased weight gain, decreased egg production, and condemnation of carcasses at slaughter (88). During the processing of turkeys, a high correlation between green-discolored livers and *S. aureus* has been made and termed green-liver osteomyelitis complex (12, 20). Although *S. aureus* is the most commonly isolated pathogen in this condition, *Escherichia coli* and numerous opportunistic bacteria have also been isolated from affected turkeys (12).

Public Health Significance

In addition to being a major disease-producing organism for poultry, approximately 50% of typical and atypical *S. aureus* strains produce enterotoxins that can cause food poisoning in human beings (41, 45, 53, 99, 113). Poultry-associated food poisoning can occur due to the contamination of poultry carcasses with these enterotoxin-producing *S. aureus* strains at processing. *S. aureus* strains from processed poultry are thought to be endemic to the processing plant or from the hands of workers in the plant (1, 71, 96, 115). The literature varies as to the origin of processing plant strains with biotyping indicating the passage of

human staphylococcal strains to poultry in processing plants; plasmid profiling indicates that endemic strains in the processing plant are introduced by incoming birds (35).

Methicillin-resistant *Staphylococcus aureus* (MRSA), which has emerged as an important human pathogen, may also be a concern in chicken meat (37, 73, 125). Methicillin-resistant strains of *S. aureus* are resistant to beta-lactam antibiotics including the semi-synthetic penicillins (125). Many isolates are also resistant to numerous other antibiotics including the fluoroquinolones. Although there have been no reports of transmission between poultry and humans, MRSA has uncommonly been transmitted between humans and companion animals or horses (9, 37, 75, 79, 103, 119, 120, 125, 126). The possibility of MRSA transmission to humans in foods of animal origin, including poultry, has also been proposed (73). MRSA has been reported in poultry. In Korea, where MRSA is common in humans, 421 of 1913 specimens from cattle, pigs, and chickens collected between 2001 and 2003 contained *S. aureus* (73). Three isolates from chickens, one from a suppurative area in the meat and two from joints, were MRSA. MRSA has also been isolated from raw retail chicken meat in Japan (65). In addition, it is theoretically possible for the *mecA* gene, which is responsible for methicillin resistance, to be transmitted between species of staphylococci found in animals and staphylococci found in humans (37). For this reason, methicillin-resistant species other than *S. aureus* can also be a concern in poultry. At one farm in Japan, *S. sciuri, S. epidermidis,* and *S. saprophyticus* all containing the *mecA* gene were isolated from the nares and skin of healthy chickens (61).

History

Staphylococcosis in poultry and other avian species has been recognized for more than 100 years; most early reports describe arthritis and synovitis (51, 57, 60, 78).

Etiology

Classification

The genus *Staphylococcus* contains approximately 36 species and 21 subspecies (40). It is the most important genus in the family Staphylococcaceae. The general term staphylococcus refers to the morphology of these microorganisms; in stained smears, they often resemble clusters of grapes. Other genera in the family in-

Table 23.1.   Staphylococcal-related infections in poultry.

Location	Age	Lesion	Usual outcome
Bone	Any, usually older	Osteomyelitis	Lameness
Joint	Any, usually older	Arthritis/Synovitis	Lameness
Yolk sac	Chicks, poults	Omphalitis	Death
Blood	Any	Generalized necrosis	Death
Skin	Young	Gangrenous dermatitis	Death
Feet	Mature	Bumblefoot	Lameness

clude *Gemella, Macrococcus, and Salinicoccus* (40). *Macrococcus* and *Salinicoccus* are considered to be nonpathogenic. *Gemella* spp. have, in rare cases, been involved in human disease (76, 118).

A number of *Staphylococcus* species have been isolated from the skin and nares of healthy poultry, including *S. aureus, S. epidermidis, S. xylosus, S. cohnii, S. lentus, S. saprophyticus, S. sciuri,* and *S. gallinarum* (31–33, 63, 90, 102, 109). *S. aureus* is the most common species isolated from poultry that are ill (13, 14, 17, 19, 56, 77, 87, 121, 131). Other species are also found occasionally and may in some cases be opportunists. In one outbreak of systemic illness, the major staphylococcal species isolated from the liver, blood, and hock of sick 6-week-old chickens included *S. lentus, S. simulans, S. cohnii, S. gallinarum,* and *S. capitis* (8). In this study, *S. aureus* was uncommon. *S. hyicus* has been associated with fibrinoheterophilic blepharitis in chickens and turkeys (19) and was isolated from 5 of 9 tibiotarsal growth plates of turkeys with stifle joint osteoarthritis (112). *S. sciuri, S. simulans, S. epidermidis, S. lentus, S. warneri, S. cohnii,* and *S. intermedius* have been reported from scabby hip lesions in broiler chickens (102). Other staphylococci found in human beings and domestic animals are not known to be important pathogens in poultry.

Morphology and Staining
Typical staphylococci are gram-positive, coccoid in shape, and found in clusters when grown on solid media. In liquid media, they may occur in short chains. Older cultures (> 24 hours) may stain gram-negative.

Growth Requirements
Staphylococci are readily isolated on 5% blood agar with growth evident in 18–24 hours.

Colony Morphology
S. aureus is considered to be the most pathogenic staphylococcal species in poultry and is isolated from the majority of clinical infections. Within 24 hours, aerobic growth of *S. aureus* results in circular, smooth, ß-hemolytic colonies, 1–3 mm in diameter, which are often pigmented white to orange (130). Colonies of coagulase-negative staphylococci are similar but are often gray to cream or white and nonhemolytic.

Biochemical Properties
S. aureus is aerobic, facultatively anaerobic, ß-hemolytic, usually coagulase-positive, catalase-positive, fermentative for glucose and mannitol, and gelatinase-positive. *S. hyicus* is similar biochemically to *S. aureus* but some strains have a delayed positive coagulase reaction. Most other staphylococci found in poultry are coagulase negative. Coagulase-negative staphylococci can be identified to the species level using panels of biochemical tests (23, 34, 68), automated systems (23, 66), or genetic testing (23, 26, 36, 44, 81, 110). However, this is infrequently done in clinical laboratories.

Susceptibility to Chemical and Physical Agents
Staphylococci are extremely hardy and remain viable for long periods of time on solid media or in exudates. Some strains are heat and disinfectant resistant (80). A resistance feature used to isolate *S. aureus* from heavily contaminated clinical material is its tolerance to high (7.5%) concentrations of NaCl (67, 97).

Antigenic Structure and Toxins
The antigenic nature of *S. aureus* is often complex. Strains may have a capsule consisting of glucosaminouronic acid, manosaminouronic acid, lysine, glutamic acid, glycine, alanine, or glucosamine; polysaccharide A consisting of linear ribitol teichoic acid, N-acetylglucosamine, and D-alanine; and protein-A, a cell-wall component that interacts nonspecifically with the Fc portion of immunoglobulin and may be a virulence factor. A variety of enzymes and toxins including hyaluronidase (spreading factor), deoxyribonuclease, fibrinolysin, lipase, protease, hemolysins, leukocidin, dermonecrotic toxin, hemolysins, exfoliative toxins, and enterotoxins also can contribute to a strain's pathogenicity and virulence (2, 6, 85, 130). Toxic shock syndrome toxin 1 (TSST-1) has also been found in *S. aureus* isolated from chickens, but there is currently no evidence that this toxin is directly linked to disease in poultry (65).

Strain Classification
Phenotyping techniques, such as biotyping and phage typing, have been used to classify poultry *S. aureus*. Biotyping can determine the origin and epidemiological connections of *S. aureus* isolates as host-specific (human being or domestic animal) ecovars (29, 52) or nonhost-specific biotypes (107). Phage typing has been used for poultry and human *S. aureus* strains (46, 104, 105, 106, 107). In poultry, phage typing has been used to determine the association between country of origin (Europe, Australia, Argentina, Japan) and pathogenic and nonpathogenic strains (46, 64, 104, 107, 116), but 2.2–25.8% of chicken *S. au-*

reus remain nontypable (107). Phages tend to be specific for *S. aureus* of poultry origin and cannot be used to type strains from other species (106). Genomic fingerprinting by pulsed-field gel electrophoresis is also a useful method for discriminating poultry *S. aureus* strains and for subtyping strains of avian phage groups or poultry-specific ecovars (16, 55, 107). This technique was able to type all chicken *S. aureus* strains, including those that were not phage typable (107).

Strains also have been classified using antibiotic susceptibility patterns, plasmid profiles (67), and serotyping based on capsular polysaccharides (25). Chicken capsular types were type 5 (91%) and type 8 (9%), and turkey capsule types were type 5 (33%), type 8 (38%), and nontypable (29%) (25).

Virulence Factors

Coagulase-positive isolates of *S. aureus* are considered to be pathogenic for poultry. Coagulase-negative strains are often non-pathogenic in poultry but can be pathogenic in some species.

Pathobiology and Epidemiology

Incidence and Distribution

Staphylococcus spp. are ubiquitous, normal inhabitants of skin and mucous membranes and are common environmental organisms where poultry are hatched, reared, or processed. Most staphylococcal species are considered to be normal flora, which suppress other potential pathogens through interference or competitive exclusion. Some have the potential to be pathogenic and produce disease, if allowed entry through the skin or mucous membranes.

Staphylococcus spp. and staphylococcosis have been associated with poultry throughout the world including Argentina (114), Australia (64), Belgium (27, 28), Bulgaria (10), Canada (88), China (18), Costa Rica (86), France (129), Germany (70, 71), Hungary (47), India (98), Italy (50), Japan (107), the Netherlands (96), Pakistan (117), Poland (133), Romania (84), Taiwan (122), the United Kingdom (116), and the United States (58).

Natural and Experimental Hosts

All avian species are susceptible to staphylococcal infections.

Transmission, Carriers, and Vectors

The pathogenesis of *S. aureus* infections is not completely defined, but for infection to occur, a breakdown in the natural defense mechanisms of the host must occur (2, 6). In most cases, this would involve damage to an environmental barrier, such as a skin wound or inflamed mucous membrane, and hematogenous dissemination where a locus of infection (e.g., osteomyelitis) is established, usually in the metaphyseal joint (10, 13, 24, 91). The open navel of newly hatched chicks leading to omphalitis, minor surgical procedures (e.g., trimming of toes, beak, or comb; removal of the snood), and parenteral vaccinations may offer additional means of entry for staphylococci.

Another type of host defense impairment occurs following infectious bursal disease (101), chicken infectious anemia, or possibly Marek's disease, in which the bursa of Fabricius or thy-

mus is damaged and the immune system is compromised. Under these conditions, septicemic staphylococcal infections can occur and cause acute death. Gangrenous dermatitis caused by *S. aureus*, either with or without *Clostridium septicum* (127), can be seen following early infectious bursal disease virus infection (43, 100).

Escherichia coli was discovered to be the predominant bacterial organism in the livers of turkeys immediately following challenge with virulent hemorrhagic enteritis virus (HEV). However, when livers of survivors were cultured 2 weeks post-exposure, *Staphylococcus* spp. were the predominant bacteria (92). This suggests HEV, and possibly other similar viral intestinal infections, may create portals of entry and provide the underlying basis for subsequent staphylococcal problems associated with older, commercial turkeys.

Susceptibility to staphylococcal infections also may be genetically influenced. Two related lines of New Hampshire chickens had significant differences in mortality following experimental infection (22). The avian major histocompatibility complex influences the susceptibility to staphylococcal skeletal disease in chickens (59).

Incubation Period

The incubation period is short. Experimentally, chickens can be readily infected by the intravenous route but not as well by the intratracheal or aerosol routes (58). In experimental infections of chickens, clinical signs were evident 48–72 hours following intravenous inoculation, but the severity of lesions was dose dependent (4). The ability to consistently produce experimental disease is dependent on the number of intravenously administered bacteria (4). At least 10^5 organisms/kg body weight are necessary (88, 89).

Clinical Signs

Early clinical signs include ruffled feathers, lameness in one or both legs, drooping of one or both wings, reluctance to walk, and fever (88). This can be followed by severe depression and death. Birds surviving the acute disease have swollen joints, sit on their hocks and keel bone, and are reluctant or unable to stand (39, 88). Clinical signs of septicemic staphylococcal infection and gangrenous dermatitis occur in birds in good condition and may be evident only because of increased mortality in the flock (14, 43, 100).

Morbidity and Mortality

Morbidity and mortality due to staphylococcosis is usually low, even in the face of septicemia, unless there has been massive contamination of chicks because of exposure to unusually high numbers of bacteria in the hatchery environment or through vaccination or service procedures. Reluctance to walk to feeders and waters can lead to debilitation and death. Several reports from diagnostic laboratories have indicated that *S. aureus* is the most common bacterial agent isolated from infected legs and joints (62, 69). The number of chickens that develop gangrenous dermatitis is low, but usually all chickens that develop lesions succumb to the infection (15, 43, 69).

Pathology

Gross

Gross lesions of osteomyelitis in bone consist of focal yellow areas of caseous exudate or lytic areas (Fig. 23.1A), which cause affected bones to be fragile. Bones and sites most frequently involved are the proximal tibiotarsus and proximal femur. Less commonly, the proximal tarsometatarsus, distal femur, distal tibiotarsus, proximal humerus, ribs, or vertebrae may be involved. In affected birds, the femoral head often separates from the shaft by a fracture through the neck when the coxofemoral joint is disarticulated (femoral head necrosis) (Fig. 23.1C) (88, 91).

Arthritis, periarthritis, and synovitis are common. Affected joints are swollen and filled with inflammatory exudate as the infection (osteomyelitis) extends from nearby metaphyseal areas (Fig. 23.1D) (83, 91). Spondylitis involving articulating thoracolumbar vertebrae may cause lameness indirectly because of the impingement on the spinal cord (17, 91).

Gross lesions of septicemic staphylococcal infection consist of necrosis and vascular congestion in many internal organs including the liver (Fig. 23.1E), spleen, kidneys, and lungs (14). Dark, moist areas under the skin with crepitation are seen in gangrenous dermatitis (14, 43). Following mild trauma, gangrenous dermatitis lesions develop on the wing tips of birds infected with chicken infectious anemia virus. This condition has been referred to as "blue-wing disease."

Staphylococcal-related hatchery infections are common and can cause increased mortality within the first few days after hatching. Chicks have wet navel areas and deteriorate rapidly. Internally, the yolk sacs are enlarged with abnormal color and consistency.

Plantar abscess ("bumblefoot") is a common infection seen in mature chickens that leads to massive swelling of the foot and lameness.

Partially, or less commonly, entirely green-discolored livers (Fig. 23.1F) have been associated with osteomyelitis and/or associated soft tissue lesions (e.g., arthritis, periarthritis, tenosynovitis) in commercial turkeys at processing; this condition is called green-liver osteomyelitis complex. Carcasses with lesions from which staphylococci or other bacteria are isolated also have liver discoloration, but frequently turkeys with liver discoloration do not have demonstrable osteomyelitis or associated lesions, or bacteria cannot be isolated from the lesions (12, 20).

Liver spots are another common cause of condemnation in commercial turkeys, but most affected livers yield no aerobic or facultatively anaerobic bacteria. In one study, *S. cohnii* and other staphylococci were isolated most frequently from the few culture-positive livers in 2 flocks with histories of high liver condemnation (95). Ascarid larval migration appeared to be the most likely cause of the liver lesions(95).

Microscopic

Histologically, staphylococcal lesions consist of necrosis; bacterial colonies are composed of large numbers of gram-positive, coccoid bacteria and heterophils (Fig. 23.1B) (6, 38, 48, 88). Supernatants from pathogenic *S. aureus* resulted in increased chemotaxis of heterophils compared to supernatants from non-

pathogenic *S. xylosus*; this appears to correlate with the heterophilic infiltrate seen in staphylococcal lesions (5). Long-standing lesions are primarily granulomatous.

Immunity

Neither active nor passive immunity appears to be effective in preventing *S. aureus* infections in poultry. It has been implied that specific antibody to *S. aureus* may promote the development of *S. aureus*-related infections in chickens (42, 49). Additionally, anti-staphylococcal antibodies may not significantly increase the opsonization and phagocytosis of *S. aureus* compared to the naturally exposed complement-activating cell wall materials during infection (3). Whole-cell bacterins and toxoids have not proven to be effective in other species (2, 6, 85). *S. aureus* vaccines directed against cell wall components, such as peptidoglycan and teichoic acid, or capsular polysaccharides have been used in other species with variable results (3, 108).

Diagnosis

Isolation and Identification of Causative Agent

Staphylococcosis is diagnosed by culturing suspected clinical material including exudate from joints, yolk material, and stab swabs of internal organs. The basic medium for growing staphylococci is blood agar (preferably sheep or bovine). Organisms grow well with colonies 1–3 mm in diameter within 18–24 hours. Most *S. aureus* strains are ß-hemolytic; other staphylococci are usually nonhemolytic. Heavily contaminated material should be streaked onto a selective medium inhibitory for gram-negative bacteria, such as mannitol-salt or phenylethyl-alcohol agar (67, 97, 130).

Most *S. aureus* colonies will be pigmented, while most other staphylococcal colonies are gray to white. Colonies should be selected and gram stained. Staphylococci are gram-positive cocci. Biochemical tests such as the catalase test can differentiate staphylococci from other gram-positive organisms such as *Streptococcus*. Coagulase and mannitol fermentation tests are useful in the presumptive identification of *S. aureus*. The coagulase test is commonly used to differentiate *S. aureus* from coagulase-negative staphylococci such as *S. epidermidis* (Table 23.2). A few other staphylococcal species including *S. intermedius, S. hyicus, S. lugdunensis, S. schleiferi*, and *S. delphini* may also be coagulase positive (11) but these species are uncommonly associated with clinical disease in chickens. Unlike most other staphylococci, *S. aureus* also ferments mannitol. Panels of

Table 23.2.   Differentiation of *Staphylococcus aureus* and *S. epidermidis.*

Characteristic	S. aureus	S. epidermidis

D. mannitol fermentation	+	–

biochemical tests (23, 34, 68) and genetic testing (23, 26, 36, 44, 81, 110) can be used for the definitive identification of staphylococci to the species level; however, this is rarely done in clinical laboratories. Commercially available systems can also be used (23, 66), but these systems may have difficulty identifying some species from veterinary specimens (124).

Serology

Serology is not generally used for the diagnosis of staphylococcosis, but a microtiter plate agglutination assay (3, 42) and an indirect immunofluorescent antibody titer assay have been described (3). Both have primarily been used in research.

Differential Diagnosis

Staphylococcosis can resemble infection with *E. coli, Pasteurella multocida, Salmonella gallinarum, Mycoplasma synoviae,* reoviruses, or any other infection of bones or joints that is hatchery-related, associated with mechanical trauma, or causes septicemia.

Intervention Strategies

Management Procedures

Any management procedure reducing damage to host defense mechanisms will help prevent staphylococcosis. Because wounds are a portal of entry for *S. aureus* into the body, interventions that decrease the risk of injury will also help prevent infection. Sharp objects such as splinters, jagged rocks, or metal edges that can cut or puncture the feet should be eliminated from areas where poultry are reared. Maintenance of good litter quality will reduce foot pad ulceration. Particular attention should be given to hatchery management and sanitation. *S. aureus* is ubiquitous, and conditions in incubators and hatchers are ideal for bacterial growth. Recently hatched and hatching chicks with open navels and immature immune systems can be infected easily, leading to mortality and chronic infections shortly after hatching. Prevention of early infections with infectious bursal disease virus and chicken infectious anemia virus also will help prevent staphylococcosis (101).

Poultry under mild stress are more resistant to experimental staphylococcosis than those not stressed (21, 54, 72, 88). Resistance is attributed to an increase in heterophil numbers, which occurs in birds under stress. The heterophil is thought to be the most important cell in controlling bacterial infections, particularly *S. aureus* (4, 89).

Vaccination

Staphylococcal bacterins have been ineffective in preventing infections in poultry (2, 6), but the use of live, avirulent vaccines based on the principle of bacterial interference have shown some promise. Avirulent *S. aureus* strain 502A has been used in humans to manage recurrent furunculosis and to abort nursery outbreaks (85). One strain of staphylococcus was shown to interfere with the colonization of chickens by other strains of *S. aureus* (30). Using the principle of bacterial interference, a live, avirulent vaccine for the prevention of staphylococcosis in turkeys has been developed. A naturally occurring, coagulase-negative, avir-

ulent *S. epidermidis* isolate, designated strain 115, that colonizes cells and tissues in the respiratory tract and prevents adherence of virulent strains of *S. aureus* is used (82). In addition to interfering with the colonization of virulent *S. aureus, S. epidermidis* 115 secretes a stable, antibiotic-like bacteriocin capable of inhibiting and killing virulent *S. aureus*. The vaccine is administered by aerosol at 1–10 days and again at 4–6 weeks of age. Use of strain 115 in commercial flocks has reduced the number of turkeys with staphylococcosis and improved overall health and survival. Similar results were found when strain 115 was used in chickens (58, 74, 82, 93, 94, 128).

Competitive gut exclusion using *Lactobacillus acidophilus* was attempted to exclude *S. aureus* from experimentally infected, germ-free chickens. The treatment was effective in reducing *S. aureus* counts in crop contents, but counts in the ceca and rectum were unaffected (123).

Treatment

S. aureus infection sometimes can be treated successfully, but sensitivity tests should always be performed, because antibiotic resistance is common (28, 31, 111, 132). Drugs used successfully for treatment include penicillin, streptomycin, tetracyclines, erythromycin, novobiocin, sulfonamides, lincomycin, and spectinomycin.

Streptococcus and Enterococcus

Stephan G. Thayer, W. Douglas Waltman, and Dennis P. Wages

Streptococcus

Introduction

Streptococcosis in avian species is worldwide in distribution, occurring as both acute septicemic and chronic infections with mortality ranging from 0.5%–50%. Infection is considered secondary, because streptococci may form part of the normal intestinal and mucosal flora of most avian species, including wild birds (5). Streptococci are ubiquitous in nature and commonly found in various poultry environments.

The previously published chapter on streptococcosis included streptococci in both Lancefield antigenic serogroups C and D. Lancefield group D *Streptococcus* spp. are commonly referred to as "fecal strep." The application of new bacteriologic techniques, especially DNA-DNA and DNA-rRNA hybridization has led to the reclassification of the Lancefield group D streptococci to the *Enterococcus* spp. (29, 64). In reviewing this chapter, the reader must keep in mind the change in reference nomenclature of both *Streptococcus* spp. and *Enterococcus* spp. Earlier studies and reports that identified bacteria by genus only could have been classified as *Enterococcus* spp. in present day classification instead of *Streptococcus* spp. When researching diseases caused by the Lancefield antigenic serogroup D, review "Enterococcosis" which follows.

History

Acute streptococcal infections of poultry were first described in chickens in 1902 (56) and 1908 (50) as apoplectiform septicemia. Chronic streptococcosis caused 50% mortality in a flock over a 4-month period (37) and was identified as the cause of mortality due to salpingitis and peritonitis in chickens (25). Streptococcosis in turkeys was reported as early as 1932 (78).

Bacterial or vegetative endocarditis associated with streptococci was first reported in 1927 (63) and again in 1947 (60). A more extensive historical review of streptococcosis can be found in Peckham (58).

Etiology

The genus *Streptococcus* is composed of gram-positive, spherical bacteria occurring singly, in pairs, or short chains, which are nonmotile, non-spore-forming, facultative anaerobes. They are catalase-negative and ferment sugars, usually to lactic acid. The relationship of these characteristics to pathogenicity is unknown. *Streptococcus* spp., isolated from avian species and associated with disease, includes *S. zooepidemicus* (occasionally referred to as *S. gallinarum*) from Lancefield antigenic serogroup type C, *S. bovis*, and *S. dysgalactiae*. A new species, *S. pleomorphus,* an obligate anaerobe in normal cecal contents of chickens, turkeys, and ducks, has also been described. Its possible role in disease for these species is undetermined (1). *S. mutans*, a common bacterium in the human oral cavity, has been associated with septicemia and mortality in geese. Contaminated drinking water and poor quality litter were possible predisposing factors (40).

Both experimental and naturally occurring infections of *S. bovis* causing acute septicemia and joint infections have been found in racing pigeons (20, 22).

S. dysgalactiae has been cultured from broilers with cellulitis, a condition observed on the skin and subcutaneous tissue at processing (77).

Streptococcus spp. has been isolated from lesions of osteomyelitis in turkeys, along with *E. coli* and *Staphylococcus* spp. (17).

Naturally occurring and experimental poultry infections resulting in bacterial endocarditis commonly are associated with streptococci and other bacteria. These include *S. zooepidemicus* (51), *S. gallinaceous* (11), *E. faecalis* (13, 25, 41), *E. faecium* (25, 65), *E. durans* (13, 25), *Staphylococcus aureus*, and *Pasteurella multocida* (33).

Pathobiology and Epidemiology

S. zooepidemicus occurs almost exclusively in mature chickens but has been documented as a cause of mortality in wild birds (41). Experimentally, rabbits, mice, turkeys, pigeons, ducks, and geese are susceptible.

Transmission of streptococci occurs most commonly via oral and aerosol routes. Transmission can occur, however, through skin injuries, especially in caged layers. Aerosol transmission of *S. zooepidemicus* results in acute septicemia in chickens. Incubation periods range from 1 day to several weeks, with 5–21 days being most common.

Endocarditis occurs when septicemic streptococcal infection progresses to a subacute or chronic stage (42).

Clinical Signs

With *S. zooepidemicus* infections, clinical signs are typical of an acute septicemic infection and include lassitude, bloodstained tissue and feathers around the head, yellow droppings, emaciation, and pale combs and wattles. Cyanosis in the terminal stages has also been described (58). Mortality can range from low to 50%. Chickens in production may have an egg production drop of as much as 15%.

Streptococcus spp. and *Staphylococcus aureus* have been isolated in cases of acute fibronopurulent conjunctivitis (10).

In pigeons, *S. bovis* infection produced the acute onset of mortality with occasional lameness, inappetence, diarrhea, and the inability to fly (20).

Pathology

Gross

Gross lesions of *S. zooepidemicus* in acute disease are characterized by splenomegaly, hepatomegaly (with or without miliary to 1 cm red, tan, or white foci), enlarged kidneys, congestion of subcutaneous tissue, and peritonitis. Subcutaneous and pericardial fluid may appear serosanguineous. Bloodstained feathers around the mouth and head with blood coming from the mouth have been described (50, 58). In pigeons, congestion of the spleen and liver with accumulations of fluid around the pectoral muscles has been observed (20). In broilers, cellulitis involving the skin and subcutaneous tissues observed at processing has been associated with both *Escherichia coli* and *S. dysgalactiae* (77).

Microscopic

Microscopically, the liver has dilated sinusoids congested with red blood cells and increased heterophils. If foci are present grossly, there are multiple areas of necrosis and/or infarction with heterophil accumulation and thrombosis.

In experimental inoculations of pigeons with *S. bovis*, leptomeningitis and encephalitis with diffuse heterophil infiltration and perivascular cuffing are common (20).

Lesions of chronic streptococcal infections include fibrinous arthritis and/or tenosynovitis, osteomyelitis, salpingitis, fibrinous pericarditis and perihepatitis, necrotic myocarditis, and valvular endocarditis (Fig. 23.2). Vegetative valvular lesions are usually yellow, white, or tan; are small; and have raised rough areas on the valvular surface (Fig. 23.3). Valve lesions most consistently

23.2.   *Streptococcus zooepidemicus* infection showing perihepatitis and peritonitis. (M. C. Peckham)
23.3.   Bacterial endocarditis showing vegetations of mitral valve (arrows).

23.4. Bacterial endocarditis, showing infarcts of liver and myocardium.

are found on the mitral valve, and less frequently are found on the aortic or right atrioventricular valve. Additional gross lesions associated with valvular endocarditis include enlarged, pale, flaccid heart; pale to hemorrhagic areas in the myocardium, especially at the base of the valves, below the affected valve, or apex of the heart; infarcts in the liver, spleen, or heart and, less commonly, infarcts in the lung, kidney, and brain. Infarcts can be light colored or hemorrhagic with sharp margins. In the liver, infarcts usually are located near the ventral and posterior margins and are well demarcated, extending beneath the capsule into the parenchyma (31) (Fig. 23.4). Lesions of longer duration tend to have a sharp, narrow, lighter colored band just inside the infarct margin (42).

Microscopically, valvular lesions consist primarily of fibrin with bacteria, heterophils, macrophages, and fibroblasts. There is interstitial edema and infiltrative valvular distortion, with focal deposition of platelets and fibrin and subsequent microbial growth (35, 42). Cardiac histiocytes (Anichkov's myocytes) are numerous in the fibrous portion of the valve. Events leading to the vegetative valve lesion are 1) edema that loosens the valve surface epithelium, 2) fibrin deposition, and 3) bacterial attachment to the fibrin and colony formation. Other microscopic lesions related to endocarditis include cerebral vasculitis and infarcts, leptomeningitis, glomerulonephritis, and thrombosed pulmonary vessels (42). Cerebral lesions usually are confined to the corpus striatum. Focal granulomas can be found in virtually any tissue as a result of septic emboli. Liver infarcts are characterized by portal venous thrombosis followed by necrosis. Aggregates of bacteria are present throughout necrotic areas with a zone of heterophils just within the necrotic border, a characteristic feature of the lesion (Fig. 23.5). Gram-positive bacterial colonies are observed readily in thrombosed vessels and within necrotic foci with tissue gram stains.
23.5. Margin of liver infarct associated with bacterial endocarditis, showing clumps of bacteria (arrows), necrotic area (N), zone of necrotic heterophils (H), and relatively normal liver tissue (L). H & E, ×400.
23.6. *Streptococcus zooepidemicus* in blood of naturally infected chicken. Gram, ×800. (23)

Diagnosis

Isolation and Identification of Causative Agent

Demonstration of bacteria typical of streptococci in blood films (Fig. 23.6) or impression smears of affected heart valves or lesions from birds with typical signs and lesions will provide a presumptive diagnosis of streptococcosis.

Isolation of *S. zooepidemicus*, or any other Lancefield serogroup C streptococci from typical lesions in poultry with appropriate clinical signs, will confirm streptococcosis. Streptococci are isolated easily on blood agar. The lack of growth on MacConkey agar, different types of hemolysis, variable PYR (pyrrolidonylarylamidase) reaction and variable reactivity on bile esculin agar help to differentiate the avian streptococci. The fermentation of mannitol, sorbitol, arabinose, sucrose and raffinose are useful in the speciation of Lancefield serogroup D streptococci. *S. zooepidemicus* and other Lancefield serogroup C streptococci can be further differentiated using additional conventional tests or automated systems(38, 51, 81). Preferred tissues for culture include liver, spleen, blood, yolk, embryo fluids, or any suspected lesion area. Diagnosis of bacterial endocarditis can be made based on valvular vegetations with secondary infarcts of myocardium, liver, and/or spleen. In suspected cases, it is important to culture lesions to establish a definitive diagnosis and rule out other bacteria.

Serology

A rapid detection test by latex agglutination has been described for the identification of antigenic serogroup C streptococci in animals (38).

Differential Diagnosis

Differential diagnosis includes other bacterial septicemic diseases (e.g., staphylococcosis, colibacillosis, pasteurellosis, and erysipelas).

Treatment

Treatment includes the use of antibiotics such as penicillin, erythromycin, novobiocin, oxytetracycline, chlortetracycline,

and tetracycline in acute and subacute infections. Clinically affected birds respond well early in the course of the disease. As the disease progresses within a flock, treatment efficacy decreases. Antibacterial susceptibility should be performed on bacterial isolates in any clinical cases of streptococcosis. There is no treatment for poultry with bacterial endocarditis.

In vitro susceptibility of *S. bovis* from pigeons has been demonstrated to the penicillins, macrolides, lincomycin, tetracyclines, chloramphenicol, and nitrofurans (21).

Prevention and control require reducing stress and preventing immunodepressive diseases and conditions. Proper cleaning and disinfection can reduce environmental streptococcal resident flora to minimize external exposure. The use of formaldehyde reduces the total count of *Streptococcus* spp. in the hatchers by as much as 85.7%. Reduction of 7 log-10 bacterial counts has also been demonstrated compared with ozone use, which had bacterial-count reduction of 4 log-10 (82).

Enterococcus

Introduction

The previous chapter on streptococcosis included streptococci in both Lancefield antigenic serogroups C and D. Lancefield group D *Streptococcus* spp. are commonly referred to as "fecal strep" (35). The application of new bacteriologic techniques, especially DNA-DNA and DNA-rRNA hybridization, has led to the reclassification of the Lancefield group D streptococci to the *Enterococcus* spp. (29, 64). This chapter reviews the diseases specific to *Enterococcus* spp. In reviewing this chapter, the reader must keep in mind the change in reference nomenclature of both *Streptococcus* spp. and *Enterococcus* spp. Earlier studies and reports that identified bacteria by genus only could have been classified as *Enterococcus* spp. in present-day classification instead of *Streptococcus* spp., identified in previous chapter nomenclature. When researching diseases caused by the Lancefield antigenic serogroup C and other *Streptococcus* spp., the streptococcosis chapter in this book should be reviewed.

Enterococcus spp. in avian species is worldwide in distribution. Enterococci are ubiquitous in nature and commonly found in various poultry environments. *Enterococcus* spp. are considered normal microflora of the intestinal tract of poultry (23). Though found in the intestinal tract of chickens comparatively few enterococci can be found in the litter (47). A low percentage (16.67%) of poultry meat contamination with *E. faecalis* has been found in ready-to-cook products; however, no incrimination of food poisoning in humans has been found (34). However, later studies found a much higher percentage of gram-positive cocci including *Enterococcus* spp. present on meat samples at processing (67).

History

The history of *Enterococcus* spp. infections is minimal due to the inclusion of the Lancefield antigenic serogroup D in the *Streptococcus* genus. Early reports of "fecal strep" infections in poultry were reported as early as 1947 (58), 1956 (3), 1962 (33), and 1971 (42). Most of these reports named the enterococci in

the *Streptococcus* species, which makes the confirmation of earlier reports difficult. Most of the earlier reported cases involved bacterial endocarditis, hepatic granulomas, and occasionally acute septicemia.

Etiology

The genus *Enterococcus* is composed of gram-positive, spherical bacteria occurring singly, in pairs, or short chains, which are nonmotile, nonspore-forming, facultative anaerobes. They are catalase-negative and ferment sugars usually to lactic acid with a significant acid pH shift. Common avian isolates can be separated by their differential ability to ferment mannitol, sorbitol, L-arabinose, sucrose, and raffinose and by their lack of growth on MacConkey agar containing crystal violet (Fig. 23.7) (Table 23.3)(81). The relationship of these characteristics to pathogenicity is unknown. *Enterococcus* spp. isolated from avian species and associated with disease includes *E. faecalis, E. faecium, E. durans, E. avium*, and *E. hirae* from Lancefield antigenic serogroup D streptococci. In this chapter, *E. faecalis* subsp. *faecalis, E. faecalis* subsp. *liquefaciens*, and *E. faecalis* subsp. *zymogenes* will all be considered as *E. faecalis*. Other enterococci species have also been isolated from poultry (14, 18).

Bacterial endocarditis, commonly associated with both streptococci and enterococci, can be caused by many different bacteria in naturally occurring and experimental poultry infections. These include *E. faecalis* (23, 30, 39), *E. faecium* (67), *E. durans* (26), *E. hirae* (14), *Streptococcus zooepidemicus, Staphylococcus aureus*, and *Pasteurella multocida* (33). Of the enterococci isolated from naturally occurring infections, *E. faecalis* has been the most common isolate and the one most consistent in producing bacterial endocarditis in experimental infections via the intravenous route.

Pathobiology and Epidemiology

E. faecalis affects species of all ages; it is a serious disease occurring in embryos and young chicks from fecally contaminated eggs (3, 4). *E. faecium* has been identified as a cause of mortality in ducklings (67).

Transmission of enterococci occurs most commonly via oral and aerosol routes. Transmission can occur, however, through skin injuries, especially in caged layers. Most enterococci are pathogenic when administered intravenously. Aerosol transmission of *E. faecalis* results in acute septicemia in chickens (3). High mortality from acute septicemia and liver granulomas occur after experimental oral inoculation with *E. faecalis* (35). *E. faecalis* has been incriminated as the cause of loss of intestinal epithelium integrity allowing bacteria (e.g., *Bacteroides* spp., *Catenabacterium* spp., *Eubacterium* spp., and *Streptococcus* spp.) to produce liver granulomas in turkeys (55). These bacteria and *Proprionibacterium* spp., *Corynebacterium* spp., *Staphylococcus* spp., and *Lactobacillus* spp. can often be isolated from turkey liver granulomas. Concurrent enteric infections, or any condition compromising the intestinal villous epithelium and allowing penetration of resident enterococci, can result in septicemia and/or bacterial endocarditis. Incubation periods range from 1 day to several weeks, with 5–21 days being most common.

23.7. *Enterococcus faecalis* on a Blood agar/MacConkey agar bi-plate demonstrating growth on blood agar and no growth on MacConkey agar containing crystal violet.

Table 23.3. *Enterococcus* differential fermentation characteristics.

E. faecalis	+	+	–		
E. faecium	+	–	+		
E. hirae	–	–	–	+	+
** *Enterococcus does not grow on MacConkey agar containing crystal violet.*					

Experimental bacterial endocarditis (vegetative or valvular) results from intravenous exposure. *E. faecalis* isolates and other species of enterococci from intestines of apparently normal birds can produce endocarditis (33, 53, 60, 62). Endocarditis can occur when a septicemic enterococcal infection progresses to a subacute or chronic stage (42).

Chicks experimentally inoculated with *E. faecalis* had higher retained yolk weights, higher total plasma protein levels, and decreased Newcastle disease antibody passive transfer (absorption) through infected yolk sacs (65).

Enterococcus spp. has been associated with brain necrosis and encephalomalacia in young chickens (2, 11, 15, 24).

Some enterococci, however, have been demonstrated to have a beneficial effect on growth and feed efficiency (57) and are the subject of research as potential probiotics.

E. faecalis has been reported to be a bacterial component of amyloid arthropathy in chickens (48, 49).

Clinical Signs

Enterococcus spp. in poultry can result in 2 distinct clinical forms of disease, acute and subacute/chronic. In the acute form, clinical signs are related to septicemia and include depression, lethargy, lassitude, pale combs and wattles, ruffled feathers, diarrhea, fine head tremors, and decrease or cessation of egg production. Often, only dead birds are found.

In the subacute/chronic form, depression, loss of body weight, lameness, and head tremors may be observed. Chickens experimentally inoculated intravenously with *E. faecalis* develop leukocytosis 2–3 days postinoculation; highest values occur in birds that develop endocarditis (33). Heterophils predominate, along with a slight monocytosis. Body temperatures are elevated in birds with persistent bacteremia. Numbers of bacteria present in peripheral blood vary considerably. Clinically affected birds eventually die if not treated.

Egg transmission or fecal contamination of hatching eggs with enterococci may result in late embryo mortality and an increased number of chicks or poults unable to "pip" or penetrate through the shell at hatch (4). Overall bacterial contamination, including *Enterococci* spp., at the time of hatching can contribute to mortality of chicks early in life (65).

Pathology

Gross

Gross lesions of enterococci in acute disease are characterized by splenomegaly, hepatomegaly (with or without foci), enlarged kidneys, and congestion of subcutaneous tissue. Omphalitis and/or enlarged yolk sacs are observed in chicks or poults infected at hatching (4, 66, 40). Hepatomegaly, splenic necrosis, fibrinous pericarditis, perihepatitis, and airsacculitis were observed in ducks infected with *E. faecium* (67).

Lesions of chronic enterococcal infections include fibrinous arthritis and/or tenosynovitis, osteomyelitis, fibrinous pericarditis and perihepatitis, necrotic myocarditis, and valvular endocarditis. Vegetative valvular lesions are usually yellow, white, or tan; are small; and have raised rough areas on the valvular surface. Valve lesions most consistently are found on the mitral

valve, and less frequently on the aortic or right atrioventricular valves. The changes are similar to those observed with *S. zooepidemicus* infection. Additional gross lesions associated with valvular endocarditis include enlarged, pale, flaccid heart; pale to hemorrhagic areas in the myocardium, especially at the base of the valve, below the affected valve, or at the apex of the heart (42); infarcts in the liver, spleen, or heart; and, less commonly, infarcts in the lung, kidney, and brain. Infarcts can be light colored or hemorrhagic with sharp margins. In the liver, infarcts usually are located near the ventral and posterior margins and are well demarcated, extending beneath the capsule into the parenchyma (33). Lesions of longer duration tend to have a sharp, narrow, lighter colored band just inside the infarct margin (42).

Microscopic

Microscopically, the liver has dilated sinusoids congested with red blood cells and increased heterophils. If foci are present grossly, there are multiple areas of necrosis and/or infarction with heterophil accumulation and thrombosis. Splenomegaly is characterized by congestion and hyperplasia of cells in the mononuclear phagocytic system (35).

Microscopically, valvular lesions consist primarily of fibrin with bacteria, heterophils, macrophages, and fibroblasts. There is interstitial edema and infiltrative valvular distortion, with focal deposition of platelets and fibrin and subsequent microbial growth (33, 42). Cardiac histiocytes (Anichkov's myocytes) are numerous in the fibrous portion of the valve. Other microscopic lesions related to endocarditis include cerebral vasculitis and infarcts, leptomeningitis, glomerulonephritis, and thrombosed pulmonary vessels (39). Cerebral lesions usually are confined to the corpus striatum. Focal granulomas can be found in virtually any tissue as a result of septic emboli. Liver infarcts are characterized by portal venous thrombosis followed by necrosis. Aggregates of bacteria are present throughout necrotic areas with a zone of heterophils just within the necrotic border; a characteristic feature of the lesion, gram-positive bacterial colonies, are readily observed in thrombosed vessels and within necrotic foci with tissue gram stains.

Diagnosis

Demonstration of bacteria typical of enterococci in blood films or impression smears of affected heart valves or lesions from birds with typical signs and lesions will provide a presumptive diagnosis of enterococcosis.

Isolation of *Enterococcus* spp. (without fecal contamination) from typical lesions in poultry with appropriate clinical signs will confirm enterococcosis. Enterococci are easily isolated using blood agar and MacConkey agar as primary isolation media (26, 81). There is a distinct lack of growth of the enterococci on MacConkey agar due to the presence of crystal violet in the more modern formulations (Fig. 23.7). For contaminated specimens the addition of PEA (phenylethanol) agar to the standard battery of media provides selectivity for gram positive organisms. Presumptive identification of enterococci can be accomplished noting gamma (no) hemolysis on blood agar, black precipitate on bile esculin agar and a positive reaction on PYR
23.8. *Enterococcus faecalis* on a tri-plate with blood agar, bile esculin agar, and PYR agar. Note gamma (none) hemolysis on blood agar, black precipitate on bile esculin agar, and magenta color which developed after addition of PYR reagent to 18–24 hour culture. This combination of reactions is indicative of Group D Enterococcus. Speciation requires carbohydrate testing. See table 23.3.

(pyrrolidonyl-beta-naphthalamide) agar (51) (Fig. 23.8). Further speciation can then be accomplished using *differential fermentation* of mannitol, sorbitol, arabinose, sucrose, raffinose (Table 23.3). Numerous commercial systems are available for bacterial identification but care should be used in interpretation or acceptance of identifications. Suspected inaccuracies should always be backed up with secondary methods often including conventional biochemical tests (39, 69, 72). Preferred tissues for culture include liver, spleen, blood, yolk, embryo fluids, or any suspected lesion area. Diagnosis of bacterial endocarditis can be made based on valvular vegetations with secondary infarcts of myocardium, liver, and/or spleen. In suspected cases, it is important to culture lesions to establish a definitive diagnosis and rule out other bacteria.

Differential diagnosis includes other bacterial septicemic diseases (e.g., staphylococcosis, colibacillosis, pasteurellosis, and erysipelas).

Intervention Strategies
Prevention and control require reducing stress and preventing immunodepressive diseases and conditions. Proper cleaning and disinfection can reduce environmental enterococcal resident flora to minimize external exposure.

Treatment
Treatment can include the use of antibiotics such as penicillin, erythromycin, novobiocin, oxytetracycline, chlortetracycline, tetracycline, or nitrofurans in acute and subacute infections. Clinically affected birds respond well early in the course of the disease. As the disease progresses within a flock, treatment efficacy decreases. Novobiocin has been found to be efficacious in ducks with *E. faecium* infection (66). Dietary bacitracin decreases the incidence of some strains of enterococci in young chickens (7). Certain enterococcus strains can develop resistance after exposure to antibiotics such as tylosin, but treatment with such antibiotics may not shift the overall number of resistant organisms (20). Chickens fed certain growth-promoting antibiotics may develop greater numbers of *E. faecium* and *E. faecalis* populations in comparison to other enterococci (44, 45). Antimicrobial susceptibility should be performed on bacterial isolates in clinical cases of enterococcosis prior to the initiation of treatment. Enterococci vary in their resistance and susceptibility to growth-promoting agents (27). Chickens fed 50 grams of chlortetracycline compared to nonmedicated controls had diversity in antimicrobial resistance patterns suggesting that other factors are involved in antibiotic resistance acquisition besides feeding low-level antibiotics (52). Environmental forces, feeding schedules, stress, and interactions between different genotypes and housing influence the response of chickens to enterococcal infections (43, 68). There is no treatment for poultry with bacterial endocarditis.

Public Health Significance
Most streptococci found in avian species are considered zoonotic and have been isolated from both animal and human infections (74). Antimicrobial susceptibilities vary widely among the species of enterococci (27, 71). The use of growth promoting antibiotic feed additives has been suggested as a direct link to the development of antimicrobial resistance in enterococcal isolates in humans (6). However bans of several growth-promoting antibiotics in the European Union have failed to reduce the rate of antibiotic resistance in human enterococcus isolates (12, 32). Other scientific studies fail to prove association of antibiotic usage and the incidence of antimicrobial resistance in human enterococcus isolates and suggest there are other contributing factors (52, 19, 59).

Erysipelas

Joseph M. Bricker and Y. M. Saif

Introduction

Definition and Synonyms

Erysipelas in birds is generally an acute, fulminating infection of individuals within a flock. The infection and disease have been reported from many different vertebrate species, either as a contaminant (fish) or an infection. The etiologic agent of erysipelas is a small gram-positive bacterium, *Erysipelothrix rhusiopathiae,* which also causes swine erysipelas and erysipeloid in humans. The organism is distributed worldwide in nature and although the disease is sporadic in poultry, endemic areas exist.

Economic Significance

In birds, its primary economic importance is as a disease of turkeys. Outbreaks of economic significance are infrequent in other avian species. Occasional losses of individual birds within a flock have been reported, and a few economically significant outbreaks in chickens and ducklings have occurred (67). Salem *et al.* (97) reported erysipelas in meat-type chickens including both breeders and broiler-type chickens. *E. rhusiopathiae* has caused outbreaks of erysipelas in pheasants, ducks, geese, guinea fowl, chukars, grebes, and emus (19, 31, 42, 44, 51, 52, 56, 88, 128).

Erysipelas not only causes death but frequently affects the fertility of the male. Further marketing losses may result from lack of finish, condemnation, or downgrading, resulting from postmortem evidence of septicemia. Affected chicken flocks have been reported to suffer depression of egg production.

Public Health Significance

Erysipeloid in humans may be a local or septicemic, and occasionally fatal, infection. Erysipeloid is considered an occupational disease affecting particularly fish handlers, butchers, kitchen workers, veterinarians, and animal caretakers.

In most cases, the disease is preceded by an injury such as a cut. Presumptive diagnoses of the infection have been made in turkey flocks as a result of infection of a turkey handler or an insemination crew member. Mutalib *et al.* (78) described suspected erysipeloid in several plant employees processing quail from a confirmed outbreak of erysipelas. Erysipeloid was also suspected in animal caretakers following an outbreak of erysipelas in caged chicken layers (77). Although localized cutaneous infections are most often observed, Dunbar and Clarridge (33) reported several cases of *E. rhusiopathiae* infection associated with a wide range of clinical symptoms.

Silberstein (114) reported endocarditis and encephalitis in humans treated with penicillin. Several reviews of *E. rhusiopathiae* as an occupational pathogen have been compiled (17, 89).

History

Sporadic cases of infection were reported in various avian species prior to 1936. Beaudette and Hudson (6) were the first to call attention to the economic significance of the disease in North American turkeys; other outbreaks were reported shortly thereafter. The disease is of economic concern to turkey growers in some parts of the United States. The infection has been reported from time to time in one or small groups of other species of birds; with the advent of widespread artificial insemination of turkeys, prevention of erysipelas became a problem facing producers of turkey hatching eggs. With more confinement growing of turkeys, it has become a less important problem, except in endemic areas.

Following the introduction of bacterins in the early 1950s and the availability of penicillin as a treatment, various programs of preventive vaccination, and/or treatment have been followed. Despite this, cases of post-insemination erysipelas occur in turkey hens.

Etiology

Classification

Name and Synonyms

E. rhusiopathiae (formerly *E. insidiosa*) belongs to the family Lactobacillaceae (18). A second genomic species, *E. tonsillarum,* was described based on DNA homology studies with type strains of *E. rhusiopathiae* (118). Some investigators have provided evidence that there may be an additional distinct genomic species other than *E. rhusiopathiae* and *E. tonsillarum* (84, 119) or perhaps 2 additional distinct new species (123). Recently, Verbarg *et al.* (130) identified a new third genomic species with a proposed species name of *Erysipelothrix inopinata.* Only *E. rhusiopathiae* is considered the causative agent of erysipelas in avian species.

Morphology and Staining

The organism stains gram-positive but tends to decolorize, a trait particularly noticeable in older cultures. *E. rhusiopathiae* is nonmotile, does not form spores, and does not stain acid-fast. The cellular morphology of the organism is variable. Cells taken from smooth colonies or isolated from the tissues of acutely infected birds are slender, straight, or slightly curved rods measuring 0.2–0.4 by 0.8–2.5 μm and may occur singly or in short chains. Organisms from older cultures or rough colonies are filamentous rods and may form masses that resemble mycelia. These filamentous rods usually appear somewhat thickened and may appear beaded following staining. The filamentous form begins to appear after several passages on artificial media. Both short rods and short filaments may be observed from a single colony (intermediate colony type). *E. tonsillarum* is morphologically indistinguishable from *E. rhusiopathiae.*

Growth Requirements

E. rhusiopathiae is facultatively anaerobic and grows readily, although sparsely, on ordinary culture media and moderately well

in thioglycollate broth and various other broths containing serum and serum components. The addition of serum to broth media supports heavier growth with a powdery sediment forming after 24 hours. Protein hydrolysates, glucose, and certain detergents, such as Tween 80, also enhance growth. The organism grows especially well in deep stabs of semisolid medium prepared by adding 0.5% agar to tryptose phosphate broth. Feist *et al.* (37) described a medium, which supported high bacterial yields, but was devoid of serum. Using 6 different strains of *E. rhusiopathiae*, Groschup and Timoney (46) indicated higher cell densities were obtained with Feist medium than with horse serum-supplemented brain heart infusion broth. However, Sato *et al.* (100) reported higher bacterial yields with tryptic soy broth supplemented with 0.3% Tris and 0.1% Tween 80 than with Feist medium or 2 different supplemented heart infusion broths. Reduced oxygen or increased carbon dioxide (5–10%) enhances growth, but neither is necessary to support growth. Smith (115) described the appearance of growth in a meat-infusion broth culture at 24 hours as "a faint opalescence..., which on shaking was resolved for the moment into delicate rolling clouds."

E. rhusiopathiae grows in a temperature range from 4°C (slow growth) to 42°C, with an optimal range of 35–37°C. The optimal pH for growth is mildly alkaline, pH 7.4–7.8. Oleic acid and riboflavin have been reported as essential for growth. The organism does not form a pellicle.

Colony Morphology

Three different colony types have been described for *E. rhusiopathiae.* Smooth colonies are dewy, colorless to bluish gray, and of pinpoint size (0.5–0.8 mm) with smooth edges. Most strains of *E. rhusiopathiae* and organisms isolated directly from infected tissues form this colony type. Some strains, however, form rough colonies that consist of long thickened filamentous rods. Rough colonies are opaque, flat, dry, and of pinhead size (1–2 mm) with irregular or lobed edges. The dissociation from smooth to rough colony type is described as intermediate colony type in which both short rods and short filaments may be identified. Most strains produce a narrow zone of alpha hemolysis in a medium containing 5–10% horse or bovine blood after 2–3 days incubation at 37°C in an atmosphere of 5–10% carbon dioxide. A test-tube brush type of growth (lateral radiating projections) occurs 48 hours post-inoculation in gelatin stab culture incubated at 21°C.

Biochemical Properties

E. rhusiopathiae ferments galactose, dextrose, fructose, maltose, lactose, and levulose without gas production. *E. tonsillarum* differs in its ability to ferment sucrose (119); however, investigators have indicated that this property may not be unique to *E. tonsillarum* (84). Lead acetate agar or triple-sugar iron (TSI) agar is usually blackened, indicating hydrogen sulfide (H_2S) production, and xylose is occasionally fermented. Strains that do not produce H_2S have been isolated (10). Litmus milk occasionally is acidified slightly without coagulation. The organism is catalase negative, does not produce indole, does not reduce nitrites, is Voges-Proskauer and methyl red negative, does not hydrolyze esculin, and does not reduce 0.1% methylene blue. White and Shuman

(135) found that the fermentation pattern varied with the medium, indicator, and method of measuring acid production; they stated that the most dependable medium was Andrade's base plus serum. Of 3 methods used to measure acid production (chemical indicator, change in pH, and production of titratable acidity), they found that the chemical indicator gave the most valid reproducible results.

Susceptibility to Chemical and Physical Agents

E. rhusiopathiae is fairly resistant to various environmental and chemical factors. It is very resistant to desiccation and may survive the smoking and pickling processes used for processing meat and remain viable in frozen or chilled meat, dried blood, decaying carcasses, or fish meal. Apart from tissues, it is killed at 70°C in 5–10 minutes.

E. rhusiopathiae is destroyed in a short time by a 1:1000 concentration of bichloride of mercury, 0.5% sodium hydroxide solution, 3.5% liquid cresol, or a 5% solution of phenol. *E. rhusiopathiae* is also inactivated with 0.5% formalin. The organism is resistant to 0.001% crystal violet and 0.5% potassium tellurite and can grow in the presence of 0.1% sodium azide.

Vallee (129) suggested that the organism remained viable in soil and multiplied in alkaline soils during warm weather. Wood (138), however, reported that under experimental conditions, *E. rhusiopathiae* was inactivated at different rates in soil when parameters of temperature, pH, and organic matter content were tested. Temperature exerted the greatest effect on viability. Populations of the pathogen survived 35 days at 3°C and 2 days at 30°C. Organisms did not survive longer than 11–18 days under various conditions of organic matter content and pH.

Antigenic Structure and Toxins

Essentially all strains of *E. rhusiopathiae* possess at least one or more common antigens (40, 102, 116, 139). These antigens are heat labile and consist of protein or a complex of protein, carbohydrate, and lipid (136). The cellular fatty acid profiles of several strains of *E. rhusiopathiae* and *E. tonsillarum* were determined, which demonstrated no differences between the 2 species (121). Schubert and Fiedler (103) investigated the murein component of the cell wall and determined the murein belongs to the B1delta type. Barber (5) and Nelson and Shelton (81) reported that *E. rhusiopathiae* resembles *Listeria* sp.; however, they demonstrated marked cultural differences between them. It resembles mycobacteria in that it has a high lipid content in its cell wall (almost 30%). Similar to some gram-negative bacteria, *E. rhusiopathiae* has a rather low hexosamine content but differs from them in having a limited complement of amino acids (58). *E. rhusiopathiae* produces no known toxins.

Strain Classification

Antigenicity

At present, strain classification is based for the most part on serologic, not biologic or biochemical, activity. The serotype-based scheme utilizes a heat-stable antigen (cell wall peptidoglycan) to differentiate *E. rhusiopathiae* into serotypes. These antigens are

extracted easily from the organism using acid or by autoclaving a washed whole-cell inactivated culture for 1 hour at 121°C. Determination of serotype is accomplished with a double-diffusion gel system using specific hyperimmune rabbit sera. The preferred system for serotyping *E. rhusiopathiae* isolates is a numerical system described by Kuscera (65). Using the numerical system, strains previously designated as types A or B now become types 1 and 2, respectively. Subtypes of some serotypes have been described (e.g., serotypes 1 and 2) and are designated by a number followed by a lowercase letter. Although 26 serotypes of *E. rhusiopathiae* have been described (4, 35), the identification of *E. tonsillarum* as a distinct species has led to a division of the serotyping scheme. The majority of *E. rhusiopathiae* strains isolated from poultry fall into 3 major serotypes: types 1 (both subtypes 1a and 1b) and 2 and 5 (30, 34, 128, 143).

Immunogenicity or Protective Characteristics
Traub (126) described a "soluble immunizing substance" produced by certain *E. rhusiopathiae* strains belonging to serotype 2. This soluble immunizing substance is present on the whole bacterial cell and is released into the culture medium when the organism is grown in a complex medium containing serum. Several reports confirm Traub's initial observation that not all serotype 2 strains produce effective levels of this substance for incorporation into bacterins (61, 144).

Based on the description of a soluble immunizing substance, several different approaches were employed in attempts to characterize a protective antigen (94, 125, 136). Galan and Timoney (40) described a 64,000–66,000-MW protein gene, which was cloned and expressed as a fusion protein in a heterologous vector. Groschup *et al.* (45) demonstrated that a 64,000–66,000-MW protein was protective for mice. Sato *et al.* (98) isolated 64,000- and 43,000-MW protective proteins from culture filtrates of *E. rhusiopathiae* strains representing several different serotypes. In a later report, Sato *et al.* (100) demonstrated that the concentration of protective antigen was higher in alkaline extracts of bacteria using 0.05–1% NaOH than in culture filtrates or "ultrasonicated" extracts. Makino *et al.* (69) identified a gene encoding a surface protein with a molecular weight of 69,000 designated surface protein A (SpaA). SpaA consists of a 160-residue C-terminal repeat containing 8 repeats of 20 and 19 amino acids. Each repeat begins with the dipeptide GW, which appears to bind the protein to the cell surface (71). Shimoji *et al.* (111) described a protein designated SpaA.1 whose sequence was different from SpaA at the C-terminal region and at residues 426 and 435. Monoclonal antibodies reactive to the protective antigen have been described (61, 69, 101).

Recently, Shimoji *et al.* (106) identified two adhesive surface proteins designated RspA and RspB. Both proteins were present in surface extracts of *E. rhusiopathiae* and in culture supernatants. Recombinant RspA, expressed in *E.coli* as a fusion protein, induced partial protection in mice following challenge.

Genetic or Molecular
Methodologies including molecular and genetic techniques are challenging the current serotype-based classification scheme of

Erysipelothrix spp., but the comparison between the two approaches is not clear-cut. Using DNA-DNA hybridization Takahashi (119) reported that strains of serotypes 3, 7, 10, 14, 20, 22, and 23 are *E. tonsillarum* and that strains of *E. rhusiopathiae* belong to serotypes 1, 2, 4, 5, 6, 8, 9, 11, 12, 15, 16, 17, 19, and 21 and type N. Strains not possessing a type-specific antigen are designated type N. Strains belonging to serotypes 13 and 18 exhibited low levels of DNA homology with *E. rhusiopathiae* and *E. tonsillarum* and possibly constitute a distinct genomic species. Takeshi *et al.* (123) have suggested that strains belonging to serotypes 13 and 18 represent 2 new and distinct species of *Erysipelothrix*. The classification of strains belonging to serotypes 24, 25, and 26 were not reported in this study. Recently, however, using randomly amplified polymorphic DNA (RAPD) analysis, Okatani *et al.* (83) determined that 2 strains belonging to serotypes 15 and 16 had the RAPD pattern of *E. tonsillarum*. Furthermore, a serotype 10 strain had the RAPD profile of *E. rhusiopathiae*. Ribotyping of the 16S rRNA genes of *Erysipelothrix* strains revealed that several strains with the same serotype could belong to either genomic species (4). Kiuchi *et al.* (62) reported that the nucleotide sequences of 16S rRNA from *E. rhusiopathiae* and *E. tonsillarum* had 99.8% homology. A rapid typing method utilizing automated ribotyping has been described (84).

Chooromoney *et al.* (22) analyzed strains of *Erysipelothrix* spp. by multilocus enzyme electrophoresis and indicated that serotyping was unreliable for epidemiologic studies, although serotype analysis was useful when one electrophoretic type contained multiple serotypes or subtypes or for strains isolated from different species and of varying virulence. Bernath *et al.* (8) evaluated the protein profiles of 12 strains of *E. rhusiopathiae* using polyacrylamide electrophoresis and autoradiography and found no significant correlation between serotype and percentages of common proteins of identical molecular weight.

Pathogenicity
There is no reported correlation between serologic grouping and the biochemical pattern of strains of *E. rhusiopathiae* isolated from birds and production of the septicemic, urticarial, or endocardial form of erysipelas or of the carrier state (11, 134).

Virulence Factors
Enzymes
The enzyme hyaluronidase initially was thought to be involved in the virulence of *E. rhusiopathiae*, but studies in mice revealed no association with hyaluronidase production and the pathogenicity of a particular strain (82, 105). Neuraminidase, however, appears to correlate better with the virulence of *E. rhusiopathiae* isolates. This enzyme is produced during logarithmic growth, and the amount of enzyme activity was reported by Müller (75) to be lower in strains of lower virulence or avirulent strains compared with highly virulent isolates. No apparent relationship exists, however, between the amount of neuraminidase activity and serotype. Using a peanut lectin hemagglutination assay, Wang *et al.* (132) demonstrated that neuraminidase production was media and pH dependent and was only produced by isolates of *E. rhusiopathiae* and not by *E. tonsillarum* strains. Abrashev and

Orozova (1) identified that large glycoproteins were better inducers of neuraminidase production in cultures of *E. rhusiopathiae.* In a review of erysipelas, Wood and Henderson (140) noted that specific antibody to this enzyme from *E. rhusiopathiae* was identified in a commercial erysipelas antiserum produced in horses. Tesh and Wood (124) reported the enzyme coagulase also was produced by strains of *E. rhusiopathiae*.

Other Factors

Lachmann and Deicher (66) inferred the presence of a capsule following their discovery of a 14,000–22,000-MW surface polysaccharide. Shimoji *et al.* (107) demonstrated a capsule using transmission electron microscopy, which showed polar thickening on some *E. rhusiopathiae* strains. Other investigators have demonstrated, at least in part, that the virulence of *E. rhusiopathiae* for mice was associated with the presence of a capsule (107, 112). Shimoji et. al. (108) discovered that murine macrophages were able to phagocytose three- to four-fold more avirulent acapsular bacteria than virulent bacteria in the presence of normal serum.

Partridge *et al.* (87) cloned and characterized a bacterial stress protein designated DnaK, which was highly expressed in *E. rhusiopathiae.* A heat shock gene homolog designated *dnaJ*, located immediately 3' to the *dnaK* gene, has also been cloned (92).

Makino *et al.* (70) reported cloning a gene from *E. rhusiopathiae*, which encoded a 16,000-MW hemolysin. A review of virulence factors of *E. rhusiopathiae* has been compiled (112).

Pathobiology and Epidemiology

Incidence and Distribution

E. rhusiopathiae is worldwide in distribution. The adaptiveness of the organism is indicated by its ability to infect a wide variety of vertebrate species. It has been isolated from the tissues of birds, mammals, reptiles, and amphibians, as well as the surface slime of fish (38, 59, 79, 80).

Outbreaks of erysipelas in poultry occur sporadically, although locations exist in the world where the disease is endemic. Although the disease in turkeys has been reported more frequently among males than females, there is no evidence of differing susceptibility between sexes. Field observations suggest that the portal of entry (skin) is breached more frequently in the male, but incidence in hens has increased due to artificial insemination and frequent handling of females.

Natural and Experimental Hosts

The organism has been isolated in nature from turkeys, chickens, ducks, geese, emus, mud hens, malleefowl, eared grebes, parrots, sparrows, canaries, finches, thrushes, blackbirds, doves, a Hawaiian crow, quail, wild mallards, white storks, herring gulls, golden eagles, pheasants, starlings, peacocks, parakeets, swine, sheep, cattle, marine and freshwater fish, various captive wild birds and mammals, chipmunks, meadow and house mice, dolphins, and crocodiles (10, 12, 13, 36, 41, 44, 55, 56, 57, 60, 67, 141, 142). From the reports, it appears that the susceptibilities of various avian populations differ. Genetic resistance may play a role in susceptibility to disease based on a report of an outbreak in turkeys with different genetic backgrounds (96). Experimental hosts are the pigeon, turkey, chicken, budgerigar, mouse, and rat.

Age of Host Commonly Affected

E. rhusiopathiae is pathogenic for turkeys at any age or sex. Hollifield *et al.* (50) reported erysipelas in 2–4-day-old turkey poults following toe-trimming at a hatchery. In addition to turkeys, other avian species are susceptible to infection with *E. rhusiopathiae,* both experimentally and under field conditions, and serious losses have been reported in chickens, ducks, and geese following naturally occurring outbreaks of the disease. Experimentally, Malik (72) demonstrated that virulent cultures of *E. rhusiopathiae* administered parenterally produced a septicemia in chickens less than 14 days old. In older chickens, however, septicemia could be produced only by intrapalpebral or subconjunctival installation of the pathogen along with injury to that tissue. Administration of hydrocortisone not only increased susceptibility to *E. rhusiopathiae* but shortened the course of infection and increased mortality, thus appearing to increase pathogenicity. Shibatani *et al.* (104) were able to induce septicemia in 3-week-old chickens using an *E. rhusiopathiae* strain previously isolated from an outbreak of erysipelas in chicken layers.

Transmission, Carriers, and Vectors

The actual portal of entry and pathogenesis of *E. rhusiopathiae* infection in birds have not been definitely established though contaminated material as the source of infection and entry through breaks in the mucous membranes or skin are the most frequent precursors. Fishmeal and fish in general have been cited as probable sources of infection for avian species (43, 76). Cousquer (29) reported an outbreak of erysipelas in racing pigeons after ingestion of composted waste. Cannibalism and fighting among birds apparently result in increased losses. Permitting the carcasses of infected dead birds to remain on the premises to be picked at or eaten by penmates also increases the spread and increases losses at unpredictable rates. Though it has been reported that the organism can survive in soil and that soil may serve as a source of the organism, current evidence indicates that soil serves only as a temporary reservoir for the organism. There is no evidence of vertical or egg transmission of *E. rhusiopathiae* (74).

Infection and disease can be produced in turkeys inoculated orally with chicken embryo yolk-propagated organisms or when allowed to feed on viscera of turkeys that died from erysipelas. Experimentally, Corstvet (25) obtained up to 50% mortality in turkeys by oral inoculation of freshly isolated virulent organisms grown in chicken embryo yolk sac. Broth culture instilled orally, intranasally, or into the conjunctival sac (without damaging the membrane) was not infectious (43). Corstvet (25) and Bricker and Saif (16) found that subcutaneous (SC) inoculation of virulent cultures resulted in local multiplication followed by septicemia, with 80–100% mortality in susceptible turkeys. Parenteral injection of most avian strains of the organism regularly kills mice (*Mus musculus*), pigeons, and turkeys, but guinea pigs and chickens usually survive. Iliadis (53) reported that pigeons were more susceptible to intravenous than to oral inocula-

tion. Takahashi *et al.* (120) reported that none of 14 *E. tonsillarum* strains tested induced any signs of disease or lesions when inoculated intramuscularly (IM) into white leghorn chickens and suggested that *E. tonsillarum* should not be considered to be a potential pathogen for chickens.

It is of interest to note that difficulties have been reported in reproducing consistent mortality experimentally with *E. rhusiopathiae* isolates of avian origin (3, 32). Reducing the number of passages on artificial media to an absolute minimum appears essential to maintaining virulence of the organism. Boyer and Brown (14) maintained virulence of an *E. rhusiopathiae* strain by storing infected liver at 4°C, which served as a source of the organism for further bird passage.

Sadler and Corstvet (95) and Corstvet *et al.* (28) showed that a few turkeys infected SC remained carriers for variable periods. Asymptomatic carriers of *E. rhusiopathiae* could not be detected before or after necropsy. The number of organisms used to challenge turkeys, route of inoculation (oral or parenteral), administration of antibiotics, time after vaccination and challenge, and age of the turkey apparently did not influence this carrier state, which is produced in very few birds. Isolations of *E. rhusiopathiae* from carriers are most frequent from cecal tonsils, liver, large intestine, heart, and blood (26, 28, 95). Xu *et al.* (143) reported a total of 95 isolates obtained from the pharynx of healthy chickens, ducks, and geese. Corstvet (25) found the organism shed in feces of a few birds up to 41 days postinoculation. In other experiments, the organism was found to persist in blood for several weeks postinoculation (28).

The role of vectors in transmission of erysipelas is still unclear. Wellmann (133) found that this pathogen could be transmitted mechanically from sick mice to pigeons by the stable fly, horsefly, mosquito, and other biting flies. Recently, Chirico *et al.* (21) identified that the poultry red mite, *Dermanyssus gallinae*, can act as a reservoir for *E. rhusiopathiae*. *E. rhusiopathiae* was isolated from the integument as well as the interior of the mite.

Incubation Period

In naturally occurring outbreaks, the incubation period cannot be readily ascertained. Experimental SC inoculation of turkeys with 10^4–10^6 organisms usually kills most of them in 44–70 hours; a few may die after 96–120 hours. With oral exposure, signs of disease generally occur 2–3 days later than with SC inoculation, and with a lower death rate. Occasionally, a turkey dies 2–3 weeks after oral exposure. A SC inoculum of 10^2, instead of 10^4 or 10^6, organisms delays clinical signs by about 24 hours. The incubation period does not seem to vary among turkeys 7, 12, 16, and 20 weeks of age or between sexes.

Clinical Signs

In turkey flocks, outbreaks usually start suddenly, with losses of one to several birds; owners may suspect that deaths are from poisoning, stampede injuries, or predators. A few droopy birds (especially toms) may be noticed, but these individuals are usually easily aroused. Just prior to death, some birds may be very droopy, with unsteady gait. Some may have cutaneous lesions;

affected males may have swollen purplish, turgid snoods (fleshy tubular appendage on dorsal surface of head). Some turkeys are now "desnooded" shortly after hatching; as a result, such lesions are infrequently seen. Gradual emaciation, weakness, and signs of anemia occur in some cases in which endocarditis is the cause of death; other turkeys with vegetations (especially vaccinated birds) may die suddenly without signs, probably as a result of emboli. Sudden losses of hens 4–5 days after artificial insemination with peritonitis, perineal congestion, and skin discoloration have been reported.

Main clinical signs in chickens are general weakness, depression, diarrhea, and sudden death. In laying chickens, egg production may be decreased. Kilian *et al.* (60) reported no immediate drop in egg production in laying pullets, although signs were evident; later, there was about a 50–70% drop. Affected ducks, geese, pheasant, and quail generally are depressed, have diarrhea, and die suddenly.

Morbidity and Mortality

Mortality rates vary among different avian species. Morbidity and mortality are frequently about the same in unvaccinated flocks of turkeys and other species of poultry because most sick birds die. These parameters are also dependent on whether prior immunization or early treatment was administered. In immunized flocks some birds may be depressed and recover. The pattern of morbidity and mortality may range from sickness or death of occasional birds in good condition to sudden loss of several within 24–48 hours. Mortality can range from much less than 1% to as high as 25–50% of a given group, although adjacent groups may not be affected.

Pathology

Gross

In naturally occurring outbreaks, the lesions are suggestive of a generalized septicemia, and the following lesions have been observed in different outbreaks in turkeys. There is generalized congestion; degeneration of fat on the anterior edge of the thigh; degeneration and hemorrhage in pericardial fat; petechial hemorrhage in abdominal fat; hemorrhage in heart muscle; and a friable, enlarged, and possibly mottled liver, spleen, and usually kidney. Other gross lesions may be fibrinopurulent exudate in joints and pericardial sac, fibrin plaques on heart muscle, thickening of the proventriculus and gizzard wall with ulceration, small yellow nodules in ceca, catarrhal or sanguinocatarrhal enteritis, vegetative endocarditis, dark crusty skin lesions, a turgid irregular reddish purple snood in toms, hydropericardium, and distended visceral blood vessels (93). Other lesions noted with varying frequency in field outbreaks were diffuse skin reddening and a dirty brick-red muscle color. Some birds that died had no lesions other than slight catarrhal enteritis and petechiae in the heart fat.

In experimental infections, some of the lesions observed in naturally occurring outbreaks are not uncommon. Endocarditis, except in vaccinated birds, is rare in experimentally infected birds. In some field cases, and in birds vaccinated twice or more with bacterin and intravenously challenged, congestive heart fail-

ure with vegetations of the atrioventricular valves (sometimes extending as much as 7 cm into the aorta) have been found. Asymptomatic carrier turkeys are usually free of gross lesions.

In at least 2 field outbreaks in chicken layers, lesions in endocardium, joints, and skin were not observed (10). In ducks, geese, and pheasant, lesions are similar to those observed in other avian species, with the addition of dark congested areas in foot webs of ducks.

Microscopic
Generally, the histopathologic features of acute erysipelas in turkeys reflect rather closely the observed gross findings, and specific cellular alterations are those expected in septicemic infections (9). Vascular changes dominate the histopathologic picture, with generalized engorgement of blood vessels and sinusoidal channels in virtually all organs. Although there may be a strong central (cardiac or vasomotor) basis for vascular congestion, there is also evidence of direct vascular damage. Intravascular aggregations of bacteria accompanied by fibrin thrombi are frequent in capillaries, sinusoids, and venules. Overt hyalinization of walls of affected vessels is not uncommon. Edema and hemorrhage, especially prominent in lung and heart (Fig. 23.9), are further evidence of severe vascular damage. In addition, rounding up of vascular endothelial cells or mononu-

clear phagocytic system (MPS) cells of sinusoids is a consistent histologic finding, and engulfed bacteria are demonstrated readily in MPS cells in liver and spleen.

Damage to parenchymal cells is generalized in acute erysipelas and is especially obvious in liver, spleen, and kidney. Degenerative changes in hepatic cells vary from cloudy swelling with cellular dissociation to overt coagulative necrosis. Focal or massive necrosis apparently related to thrombosis of major portal vessels is seen occasionally, but diffuse degenerative changes are much more common (Fig. 23.10). In spleen, the earliest observable change is necrosis and lysis of lymphoid elements. This progresses to nearly total loss of lymphocytes, with the hyalinization of sheathed arteries of white pulp and surrounding reticular elements (Fig. 23.11). The epithelium of proximal tubules undergoes early degenerative change in affected turkeys. Swelling, dissociation, and separation from the basement membrane are frequent and prominent changes that are seen in renal epithelial cells; overt coagulative necrosis is rare. Certain of these pathologic changes in kidneys have also been reported by others (127). It is not unusual to find degenerative changes or necrosis in a variety of other organs such as lung, heart, pancreas, gastrointesti-
23.11.   Acute erysipelas, turkey spleen. Hyalinized sheathed arteries within 2 malpighian corpuscles and nearly total depletion of lymphocytes are evident. Surrounding sinusoids are engorged with erythrocytes. H & E, ×100.

nal tract, skeletal muscle, and skin. These changes are, however, seldom as remarkable in frequency or magnitude as parenchymatous changes in liver, spleen, and kidney. Regardless of the site of involvement, hemorrhage and fibrin deposition frequently accompany parenchymatous necrosis.

The cellular inflammatory component of peracute or acute erysipelas lesions is minimal. In scarified skin of turkeys infected by this route, there may be extensive heterophil infiltration, congestion, edema, and necrosis. Cellular inflammatory response as judged from examination of field cases is more prominent in turkeys with subacute or chronic disease. Heterophil and mononuclear leukocytic infiltration as well as proliferation of MPS cells can be found around necrotizing lesions in liver and spleen as well as in heart valves and synovial membranes of joints. The pathology of experimentally induced subacute or chronic erysipelas in turkeys has not been reported.

In a study of acute erysipelas outbreaks in chickens (10), histopathologic alterations very similar to those described in turkeys were reported. Shibatani et al. (104) described disseminated intravascular coagulation in chickens inoculated experimentally. These investigators also observed depletion of lympho-

cytes in the bursa of Fabricius and thymus and suggested that thromboplastin released from these tissues following depletion played a role in disseminated intravascular coagulation.

Pathogenesis of the Infectious Process

The precise mechanism(s) by which the organism causes disease is still not very well understood. *E. rhusiopathiae* appears to be able to gain access to the body by the oral route or by entry through breaks in the skin. In swine, *E. rhusiopathiae* can induce disease by gaining access through the palatine tonsils or other pharyngeal lymphoid tissue. This mode of pathogenesis is probable for turkeys based on experimental evidence with orally administered challenge cultures (25) and live vaccines (16).

Although not completely clear, the pathogenicity of different isolates of *E. rhusiopathiae* may be related to their ability to produce various virulence factors to help them to resist or survive phagocytosis and to avoid host defenses. These factors include specific attachment factors (capsule or adhesins), enzymes such as neuraminidase and coagulase, and stress proteins. Takahashi *et al.* (117) reported a correlation between pathogenicity for mice and swine and the ability of *E. rhusiopathiae* to adhere to porcine kidney cells. Other investigators have demonstrated that *E. rhusiopathiae* isolated from swine with endocarditis showed a higher degree of adherence to porcine heart valve tissue (15, 63). Recently, Shimoji *et al.* (106) identified two adhesive surface proteins designated RspA and RspB that were able to bind to fibronectin and type I and IV collagens. Partridge *et al.* (87) suggested the expression of high levels of a stress protein could allow the organism to resist oxidation and survive the low pH environment of the phagolysosome following phagocytosis. The production of coagulase may allow *E. rhusiopathiae* to wall itself off from host defenses. More studies are needed to fully elucidate the pathogenesis of *E. rhusiopathiae* in avian species.

Immunity

Active

Birds recovered from acute infections have a high degree of resistance to reinfection and death. Killed bacterins, the current commercially available immunoprophylactic agent for the immunization of turkeys against erysipelas, will prevent disease under both experimental and field conditions. Bacterin in conjunction with penicillin at the beginning of an outbreak will usually control losses. Long-lasting immunity is not produced by only one bacterin injection in turkeys. The immune response is more effective from 2 or more doses at intervals of at least 2–4 weeks. Experiments with 4–7-week-old turkeys have shown that protective immunity begins to decline between 4 and 5 weeks postvaccination. Krasnodebska-Depta and Janowska (64) reported that 28- and 30-week-old turkeys vaccinated with a bacterin made for swine were resistant to challenge 2 months post-vaccination. Aerosol immunization of ducks with an erysipelas vaccine has been reported to be very effective in eliminating the disease.

Osebold *et al.* (85) reported limited protection with a live vaccine strain that they administered SC to turkeys followed by subsequent challenge with a virulent strain. Bricker and Saif (16) reported on an effective level of protection in turkeys vaccinated

through the drinking water with a live serotype 1a strain of *E. rhusiopathiae,* followed by challenge with the homologous serotype. Two vaccine doses administered 2–3 weeks apart were necessary to induce a sufficient protective response that lasted at least 3 weeks following administration of the second vaccine dose. Administration of this live vaccine directly into the esophagus of turkeys did not induce a protective immune response. It is speculated that lymphoid tissue in the pharyngeal region plays a role in the induction of an immune response to organisms introduced by the drinking water route.

Passive

Treatment with swine erysipelas antiserum (horse origin) alone is said to be of some value if administered very early, but it is not practical because of the expense and the lack of uniform efficacy. Antiserum and penicillin have been used successfully in ducks (91).

Diagnosis

Isolation and Identification of Causative Agent

Because gross lesions of dead birds indicate septicemia, diagnosis depends on the demonstration and identification of *E. rhusiopathiae.* Rapid presumptive diagnosis is provided by the presence in liver, spleen, heart blood, or bone marrow smears of clumps and segregated gram-positive, beaded, slender, and pleomorphic rods. Particularly helpful with decomposed specimens are bone marrow culture and smear. Viemmas *et al.* (131) described the use of immunoperoxidase staining to detect *E. rhusiopathiae* from the tissues of experimentally infected turkeys.

Isolation of *E. rhusiopathiae* from sick birds that are killed and then cultured is neither as easy nor as frequently positive as culturing from birds dead of the disease. Detecting the organism from a carrier requires multiple samples from various tissues. Isolation from endocardial tissues is facilitated by finely mincing before inoculating enrichment broth. With birds dead from the infection, however, liver, spleen, or bone marrow will suffice. Useful inhibitory media are the sodium azide-crystal violet medium described by Packer (86) and the tryptose phosphate broth medium with 5% horse serum plus kanamycin, neomycin, vancomycin, and novobiocin described by Wood (137). These media are the most satisfactory, although they do not completely prevent growth of other organisms (particularly with samples of intestinal contents) and may inhibit growth of some strains of *E. rhusiopathiae* (15). Shimoji *et al.* (109) described a selective media containing tryptic soy broth, ethidium bromide, and sodium azide. For primary isolation, recovery is favored by inoculating biplates containing 5% blood agar and Packer's medium followed by incubation in an atmosphere of 5–10% CO_2 or reduced oxygen. Ordinary atmosphere is suitable after a few passages on artificial media. Typical colonies composed of gram-positive rods are selected and placed in TSI medium or Kligler's lead acetate medium and incubated for 24 hours at 37°C. An excellent presumptive test for *E. rhusiopathiae* is a blackening of the medium (due to H_2S production) before there is a very noticeable change in the medium color.

Makino *et al.* (68) described a direct, rapid, sensitive test for detection of both *E. rhusiopathiae* and *E. tonsillarum* using the polymerase chain reaction methodology. Using primers to amplify a 937-bp DNA region from *E. rhusiopathiae*, Shimoji *et al.* (109) designed a broth cultivation-PCR technique for rapid diagnosis of erysipelas. In a report comparing detection methods, Fidalgo *et al.* (38) indicated that a combination of cultural and PCR methodologies was optimal. At 24 and 48 hours of broth incubation, PCR was performed with primers ER1 and ER2 (109). Takeshi *et al.* (123) performed a PCR test using 4 specific primer sets for the identification of *E. rhusiopathiae, E. tonsillarum*, and strains representing serotypes 13 and 18. Hennig *et al.* (49) used DNA obtained from histochemically processed liver tissue to diagnose erysipelas in ring-necked pheasants by the PCR technique.

Though rarely used in diagnostic laboratories because of newer molecular-based methodologies, the mouse may be used for a confirmatory protection test using erysipelas antiserum (the *E. rhusiopathiae* isolate, however, must be pathogenic for mice). One group of experimental animals is inoculated parenterally with a 24-hour culture of the isolate; another is inoculated with *E. rhusiopathiae* antiserum and immediately thereafter with the isolate. The unprotected group should die within 4 days, whereas animals receiving antiserum will live. Cooper and Bickford (23) suggested the use of a mouse ear scarification model for isolating *E. rhusiopathiae* from a mixed culture. Briefly, 24-, 48-, and 96-hour broth cultures are applied to the scarified ears of several mice using a cotton swab. The mice usually die within 3–6 days, and the organism can be isolated in pure culture from the liver or heart blood. *E. rhusiopathiae* may be detected in tissues using the fluorescent antibody technique (73, 81), however, specific fluorescein-labeled antibody is not commercially available.

Sudden losses of adolescent turkeys in good flesh but with septicemic lesions, IM and subpleural ecchymotic and suffusion hemorrhages, and erysipeloid swelling of the snood suggest erysipelas. Also significant is a marked hemorrhagic condition of the skin, facial, and muscular tissues of the breast. In many cases, predominant losses will be in males, but in breeding flocks, sudden losses in hens with peritonitis, SC, cutaneous discoloration, and a history of insemination just prior to this suggest *E. rhusiopathiae* infection. Diagnosis is further validated by procedures described previously and in more detail by Cooper and Bickford (23).

Serology

Plate, tube, and microagglutination tests, in addition to passive hemagglutination, hemagglutination-inhibition, complement-fixation, growth agglutination, and growth-inhibition tests, have been used in swine erysipelas research, but their usefulness for the diagnosis of avian erysipelas have not been evaluated fully. Actual information regarding the nature of immunity induced in turkeys following natural exposure to *E. rhusiopathiae* or to erysipelas vaccines is scarce. Infected birds that recover appear to be solidly immune. Agglutination titers have been reported to be usually 160 or higher in antibiotic-treated recovered turkeys and turkeys that are carriers for the organism. Sikes and Tumlin

(113), however, suggested that titers of 40 or greater are indicative of *E. rhusiopathiae* infection in turkeys. Takahashi *et al.* (122) reported positive growth agglutination test titers in culled chicken layers sent to a processing plant. Currently, it is not known whether one particular serotype or strain of the organism is effective in detecting antibodies to other serologic types or strains of *E. rhusiopathiae*. Sato *et al.* (99) described latex agglutination and ELISA tests using the 64,000-MW protective antigen of *E. rhusiopathiae.* At present, these tests are mainly useful for research studies.

Differential Diagnosis

Fowl cholera, *Escherichia coli* infections, salmonellosis, and peracute Newcastle disease might be confused with the acute septicemic form of the disease. The less common forms of the disease (urticaria and endocarditis) may be caused by other miscellaneous bacterial agents or possibly fungal pathogens. All of these agents are differentiated easily from *E. rhusiopathiae* by gram staining or biochemical activity. *Lactobacillus* sp., which occasionally may be isolated from intestinal tracts or livers of poultry and is biochemically similar to *Erysipelothrix*, may be differentiated using the highly selective Packer's medium containing sodium azide and crystal violet. Gram staining, growth on Packer's medium, and the typical reaction pattern in TSI medium or Kligler's lead acetate medium are excellent presumptive tests. Confirmatory diagnosis is by molecular methodologies such as PCR, fluorescent antibody test, or animal pathogenicity tests.

Intervention Strategies

Management Procedures

It has been suggested, though not established, that various environmental factors may make avian species more susceptible to *E. rhusiopathiae* infection. Early field observations indicated that the beginning of rainy, cold weather, which frequently coincided with sexual maturity, was related to outbreaks of erysipelas in turkeys on the range. This may apply to flocks of other avian species. Source of the organism may be contaminated feed, soil, or decaying matter; infected carrier birds in the flock; or infected rodents. Apparently, the relationship between environmental factors and disease does not apply to cases involving individually confined birds, as in a zoo.

It is not possible to make clear-cut and specific recommendations for preventive or control management. A general suggestion is to use clean disinfected equipment and to rotate turkey ranges away from previously contaminated areas. Certain disinfectants, notably 1–2% sodium hydroxide (lye) solutions, are effective against *E. rhusiopathiae*; phenols, cresols, and related disinfectants; iodine; and certain household soaps are moderately effective.

Beneficial management practices in handling an outbreak of erysipelas in turkeys include thorough decontamination of equipment, prompt removal of dead birds and other carrion from premises, encouraging adequate feed and water intake, and handling birds as little and as gently as possible or practical. If unlimited range is available, it might be desirable to move the flock to clean ground, but such a practice may contaminate the new range.

With no specific and effective recommendations for management control of this disease in turkeys, it is suggested that birds be properly immunized in areas where erysipelas is known to be a problem.

Vaccination

Types of Vaccine

The most widely used products for the immunization of turkeys against erysipelas are the formalin-inactivated, aluminum hydroxide-adsorbed *E. rhusiopathiae* bacterins which may contain either whole or lysed bacterial cells. These bacterins initially were developed for use in swine and were shown to be effective in preventing erysipelas in turkeys (2, 3, 24). With the characterization of the 64,000-MW protective antigen, several investigators have suggested substitution of nonanimal evaluations, such as antigen-specific ELISA, for the routine release of these products (7, 47, 48).

Only certain strains of *E. rhusiopathiae* belonging to serotype 2, however, have been effective for use in bacterins. These strains are highly immunogenic because of the production of a soluble immunizing substance. This soluble immunizing substance is adsorbed and precipitated by aluminum hydroxide, which also adsorbs either the whole or lysed bacterial cells. The presence of this soluble substance is considered necessary for the production of an effective bacterin.

Although live erysipelas vaccines for swine have been around for more than 40 years, only recently have live vaccines become available for use in turkeys. Live erysipelas vaccines induce cross-protection against heterologous serotypes (90).

Other more recent approaches to vaccine development have focused on acapsular mutants, truncated protective antigen and the use of bacterial vectors for expressing *E. rhusiopathiae* protective antigen (20,54,110).

Field Vaccination Protocols and Regimes

A regimen of immunization can be suggested for meat turkeys as well as those kept for hatching egg production. Because the disease in other avian species is so sporadic, immunization other than in turkeys is not generally recommended. It is also important to remember that effective immunization of mice or swine is not an adequate demonstration of the ability of a bacterin to protect turkeys. Cultures avirulent for turkeys and without immunogenicity for them may kill mice or provide protection. At this time, immunizing capacity for turkeys can be assessed properly only with challenge of vaccinated turkeys.

Suggested for meat turkeys in areas of high risk is a single dose of the bacterin inoculated SC at the dorsal surface of the neck behind the atlas. The original investigation and demonstration of efficacy were based on IM injection of bacterin; however, because of the possibility of sterile abscesses (with downgrading at slaughter), SC inoculation is used now.

For turkeys kept as breeders, at least 2 doses of bacterin given at 4-week interval, should be administered prior to onset of egg production. The first dose may be given at 16–20 weeks of age (at selection time) and an additional dose given (2 mL/hen, 4 mL/tom) just prior to beginning of lay.

Improved vaccines properly used, adequate testing of the biologicals, planned immunization programs based on flock and premise history, and proper diagnosis of disease outbreaks as a basis for prompt treatment must be combined for effective prevention of erysipelas.

Treatment

The antibiotic of choice for an outbreak in market or breeder turkeys is a rapid-acting form of penicillin. Any antibiotic should be used under veterinary supervision according to current treatment procedure. Label directions should be followed carefully. As soon as diagnosis is definitely established, potassium or sodium penicillin should be administered IM at the rate of about 10,000 U/lb body weight (200,000–300,000 U) simultaneously with a full dose of erysipelas bacterin. Control usually has been attained by giving penicillin (1,000,000 U/gal) in drinking water for 4 or 5 days to all birds in the flock when a presumptive diagnosis is made. All birds in the affected flock should be treated. Some recommendations suggest the use of procaine penicillin or other longer-acting derivatives; under certain circumstances, these may be used successfully, but in outbreaks, rapid-acting formulations are almost mandatory. A combination of longer-acting and rapid-acting antibiotic formulations may provide best control if individual SC or IM injection is feasible and cost effective. Especially in meat-bird flocks, however, catching and handling each bird may be impractical or even harmful. Sterile abscesses and downgrading may follow IM injections. Care should be taken to observe the required withdrawal periods for the antibiotic used. Turkeys and possibly other birds with advanced signs of the disease at treatment time often will not recover. Experimental use of certain antibiotics including penicillin will control the infection but will not eliminate carriers. Antibiotics other than penicillin may increase the carrier rate in a flock of turkeys (27).

Comparative studies are lacking on efficacy of various antibiotics for controlling *E. rhusiopathiae* infection in avian populations. Erythromycin and broad-spectrum antibiotics have been found effective. *In vitro* studies have shown the organism to be resistant to neomycin (39). Sulfonamides and oral oxytetracycline are not effective treatments.

Avian Intestinal Spirochetosis

David J. Hampson and David E. Swayne

Introduction

Avian intestinal spirochetosis (AIS) is a disease of birds characterized by a pronounced colonization of the cecum and/or rectum with anaerobic intestinal spirochetal bacteria of the genus *Brachyspira*. AIS has been recorded mainly in flocks of laying hens and broiler (meat) breeder hens, where it causes mild to moderate, subacute to chronic disease (26, 32, 100, 142, 155, 164). AIS has not been diagnosed in broiler flocks, but has been reported as a sporadic condition in other domesticated poultry such as turkeys (131) and game birds including pheasants and partridges (73, 177). Severe AIS has been reported in common rheas (*Rhea americana*) (130, 161) and in geese (110). Subclinical colonization either with pathogenic or apathogenic *Brachyspira* species is common in feral waterfowl, particularly ducks (74, 117).

The clinical outcome following a given exposure depends on the age and species of bird involved, the pathogenic potential of the particular *Brachyspira* species or strain, the extent of colonization, and likely many other predisposing or mitigating factors. The most commonly reported clinical problems in chickens with AIS are delays or reductions in egg production, smaller and lighter eggs with poor shell quality, and a change in fecal consistency, with increased fecal output and water content (26, 36, 46, 51, 144, 155, 164). Diarrhea may be yellowish brown, mucoid and/or foamy, with increased lipid content (36, 155, 164). These changes result in fecal staining of eggshells and housing problems including contamination of cages and equipment, wet litter, reduced hygiene, increased odor and attraction of flies. Reductions in growth rate in broiler chicks hatched from infected breeding hens also have been reported (37, 132).

The spirochetes involved in AIS are distinct from *Borrelia anserina*, the etiological agent of non-relapsing, tick-borne, acute septicemic borreliosis (sometimes called avian spirochetosis) (see "Miscellaneous and Sporadic Bacterial Infections" later in this chapter). The spirochete genus *Brachyspira* currently includes seven officially named and two unofficially proposed species of intestinal spirochetes (31, 49, 65, 115, 138, 142). These nine *Brachyspira* species colonize the large intestine of various mammalian hosts, and all but two of the species have been recorded in birds. Other uncharacterized, uncultured, and probably commensal spirochete species also exist in the large intestines of birds and mammals (52).

Certain of the *Brachyspira* species form part of the normal large intestinal microbiota whilst to a greater or lesser extent others act as pathogens in individual avian or animal hosts. The four main pathogenic species found in birds are *B. intermedia, B. pilosicoli, B. alvinipulli* and *B. hyodysenteriae*. The best characterized of these is *B. hyodysenteriae*, the agent of swine dysentery

(56). Besides swine, *B. hyodysenteriae* naturally infects the common rhea, causing a severe necrotizing typhlitis (16, 17, 77, 130). *B. intermedia* is an enteric pathogen in chickens, but also is found in swine in which it sometimes may be mildly pathogenic (58). *B. pilosicoli* colonizes and is considered a pathogen in a range of avian and mammalian species, including swine, dogs, horses and humans (30, 31, 48, 57, 58, 171). *B. alvinipulli* has only been reported as a pathogen in chickens and geese (110, 155, 157).

The clinical signs of AIS are not specific, and accurate diagnosis largely relies on identification of pathogenic *Brachyspira* species in the ceca and rectum of affected birds. These spirochetes are slow growing anaerobes, requiring specialized media for isolation, and consequently only laboratories with expertise in their culture and identification are able to routinely confirm a diagnosis. In part this helps explains why AIS is relatively infrequently diagnosed, despite epidemiologic surveys identifying it as being common in laying hen and broiler breeder flocks (8, 26, 32, 100, 142).

A recent review of AIS has been published (143). A text is available on intestinal spirochete infections of domestic animals and humans (52), and this includes a chapter on AIS (154).

Definitions and Synonyms

Avian intestinal spirochetosis is a general term referring to colonization of the avian cecum and/or rectum with spirochetes. More specifically, the term is used to describe colonization with pathogenic *Brachyspira* species (*B. intermedia, B. pilosicoli* and/or *B. alvinipulli*) in flocks of chickens or other birds with reduced egg production and/or diarrhea, and for the severe typhlitis of rheas caused by *B. hyodysenteriae.*

The related term "intestinal spirochetosis" is used to describe colonization of humans with either or both of the two *Brachyspira* species *B. pilosicoli* and *B. aalborgi* (47, 103, 166). "Porcine intestinal spirochetosis" or "porcine colonic spirochetosis" is used to describe infections of swine with *B. pilosicoli* (48), whilst the name "swine dysentery" is reserved for infections of swine with *B. hyodysenteriae* (56). In the future, it may be desirable to further subdivide or refine the term AIS to link it with specific etiologic spirochete species or clinical outcomes.

Economic Significance

A recent study in the United Kingdom (UK) has suggested that AIS caused by *B. pilosicoli* results in a potential annual loss to the laying hen industry of around £4.1 million (US$ 7.6 million) (20). Inadvertantly a sum of £14 million was reported in the publication, but later it was realized that this did not take into account the prevalence of *B. pilosicoli* infections (~30%) (18). The £14 million was probably about right, however, as the calculation also did not include losses associated with *B. intermedia* infections; the latter are often more severe than *B. pilosicoli* infections, and are commonly found in noncaged (free-range and barn) flocks that account for approximately 50% of UK production (18). Losses similar to those in the UK likely occur elsewhere, as, for example, epidemiologic surveys suggest that AIS is as common amongst Australian and Italian laying hen flocks as it is in the UK (8, 100, 142).

Worldwide losses to the meat chicken industry associated with infection of breeder flocks also may be high, especially as these flocks are commonly infected (100, 142). In 1998 it was calculated that a commercial broiler flock hatched from eggs from a breeder flock with clinical AIS lost approximately £9,900 (US$ 15,800) per annum from reduced growth rates and poor feed digestion (132). Additional losses to the infected breeder flocks associated with reduced egg production and increased feed consumption were estimated at £10,600 (US$ 16,900) per flock per annum.

Besides delayed and/or reduced egg production in laying hen flocks, AIS can reduce profitability due to mortalities, downgrading of stained eggs, and increased labor costs associated with extra cleaning of cages and houses. There also may be local adverse environmental effects through increased odor from wet feces and attraction of flies.

Public Health Significance

Certain avian strains of *B. pilosicoli* are closely related to strains from humans (and other animals), and there probably is no barrier to cross-species transmission of this spirochete species (58). Strains of *B. pilosicoli* isolated from humans have been used experimentally to colonize 1-day-old chicks (34, 106, 167, 168) and adult laying hens (72), and there seems to be no reason why avian strains could not colonize humans. Nevertheless, it remains unproven whether transmission occurs from birds to humans. Colonization of people with *B. pilosicoli* is common in individuals in developing countries, whilst in developed countries it is mostly confined to homosexual males and those with suppressed immune systems (10–50% prevalence) (98, 103, 108, 166, 171). In humans, colonization with *B. pilosicoli* has been linked to problems such as abdominal pain, chronic diarrhea, reduced growth rates in children (14, 29, 47, 103, 121), and spirochetemia (81, 172). Infection is common in individuals in crowded and/or unhygienic conditions, and its occurrence has been linked with certain sources of drinking water (98, 108). *B. pilosicoli* has been isolated from lake and dam water frequented by ducks colonized by *B. pilosicoli*, emphasizing the potential for some avian intestinal spirochetes to be transmitted by ingestion of contaminated water (117). The likelihood of healthy poultry industry workers becoming infected with *B. pilosicoli* from contact with chickens is low.

History

There are several early accounts of intestinal spirochetes in birds. For example, in 1910 an intestinal spirochete called "*Spirochaeta lovati*" was described in the ceca of normal young and adult grouse (39). In 1930, helically shaped bacteria of three morphologic types were visualized in cecal droppings from both clinically normal and sick chickens obtained from Baltimore live-poultry markets (62). In 1955, large caseous nodules with associated spirochetes were identified in cecal walls of turkeys, chickens, and pheasants in the United States of America (US) (99). In the early 1970s a renewed interest in intestinal spirochetes was sparked by the discovery that the spirochete *Treponema hyodysenteriae* (later called *Serpulina hyodysenteriae* and now *Brachyspira hyodysenteriae*) was the etiologic agent

of swine dysentery, an important mucohemorrhagic diarrheal disease of pigs (56, 63, 158).

In the mid to late 1980s, a series of studies conducted mainly in the Netherlands (26, 32–37), but also in the UK (46), identified intestinal spirochete infections as being common in flocks of laying hens and in broiler breeder hens, in which they were associated with a variety of syndromes including delayed and/or reduced egg production and wet feces. At that time the species of spirochete involved were not known. Subsequent work in the US (155, 164), and more recently in Australia (100, 125, 144, 146) and Europe (8, 19, 20) has confirmed and extended these results, including the identification and naming of the pathogenic *Brachyspira* species causing disease in poultry (101). In 1990, AIS with necrotizing typhlitis and high mortality was identified in common rheas in the US (130). In recent years sporadic cases of AIS also have been identified in domestic turkeys (131), pheasants (177), partridges (73) and geese (110).

Etiology

Classification and Host Specificity

Spirochetes are classified into the order Spirochaetales in the three families Spirochaetaceae, Brachyspiraceae, and Leptospiraceae, and in 9 genera (21, 119). The intestinal spirochetes associated with clinical cases of AIS all belong in the family Brachyspiraceae, genus *Brachyspira* (119).

The genus *Brachyspira* currently contains seven official species (*B. hyodysenteriae, B. intermedia, B. innocens, B. murdochii, B. alvinipulli, B. pilosicoli* and *B. aalborgi*), and two proposed species ("*B. pulli*" and "*B. canis*") (31, 49, 65, 115, 135, 137, 138, 142, 143, 170). Most of these species were originally delineated using multilocus enzyme electrophoresis (MLEE) (91, 94, 101), coupled with analysis of their 16S ribosomal RNA gene sequences and phenotypic features (40, 120, 136). All species except *B. aalborgi* previously belonged to the genus *Serpulina* (49, 115). All the species colonize the large intestine, but only *B. pilosicoli* and *B. aalborgi* are known to attach by one of their cell ends to cecal or colonic enterocytes (103). The *Brachyspira* species have close similarities in their 16S rRNA gene sequences, indicating that they have evolved into different species relatively recently (118). Of the nine species, to date only *B. aalborgi* and "*B. canis*" have not been recovered from birds. The wide diversity of *Brachyspira* species found in birds suggests that they may have been the original hosts of an ancestral *Brachyspira*-like anaerobic spirochete when it first colonized the intestinal tract.

Recently, unusual spirochetes apparently of the genus *Brachyspira* have been identified in jackdaws, hooded crows and Rooks (genus *Corvus*), although their significance is uncertain (75). Other unclassified avian spirochetes have been described that differ biochemically, morphologically, and/or genetically from the earlier described species (101, 147, 148, 169).

Pathotypes

Based on experimental studies and naturally occurring colonization, the species *B. intermedia, B. pilosicoli, B. alvinipulli* and

B. hyodysenteriae are considered to be potential pathogens in birds and have all been used experimentally to reproduce disease. Their features are summarized in Table 23.4 (51, 101, 144, 157). The proposed species "*B. pulli*", together with *B. innocens* and *B. murdochii* are generally thought of as being commensal in birds (101). Consistent with this, strains of *B. innocens* have failed to cause disease in experimentally inoculated chicks and breeder hens (144, 167). On the other hand, a strain of "*B. pulli*" was mildly pathogenic in experimentally inoculated chicks (50), and strains of *B. murdochii* were present in many hens from a broiler breeder flock with AIS (142, 146).

Besides the spirochete species, expression of pathogenicity varies with route of inoculation, age of host, host species, environmental stressors, diet, and the presence of certain bacterial species in the large intestinal microbiota (152, 155).

Morphology and Staining

Brachyspira species are Gram-negative, helically shaped bacteria with diameters ranging from 0.25–0.6 μm, lengths from 3–19 μm, amplitudes from 0.45–0.79 μm, and wavelengths from 2.7–3.7 μm (63, 135, 137, 138, 170). They stain brown with silver-impregnation stains, blue with Wright's-Giemsa stains and are identified readily in wet mounts by dark-field or phase contrast microscopy. Each spirochete cell contains a central protoplasmic cylinder, multiple periplasmic flagella, and an outer envelope (outer sheath) (Fig. 23.12) (21). The periplasmic flagella are endocellular and divided into 2 equal sets, with each set originating from opposite poles of the protoplasmic cylinder and overlapping with the other set in the middle of the cell. This unique anatomic feature has been used as a phenotypic trait for identifying spirochetes. The number of periplasmic flagella has been used for spirochete classification, however this has limited value as the numbers can vary between and within species. *B. pilosicoli* and *B. aalborgi* typically have four flagella at each cell end, whilst the other *Brachyspira* species have eight or more at each end. The rotation of periplasmic flagella between the outer membrane and protoplasmic cylinder confers a corkscrew-like movement to spirochete cells (10, 22). These morphologic features and motility permit spirochetes to traverse highly viscous liquids, such as mucus, which immobilize externally flagellated bacteria (22, 109).

Growth Requirements

Brachyspira species are anaerobic, although they will tolerate transient exposure to air (134). Primary isolation has been accomplished on various selective solid media systems used to isolate swine intestinal spirochetes (1, 76, 86). Typically, media contain a blood agar base, such as Trypticase Soy agar with 5–10% defibrinated sheep blood, and 1–5 selective antibiotics (including spectinomycin, rifampin, spiramycin, vancomycin, polymixin and/or colistin). As the different *Brachyspira* species vary in their tolerance to these antimicrobials, a recommended "general" *Brachyspira* plate contains 400 μg/ml spectinomycin and 25 μg/ml each of colistin and vancomycin (76). These antibiotics inhibit the growth of non-spirochetal enteric bacteria that would otherwise overgrow the slow-growing spirochetes. Incubation is

Table 23.4.   Morphologic, biochemical, and other characteristics of the four main pathogenic *Brachyspira* species reported in birds.

Characteristic	Species			
	B. intermedia	*B. pilosicoli*	*B. alvinipulli*	*B. hyodysenteriae*
Birds most commonly affected	Layer and broiler breeder chickens	Layer and broiler breeder chickens; turkeys	Layer and broiler breeder chickens; geese	Common rhea
Pathogenicity	Moderate to mild	Moderate to mild	Moderate to mild (severe in geese)	Severe
Colonization of cecal epithelial surface	Random in lumen and crypts—not attached to epithelium	May be attached by one cell end to cecal enterocytes	Random in lumen and crypts—not attached to epithelium	Random in lumen and crypts—not attached to epithelium
ß-Hemolysis pattern	Weak (occasionally intermediate or strong)	Weak	Weak	Strong
Indole production	+	– (occasionally positive)	–	+ (Occasionally negative)
Hippurate hydrolysis	–	+ (occasionally negative)	+	–
Type strain	PWS/A^T – ATCC 51140	P43/6/78^T – ATCC 51139	C1^T – ATTC 51933	B78^T – ATCC 274164

23.12.   *Brachyspira alvinipulli.* Spirochete cell is helically shaped on longitudinal orientation (A). On transverse sections, an end (B) and the middle (C) of spirochete cells have 8 and 16 periplasmic flagella (arrows), respectively (157).

at 37–42°C for a minimum of 10 days; however, for most avian isolates visible growth is usually present in 2–5 days. Typical gaseous environments are 94% H_2 and 6% CO_2, generated using anaerobic gas packs in an anaerobic jar, or 80% N_2, 10% H_2 and 10% CO_2 in an anaerobic chamber (13). The spirochetes can be further propagated in anaerobic brain heart infusion broth containing 10% fetal bovine serum, with 1% oxygen to enhance growth (133), or in a pre-reduced anaerobic Trypticase Soy broth medium ("Kunkle's medium") (87). Growth of 10^8 to 10^9 cells per mL can be achieved in these broths within 2–3 days.

Colony Morphology and Hemolysis on Blood Agar

When inoculated onto agar, *Brachyspira* species grow as a dull flat sheen on the agar surface, forming confluent areas of growth with sharply defined edges, sometimes penetrating into the agar. With many isolates, growth on the agar is surrounded by a zone of hemolysis. Most of the *Brachyspira* species are weakly hemolytic, although *B. hyodysenteriae* (from pigs, rheas and ducks) is strongly hemolytic, and occasional avian strains of *B. intermedia* and other unidentified species can cause intermediate to

strong hemolysis (73, 74, 100, 101). The presence of spirochetal growth should be confirmed by the characteristic morphology and motility of the bacteria on wet mounts using dark-field or phase contrast microscopy, or in fixed smears using Wright's-Giemsa or Gram's stain. Spirochetes stain weakly gram negative.

Biochemical Properties

Brachyspira species typically contain alkaline and acid phosphatase, esterase, esterase lipase, ß-galactosidase, and phosphorylase activities (147). Differences in hemolysis patterns, production of indole, hippurate hydrolysis and the presence or absence of ß-galactosidase and ß-glucosidase activities have been used to categorize isolates (40). A commercial API ZYM system and numerical 5-digit coding system for enzyme activities has been used in differentiating avian and mammalian isolates (68, 94). As these phenotypic properties can vary, more specific molecular based techniques now have largely replaced biochemical testing for species identification.

Susceptibility to Chemical and Physical Agents

Strains of *B. pilosicoli* have been shown to survive for extended periods in water, particularly at colder temperatures (4 days at 25°C; 66 days at 4°C)(117). Similarly, strains of *B. hyodysenteriae* and *B. pilosicoli* can survive for prolonged periods in porcine feces and in soil mixed with porcine feces (78–210 days at 10°C) (12). On the other hand, strains of *B. intermedia* and *B. pilosicoli* are relatively short lived in chicken feces (~3 days at 4°C, at 109/g feces), and do not persist in the environment of chicken houses (122). This reduced viability in chicken feces is likely due to its rather dry and acidic nature. Most common disinfectants are efficacious against *Brachyspira* species (122), although it is best first to remove organic matter (24). Cleaning, disinfection and resting of empty houses between batches of hens have the potential to break cycles of AIS on infected farms (122).

Virulence Factors

The mechanisms by which *Brachyspira* species cause disease in avian and mammalian species are incompletely understood. Development of AIS probably requires the activity of multiple virulence factors, and these may vary somewhat between the pathogenic species. In general terms, virulence attributes of pathogenic *Brachyspira* species likely consist of a set of "lifestyle" virulence factors involved in initial colonization and fitness for survival and proliferation in the microenvironment adjacent to the mucosa of the large intestine, and one or more "essential" virulence factors that are required for lesion production and/or disease. To some extent the lifestyle factors, including such things as ability to survive in an anaerobic environment, use available substrates, be motile and undergo chemotaxis are likely to be shared by commensal and pathogenic *Brachyspira* species, since all *Brachyspira* species are able to colonize the large intestine. Subtle differences in such lifestyle factors presumably cause differences in behavior—for example some *Brachyspira* species show a limited host range (e.g., *B. aalborgi* is largely restricted to humans), whilst others have a much broader host range (e.g., *B. pilosicoli* colonizes many species of birds and animals).

To date only *B. hyodysenteriae* and to a lesser extent *B. pilosicoli* have been studied in relation to their potential virulence factors (in both cases, mainly in the context of swine diseases). The host range and virulence trait determination of *B. hyodysenteriae* remains poorly understood. For example *B. hyodysenteriae* strains isolated from rheas caused severe necrotizing typhlitis and high mortality rates in rheas but were apathogenic and failed to produce significant intestinal colonization in swine (140, 154). Preliminary studies on *B. hyodysenteriae* isolates from feral mallards in Sweden suggest that these are not pathogenic in mallards or in experimentally inoculated swine (74). Similarly, some strains of *B. hyodysenteriae* recovered from swine are avirulent in experimentally inoculated swine (2, 56).

In order to colonize the large intestine *Brachyspira* species cells must penetrate and move through the mucus overlying the mucosa. All *Brachyspira* species cells are motile, but they vary in their attraction to colonic mucin. For example virulent but not avirulent strains of *B. hyodysenteriae* are attracted to mucin (104), whilst the chemotactic response of *B. pilosicoli* to mucin can be modulated by certain substrates in the growth medium (179). Some avirulent strains of *B. hyodysenteriae* lack a homologue of the *mglB* gene, encoding a glucose-galactose lipoprotein, which is believed to be a chemoreceptor in glucose and galactose chemotaxis (176). This finding supports the view that chemotaxis is involved in the expression of virulence in *B. hyodysenteriae*. The role of motility in colonization also has been confirmed by experiments in which *B. hyodysenteriae* strains with disruptions introduced to their flagella genes (*flaA* and *flaB*) had reduced motility and ability to colonize (82, 129). Similar experiments have not been conducted with the other pathogenic *Brachyspira* species, but it can be assumed that motility is important for their colonization.

Another likely "lifestyle" virulence factor of *Brachyspira* species is their NADH oxidase activity, which is believed to enhance their ability to colonize the colonic mucosa by protecting them from oxygen toxicity. Consistent with this, *B. hyodysenteriae* strains with an inactivated *nox* gene showed a reduced ability both to colonize swine and cause disease (139).

Potential "essential" virulence determinants in *B. hyodysenteriae* include this spirochete's strong hemolytic activity (56). Early studies suggested that *B. hyodysenteriae* hemolysins had molecular weights of 19 kDa, 68 kDa or 74 kDa (160). The hemolysin(s) were oxygen-stable and resembled streptolysin S, a carrier-dependent toxin. Purified hemolysin was cytotoxic to a number of tissue culture cell lines and to primary pig cells (83), and damaged epithelial cells in porcine ligated intestinal loops (96) and in the murine cecum (69). Three genes (*tlyA, tlyB* and *tlyC*) encoding putative hemolysins of *B. hyodysenteriae* were originally described, based on their ability to induce a hemolytic phenotype in *Escherichia coli* (161). It now appears that the *tly* genes may be regulatory elements, rather than encoding hemolysins themselves, but nevertheless inactivation of *tlyA* reduced both the hemolytic activity and the virulence of *B. hyodysenteriae* (70). More recently, a distinct gene (*hlyA*) has been described encoding an 8.93 kDa polypeptide of *B. hyodysenteriae* with hemolytic activity (66). *B. pilosicoli* also has the *hylA* gene, but the spirochete is only weakly hemolytic (180). This difference in phenotype between the two *Brachyspira* species may be related to differences in transcription or translation of the gene, or to a different pattern of attachment of lipid moieties to the hemolysin in *B. pilosicoli* (180). The genetic basis of the strong hemolysis of certain non-*B. hyodysenteriae* isolates from ducks and game birds has not been investigated (73, 74).

The lipooligosaccharides (LOS) in the cell envelope of *Brachyspira* species have some of the same biological properties as lipopolysaccharides from other gram-negative bacteria. LOS extracted from *B. hyodysenteriae* by phenol/water was toxic for mouse peritoneal macrophages, increased uptake of red blood cells by murine peritoneal cells via Fc and C3 receptors, acted as a mitogen for murine splenocytes, and generated chemotactic factors in fresh swine serum (114). Endotoxin extracted from *B. hyodysenteriae* by butanol/water had more biological activity than LOS extracted by phenol/water, and it induced interleukin-1 and tumor necrosis factor from murine peritoneal cells and augmented natural killer activity (45). Nevertheless, the biological activities of LOS and endoxin from *B. hyodysenteriae* and *B. innocens* are similar, and therefore may not account for the different pathogenic potential of the two species (44, 111). *In vivo* studies in mice and pigs have shown that *B. hyodysenteriae* endotoxin also induces production of pro-inflammatory cytokines such as interleukin-6 (113). Studies in mice support the view that *B. hyodysenteriae* LOS has a potential role in virulence since experimentally infected C3H/HeJ mice (hyporesponsive to LOS) showed no colonic lesions whilst C3H/HeB mice (normal responders) developed lesions (112, 114). The LOS of other pathogenic *Brachyspira* species has not been studied, other than to show that it is antigenically heterogenous amongst *B. pilosicoli* strains (93).

B. pilosicoli lacks the attachment and invasion determinants encoded by the *inv, ail* and *yadA* genes of *Yersinia enterocolitica,* the *eae* gene from enteropathogenic *Escherichia coli*, and a viru-

lence plasmid of *Shigella flexneri* (61). Although the attachment of *B. pilosicoli* to epithelial cells has been confirmed using intestinal epithelial cell lines *in vitro*, to date putative adhesins or host cell receptors have not been identified (107). Three different protease activities, including a subtilisin-like serine protease similar to that of other gram-negative bacteria have been found in the membrane of *B. pilosicoli*, but their potential role in disease causation is uncertain (25, 105).

In humans infected with *B. pilosicoli* or *B. aalborgi*, it has been suggested that the end-on attachment of a dense mat of these spirochetes to individual enterocytes can cause ablation of microvilli, with diarrhea resulting from a physical impedance to water and electrolyte absorption by the massive colonization (128). A similar situation could occur in chickens heavily colonized by *B. pilosicoli*.

Generally, the identification of virulence determinants in *Brachyspira* species has been hampered by a lack of genomic information for these spirochetes. Furthermore, experiments involving gene inactivation to analyse specific gene function have only been conducted with *B. hyodysenteriae*.

Pathobiology and Epidemiology

Host Range
Spirochetes have been recorded colonizing the ceca and recta of a variety of avian species, including chickens (63, 155, 164), common rheas (15, 16, 130), grouse (39), pheasants (99, 177), partridges (73), turkeys (131), geese (110), and captive or free-living wild birds, especially acquatic birds of the orders Anseriformes and Ciconiiformes (73, 74, 117, 148). Intestinal spirochetes have been observed in the ceca of young ostriches (*Struthio camelus*) with diarrhea (97). They have not been recorded in emus (*Dromaius novaehollandiae*), although asymptomatic emus with antibodies reacting with intestinal spirochetes have been found (154).

Incidence and Distribution
Cases of AIS in poultry have been reported in Europe, North America, and Australia; they almost certainly occur elsewhere but go unrecorded. Besides caged or housed flocks, outdoor free-range flocks also possibly are even more commonly affected (19, 175). As of 2006, necrotizing typhlitis in rheas has only been reported in the US (15, 16, 60).

There have been relatively few detailed epidemiologic surveys of AIS, and in these the incidence of colonization and disease has varied with the avian species examined and the methods used for demonstrating spirochetes. The incidence of AIS in poultry in the US is unknown, but surveys in Europe and Australia have shown the condition to be remarkably common in flocks of laying hens and broiler breeder hens. In a survey conducted in the 1980s in chicken flocks mainly from the Netherlands, using a direct fluorescent antibody test (FAT) on feces, 27.6% of flocks with intestinal disorders were positive for intestinal spirochetes whilst only 4.4% of flocks without enteric signs were positive (32). A later study in Western Australia used selective culture on feces collected from 37 randomly selected laying hen flocks and 30

broiler breeder flocks (100). Overall, 53% of the breeder hen flocks and 35% of the layer hen flocks yielded samples containing intestinal spirochetes. Moreover, 64% of the flocks with diarrhea or poor production were colonized, compared to only 24% of flocks with normal feces. Within-flock prevalence varied from 10% to 95% of the samples that were tested. More recent surveys also used selective culture, but included polymerase chain reaction (PCR) assays to identify the spirochete species present. Using these modifications, even higher overall prevalence rates were found in the eastern states of Australia, where spirochetes were recovered from 43% of 28 randomly selected broiler breeder farms and from 68% of 22 laying hen farms (142). Within these farms, most of which contained multi-aged flocks, infection was detected in 26% of 112 broiler breeder flocks (each in individual houses) and in 54% of 68 laying hen flocks. Within-flock prevalence varied from 10 to 100% of samples examined, with a mean of 47%. In this study there was a highly significant correlation between colonization and wet litter, with infected flocks on average having 14% greater fecal water content than flocks that were not colonized. Spirochetes were not detected in 45 broiler flocks on 19 farms that were surveyed. In a study in Northern Italy, 21 (72.4%) of 29 laying hen flocks were infected with intestinal spirochetes (8). In this case colonization was significantly associated with reduced egg production, but not with increased fecal water content. In the Australian and Italian studies, colonization rates were significantly higher in flocks >40 weeks of age than in younger flocks.

In surveys of various bird species held in zoological collections in the US (148) and Australia (117), colonization with intestinal spirochetes was commonly detected only in waterfowl of the order Anseriformes.

Prevalence of Pathogenic Species
In the preceding surveys around 70% of laying flocks and 50% of breeding flocks contained birds colonized by intestinal spirochetes. Isolates from about 67% of these colonized flocks typically have belonged to pathogenic species, of which *B. intermedia* accounts for around 67% of the isolates and *B. pilosicoli* for the remainder (8, 142, 146). Individual flocks and hens may be colonized by both these pathogenic species (142, 146, 125). *B. alvinipulli* has not been detected in these surveys, and to date (2006) has only been reported in two flocks of laying hens in the US (155) and in two flocks of geese in Hungary (110). A closely related spirochete has been identified in a Swedish dog (80). Infection of rheas with *B. hyodysenteriae* is widespread in the US (17), and has been recorded in some feral and farmed mallards in Sweden (73, 74). It is suspected that infections with *B. hyodysenteriae* occasionally occur in chicken flocks, but this has not been documented.

Strains Present
In one study MLEE was used to examine multiple *Brachyspira* isolates from 4 chicken farms (146). On one farm 16 *B. murdochii* isolates were located in 14 different electrophoretic types (ETs), whilst 5 isolates of *B. pilosicoli* belonged to the same ET. On the second farm, 5 of 6 *B. pilosicoli* isolates belonged to the

same ET, and the sixth was distinct, whilst 2 *B. intermedia* isolates were different from each other. On the third farm, 3 isolates of *B. intermedia* all belonged to the same ET. On the fourth farm, the 4 *B. intermedia* isolates all belonged to different but related ETs. Hence some infected farms may have a dominant strain of a species present, but other strains of the same or other *Brachyspira* species also may be present. This heterogeneity was also found in a study on a Western Australian laying hen farm, where 20 *B. intermedia* isolates examined using pulsed field gel electrophoresis (PFGE) were divided into 4 different PFGE types (125). The existence of strain heterogeneity amongst isolates from a farm is important, as different strains may have different biologic properties that may affect the clinical outcome, including virulence traits and antimicrobial susceptibilities.

Such different strains on a farm may have been independently introduced or may have arisen from "microevolution" of original strains that were present (6). Some of the pathogenic *Brachyspira* species have been shown to have recombinant population structures and to undergo extensive genetic rearrangements and sequence drift that generates genetic diversity (173, 180). Novel genetic information also may be acquired from other species/ strains through the activity of a prophage-like gene transfer agent observed in different *Brachyspira* species (67, 141).

Anatomic Location

Intestinal spirochetes colonize the ceca and rectum, but not the small intestine. Spirochetes primarily are found in crypt lumina and to a lesser extent in the cecal contents adjacent to enterocytes. *B. pilosicoli* cells may be found in groups attached by one cell end to the surface epithelium (Fig. 23.13), although they can colonize the ceca without attachment being seen. Spirochetemia with *B. pilosicoli* has been reported as a rare occurrence in humans but not in other animal or avian species. It is not known whether *B. pilosicoli* spirochetemia occurs in birds and goes unrecognized because of difficulties in isolating the spirochete.

Spirochete Persistence in the Ceca

Spirochetes can persistently colonize ceca (26, 33, 36). In one study spirochetes were detected in cecal droppings from the time of experimental infection at 14 weeks of age until the termination of the experiment 23 weeks later (37); in another experiment the same spirochete strain 1380 (later identified as *B. intermedia* (101)) was still present in the feces of experimentally infected laying hens after 9 months (33).

Transmission, Carriers, and Vectors

Intestinal spirochetes are transmitted between birds by the fecaloral route, either directly or indirectly. Aerosol transmission of feces between birds that are held in close proximity in confined conditions is likely to occur. Transmission of spirochetes between flocks of birds in different houses on a farm is most likely to occur through the movement of personnel who have clothing or boots contaminated by chicken feces. Wild birds and animals such as rats and mice also potentially could introduce and/or spread infection. Insects such as flies, or species such as dogs or
23.13.   Tight association of *Brachyspira pilosicoli* with the luminal surface of cecal epithelium (A). The orientation is at right angles to the epithelial cells (B).

feral animals, might serve as mechanical carriers. A major potential source of transmission is through the water supply. Wild ducks have been shown to shed strains of *B. pilosicoli, B. hyodysenteriae* and *B. intermedia* in their feces (73, 74, 117), and these may survive in effluent ponds or dams supplying drinking water (117).

Incubation Period

The incubation period of AIS is variable. Both the dose of the organism and secondary environmental factors can profoundly influence the incubation time. Disease signs can occur in chickens as early as 5 days after experimental inoculation (157), although often it may take several weeks for significant levels of colonization and clinical signs to occur (54, 55).

Influence of Age on Spirochete Colonization

Experimentally the pathogenicity of avian intestinal spirochetes is greatest when they are given to 1-day-old birds via crop gavage (152, 157), although natural infection of such young birds is not seen. The pathogenicity of *B. hyodysenteriae* in rheas is greater for birds < 5 months old than in adults (15). In commercial laying hens it is unusual to detect colonization before 15 weeks of age, and more colonized hens are found as the flocks become older (142). This age-related distribution likely reflects increasing levels of exposure rather than differences in age susceptibility.

Influence of Diet and Microbiota on Spirochete Colonization

For *Brachyspira* species to colonize they must reach the large intestine, then establish and interact successfully within the local

microenvironment. It is assumed that the spirochetes survive passage through the upper intestinal tract inside boluses of food or feces. Studies in swine have shown that once in the large intestine the spirochetes interact with various anaerobic bacterial species forming part of the normal microbiota of the cecum and colon, including species such as *Clostridium perfringens*. These species act synergistically with *B. hyodysenteriae* to facilitate spirochete colonization and augment inflammation and lesion production (64, 79, 178).

Dietary influences on colonization with *B. intermedia* have been shown in experimentally infected laying hens. In particular, diets based on wheat seem to promote colonization with *B. intermedia* compared to diets based on barley or barley and sorghum (123). Furthermore different wheat varieties have been shown to vary in their influence on promoting colonization by *B. intermedia* (124). In one study of laying hens fed wheat-based diets the addition of exogenous enzymes designed to hydrolyse the nonstarch polysaccharides in the wheat reduced *B. intermedia* colonization following experimental infection (55). In the same study, and in a subsequent study, addition of zinc bacitracin (ZnB) to the diet reduced colonization with *B. intermedia* (54). In contrast, dietary ZnB enhanced colonization with *B. pilosicoli* (71, 144). As ZnB mainly acts on Gram-positive bacteria rather than on the spirochetes themselves, these conflicting results indicate that there are likely to be complex positive and negative interactions between different components of the cecal microbiota and different *Brachyspira* species in chickens.

Taken together, these studies suggest that different clinical outcomes may occur in infected hens depending on their diet, intestinal microenvironment and microbiota, as well as the particular *Brachyspira* species involved in the colonization. These findings may help explain some of the heterogeneity in clinical signs and pathology seen in different commercial flocks with AIS.

Clinical Signs and Pathology

Information about clinical signs and pathology of AIS is limited, and available data have come from three main sources. The first is from experimental infection of 1-day-old chicks. These data provide a guide to the pathogenic potential of certain isolates, but the results must be viewed with caution as the associated colonization and disease may not be representative of natural infections in adult birds. The second source comes from experimental infection of adult chickens using defined isolates. This system is more representative of natural disease, but also has limitations. The experimental hens are usually individually caged, appropriately fed and relatively free of stress, and these conditions do not reflect the situation in many commercial caged flocks where AIS occurs. Disease is often quite mild or absent under these experimental conditions; for example, only slight reductions in egg production and/or increased fecal water content have been observed in the absence of obvious histologic changes in the ceca of some experimentally colonized birds (51, 144). Furthermore as these experiments are time consuming, testing tends to be done with only one or a few spirochete strains under a restricted set of standard dietary and other conditions. The birds are not co-infected with other species or strains of spirochetes, or with other enteric

pathogens, as may occur in commercial flocks. The third source of information comes from observations of natural cases of AIS. These are important data of direct industry relevance in terms of observing changes in production, but are limited by the fact that often there may be co-infections that are unrecognized, or which make the attribution of production losses or pathology associated with AIS difficult to allocate. An example of this was a report of histomoniasis with concurrent AIS in a free-range flock where there were mortalities, cecal pathology and loss of egg production (38). Another problem with some of the earlier descriptions of AIS in the field is that the species of spirochete involved in causing the condition were not known (26, 46).

Besides the *Brachyspira* species and perhaps even strain involved in the colonization, the initiation and severity of clinical disease are influenced by the host species, husbandry, nutrition, environment, and genetics (85). Some specific predisposing factors for AIS that have been observed in the field include molting, recent onset of egg production, poor or inappropriate feed quality, floor housing, and light-laying breeds of hens (20, 46, 85, 155, 164). Crowding of birds induces stress and increases the opportunity for spirochete transmission between individuals held in close proximity.

Naturally occurring or experimental colonization of birds with intestinal spirochetes broadly may result in: 1) subclinical colonization, 2) mild to moderate clinical disease, or 3) severe clinical disease.

Subclinical Colonization
Colonization by spirochetes without disease has been reported in chickens (62, 100, 142), most usually associated with apparently commensal *Brachyspira* species such as *B. innocens, B. murdochii* and/or "*B. pulli*" (101). In wild birds, especially waterfowl, most spirochetes are not associated with enteric disease, and are considered to be commensals forming part of the normal microbiota. However, inoculation of 1-day-old chicks with some unidentified but apparently apathogenic wild bird isolates has resulted in mild transient diarrhea and yellowish green, frothy cecal contents (147, 156). From an epidemiologic perspective it is also important to note that wild birds may carry pathogenic species without showing obvious clinical signs (73, 74, 117).

Mild to Moderate Clinical Disease
The "mild to moderate" disease spectrum is seen particularly in association with strains of *B. intermedia, B. pilosicoli* and *B. alvinipulli,* mainly in laying hens and broiler breeder hens. These infections tend to be associated with diarrhea and/or reduced egg production, but cecal changes are mild or inapparent.

Infections with B. intermedia. In early studies *B. intermedia* strain 1380 was used to experimentally infect broiler chicks (34), laying hens (36) and 14-week-old broiler hens and cocks, where the eggs were collected and hatched (37). Infected chicks showed variable reductions in growth rate, wet droppings with increased fat content, and increased serum content of protein, lipid, carotenoids and biliruben (34). Laying hens showed increased fecal fat content (36), developed slimy, wet, frothy feces (33), or had wet droppings

and produced significantly fewer eggs (37). Spirochetes were found penetrating the cecal mucosal lining between undamaged columnar cells, in "gap-like" lesions running through the epithelium, and accumulated just under the epithelium. There was some erosion of the superficial mucosa but no clear signs of inflammation in the connective or lymphatic tissues. The eggs from infected hens were significantly lighter, had paler yolks and had a lower carotenoid content. Broiler chicks hatched from eggs from the infected hens had pale, mucoid and wet feces, and the chicks were significantly lighter than control chicks at 2 and 3 weeks of age. They tended to develop rickets and had low blood plasma concentrations of carotenoids and alkaline phosphatase activity. They were not themselves colonized by spirochetes.

Experimental infection of laying hens with *B. intermedia* strain HB60 caused reduced growth rates, increased fecal water content, and decreased egg production and egg weight, but did not induce any characteristic pathological changes in the ceca (51, 56, 124).

Infections with B. pilosicoli. Newly hatched broiler chicks have been infected with human, porcine and/or canine isolates of *B. pilosicoli* (34, 106, 167, 168). Clinical signs either were not observed (34) or the chicks developed watery diarrhea (167, 168), sometimes with a depressed growth rate (168). Gross cecal lesions were not seen, but there were variable histologic changes included the characteristic presence of a dense mat of spirochetes attached by one cell end to cecal enterocytes (106, 167, 168), sometimes with a diffuse thickening of the cecal epithelial brush border (106). There was variable crypt elongation, crypt lumina were dilated and there was mild focal infiltration of the lamina propria with heterophils. Sometimes spirochetes were found between enterocytes or producing gap-like lesions; subepithelial accumulation of spirochetes and focal erosion without an inflammatory reaction also were recorded (34). Vacuolation and protein deposition were observed in the apical cytoplasm of some luminal enterocytes. Sometimes microvilli were obscured, damaged or obliterated by large numbers of attached spirochetes, and there was disruption to the terminal web microfilaments. Individual spirochetes invaginated into the cellular membrane and indented into the terminal web cytoplasm, but did not penetrate it.

Experimental infection of broiler breeder hens with avian *B. pilosicoli* strain CPSp1 resulted in a transient increase in fecal water content, fecal staining of eggshells and/or a significant reduction in egg production (144, 145). The ceca of infected birds were gassy and the contents were frothy, fluid and pale, but no gross or histologic lesions were observed. Spirochetes were isolated but they were not found attached to the cecal epithelium. Infection of laying hens with strain CPSp1 resulted in no disease signs (71), whilst infection with a human isolate of *B. pilosicoli* resulted in a persistent and significant increase in fecal water content (72). Again neither attachment of spirochetes nor gross pathologic changes were observed.

Natural infection of two layer flocks with *B. pilosicoli* was associated with a 5% reduction in egg production, diarrhea in up to 25% of chickens, wet droppings, feces smeared on feathers around the vent ("pasty vents"), lethargy and depression (164).
23.14. Mild lymphocytic typhlitis and mild epithelial hyperplasia in a chicken colonized with *Brachyspira alvinipulli*. Bar = 50 μm. (157)

The apical surfaces of cecal enterocytes were covered by a dense layer of spirochetes aligned parallel to each other and perpendicular to the mucosal surface (Fig. 23.13, Table 23.4). Four turkey flocks with increased mortalities were infected with *B. pilosicoli* (131). Large numbers of spirochetes were attached along the surface epithelium of the ceca and extended into the middle of crypts. Focal mucosal erosions occurred in some ceca, with spirochetes attached directly to the exposed basement membrane or invading the lamina propria. This was accompanied by an increase in the number of subepithelial mononuclear inflammatory cells.

Infections with B. alvinipulli. Experimental infection of 1-day-old chicks and 14-month-old hens with *B. alvinipulli* strain 91–1207/C1 resulted in yellow, golden or orange cecal droppings (157). The ceca were dilated and contained pale-green to yellow fluid to frothy contents. Infected birds had moderately severe lymphoplastic typhlitis and proctitis with lymphocyte and/or heterophil exocytosis, mild cecal villous epithelial cell hyperplasia, edema in the lamina propria of villous tips, and submucosal lymphocytic follicles (Fig. 23.14). Some chicks had mildly dilated cecal crypts. Mats of spirochetes were present over the villous surface and in the crypts, with spirochete cells oriented randomly on the cecal epithelial luminal surface or in the crypt lumina. Spirochetes rarely invaded between and below the cecal epithelial cells (Fig. 23.15).

B. alvinipulli strain 91–1207/C1 was originally identified in two flocks of laying hens where 5% of the chickens had wet feces, clinical diarrhea, pasty vents and produced dirty, fecal-stained eggshells (155). Spirochetes were present within the crypts and/or in the lumina of the ceca, and chickens with pasty vents had mild lymphocytic typhlitis.

23.16.   *Brachyspira hyodysenteriae*. Thick necrotic pseudomembrane attached to the cecal mucosa of a juvenile common rhea with necrotizing typhlitis.

Cases of AIS in Which Spirochetes Were Not Identified. In an early study in the Netherlands, an unidentified weakly hemolytic spirochete designated "strain K1" was isolated from a hen on a laying hen farm where there was prolonged intermittent diarrhea and an early decrease in egg production (26). Strain K1 had too many periplasmic flagella to be *B. pilosicoli,* nor was it *B. intermedia* or *B. hyodysenteriae* because it was indole negative. Naturally infected birds had a mild typhlitis. There was a slight increase in numbers of goblet cells, focal "gap-like" lesions in the cecal epithelium that were filled with spirochetes, with mild degeneration and mononuclear cell infiltration beneath the gaps. Ten-week-old hens experimentally infected with mucosal homogenates or strain K1 showed a transient increase in fecal water content, and this recurred after 8–9 weeks.

A study in the UK reported retarded growth rate and delayed onset of egg production in 22-week-old pullets (46). The mucosal crypts of the ceca were distended with sloughed epithelial cells and inflammatory debris, and there was marked mononuclear leukocytic infiltration of the lamina. Spirochete cells were randomly oriented on the cecal epithelial luminal surface or in crypt lumina.

In the Netherlands observations were made on 8 broiler breeder flocks with a history of AIS caused by uncharacterized spirochetes (132). Flocks with clinical signs had decreased egg production and increased feed consumption. Three percent of eggs produced were too light for successful hatching. Commercial broiler flocks hatched from eggs layed in periods when clinical signs of AIS were present in the breeder flocks showed increased feed conversion and consumption. Weak chicks, retarded growth and poor feed digestion occurred in the broiler flocks. Antibiotic treatment of the breeder hens before the onset of lay resulted in normally-performing offspring.
Severe Disease
Descriptions of severe disease associated with AIS have been limited to the typhlitis seen in rheas naturally infected with *B. hyodysenteriae* (16, 17, 130, 153), where mortality rates can range from 25–80%, and to a similar syndrome in geese infected with *B. alvinipulli*, where 18–28% mortality was recorded over a period of 2–3 months (110).

Most clinically affected rheas are > 6 months old (16), and most US cases occur from July through October (153). Adult birds can be affected, but these cases usually involve concurrent stress such as recent shipping. Clinically, 1–2 days prior to death, a few birds may show depression, have reduced body weights, and pass watery feces with caseous cores (152); however, rheas often die suddenly without clinical signs (130). Ceca are dilated and have thickened walls with ulcerations and lumina containing thick pseudomembranes (Fig. 23.16) (130, 152). Cecal walls have severe mucosal necrosis, crypt elongation, hyperplasia of glandular epithelial and goblet cells, and the cecal lumina contain mucus, colonies of spirochetes, bacilli, and fibrinonecrotic debris (Fig. 23.17). Experimental inoculation of 1-day-old chickens and turkeys with intestinal spirochetes from rheas produced similar but less severe lesions (77).

In the original rhea cases, a strongly ß-hemolytic spirochete was isolated and identified as *B. hyodysenteriae* (77). Inoculation of 1-day-old common rhea chicks reproduced the gross and histologic lesions within 5–9 days (152). In other cases unclassified weakly ß-hemolytic spirochetes have been isolated (130). In addition, various indigenous anaerobic bacilli can be recovered with spirochetes from cecal lesions (15). Production of AIS in rheas may require synergism between spirochetes and other anaerobic cecal microbiota.

Natural colonization of poultry with *B. hyodysenteriae* has not been reported. Experimental infection of 1-day-old chicks with porcine strains of *B. hyodysenteriae* resulted in reduced weight gain, atrophic and thickened ceca with mucus in the cecal lu-
23.17. *Brachyspira hyodysenteriae*—juvenile rhea. Thickened cecal mucosa contains dilated crypts filled with mucus. Lumen has a necrotic pseudomembrane composed of necrotic heterophils and sloughed epithelium, bacteria, and mucus. H & E. Bar = 50 μm.

mina, epithelial and goblet cell hyperplasia, and crypt elongation (3, 149, 150, 167). There was goblet cell hyperplasia, necrosis of the epithelium at tips of plicae, abundant spirochetes in crypts, and edematous lamina propria with accompanying heterophilic inflammation.

Severe disease associated with *B. alvinipulli* infection has been recorded in two goose flocks in Hungary (110). Following molting at the end of the first egg laying season, 28% of the 1,500 laying birds in flock A died during an 8-week period and 18% of the 4,500 laying birds in flock B died during a 12-week period. Affected geese had hemorrhagic to necrotic inflammation of the colon/rectum and fibrinonecrotic typhlitis accompanied by severe degeneration. Spirochetes were present in the mucous membrane of the large intestine. The kidneys were swollen, and some geese had visceral gout. The large intestine had a necrotic epithelial layer and the lamina propria contained hemorrhage as well as infiltration with lymphocytes, histiocytes and heterophilic granulocytes. Sometimes necrosis extended into the upper third of the lamina. Kidneys had degeneration of the tubular epithelial cells, focal or diffuse intertubular fibroblast cell proliferation, with atrophy of the glomeruli and tubules, and mineral deposition. Lymphohistiocytic inflammation of the liver was observed. Nine isolates were identified as *B. alvinipulli* whilst another (from flock A) was strongly beta-hemolytic but indole negative, and was tentatively identified as *B. hyodysenteriae.*

Immunity

Little is known about immunity to intestinal spirochetes in birds, and, as previously stated, prolonged colonizations of individual experimentally infected birds have been observed (33). Humoral antibodies to *Brachyspira* spp. preparations may or may not be produced following naturally occurring colonization. Antibodies can be detected in birds from which spirochetes cannot be isolated, and other birds may yield spirochetes on culture but be serologically negative (147, 148).

Diagnosis

Introduction

Gross pathologic and histologic examinations are rarely sufficient to allow an unequivocal diagnosis of AIS. Hence the diagnosis of AIS is usually confirmed using microbiological techniques to identify the associated spirochetes in birds with clinical, pathologic and/or production data consistent with AIS.

Visualization of Spirochetes

Visual demonstration of helical-shaped bacteria in feces or cecal droppings by dark-field or light microscopy is sufficient for presumptive identification of spirochetes. However, because spirochetes can be normal microbiota or produce subclinical colonizations, characteristic clinical signs and lesions must be present for a presumptive diagnosis of AIS.

Confirmation of bacteria as spirochetes should be through visualization of distinctive ultrastructural features, demonstration of spirochete antigens, isolation in culture, or by polymerase chain reaction (PCR) on feces. The demonstration of organisms with periplasmic flagella in ultrathin sections of cecal mucosa or in negative-stained preparations of clarified cecal contents is diagnostic for spirochetes. Demonstration of spirochete antigens by direct or indirect fluorescent antibody tests (IFAT) (26, 32, 92) or immunohistochemical (IHC) methods using polyclonal antisera is easier and more rapid than electron microscopy (42, 177). IFAT using antiserum raised against *B. hyodysenteriae* was used in the early epidemiologic surveys for AIS (26, 32). However, neither ultrastructural morphology nor identification of antigens by IFAT or IHC using polyclonal antisera will reliably distinguish between spirochete groups or species. Monoclonal antibodies (Mab) to cell envelope proteins of *B. pilosicoli* have been described (92, 159), and these could increase the specificity of IFAT for identifying this species in chickens. Similar reagents are needed for the other avian pathogenic spirochete species. Unfortunately, a Mab-based immunomagnetic separation of *B. pilosicoli* from swine feces did not improve sensitivity of detection above that achieved with standard culture followed by PCR (23). The direct use of PCR on chicken feces is discussed later.

Isolation of Causative Spirochetes

Culturing and further characterization is important to help identify the spirochete species, and to allow strain typing and determination of antimicrobial sensitivity. The level of detection of

culture is dependent on the number of organisms and type and condition of the sample. Fresh cecal droppings or cecal mucosa are optimal samples, but samples chilled at 4°C for up to 1 week are acceptable.

Identification of Causative Spirochetes

Phenotypic Properties

Isolated bacteria can be confirmed as spirochetes by their characteristic morphology and motility under dark-field or phase contrast microscopy, the presence of periplasmic flagella observed under transmission electron microscopy, and/or their reactivity in immunofluorescent microscopy using specific antisera (see above). As discussed earlier under "Etiology", the observation of hemolytic patterns on blood agar and the patterns of biochemical reactivity can allow a presumptive identification of some *Brachyspira* species (Table 23.4).

Genotypic Properties

The use of molecular methodology for spirochete identification (and detection) has greatly improved diagnostic capacity. MLEE has been extremely useful in defining the current *Brachyspira* species (94, 101, 146), but is too slow and cumbersome for routine diagnosis.

PCR assays have been used on isolated spirochetes or on the growth on primary isolation plates to identify and differentiate *Brachyspira* species (5, 7, 95, 151). Laser capture has also been used to recover *B. pilosicoli* from fixed cecal mucosa of turkeys prior to PCR amplification (131). To date the most reliable PCR assays for amplification of DNA from *B. pilosicoli* have been based on the 16S rRNA gene, whilst a recently improved PCR based on the NADH-oxidase (*nox*) gene works well for *B. intermedia* (125, 126). Both *nox* and *tly* gene PCRs are regularly used for *B. hyodysenteriae* (41, 89). No PCR assays have yet been described for *B. alvinipulli*.

A number of other schemes have been developed to detect and/or identify *Brachyspira* species without the need for culture and biochemical analysis. These involve PCR amplification of specific gene sequences, followed by restriction enzyme digestion of the products to give species-specific banding patterns after gel electrophoresis. Genes that have been used in this way for identifying different (mainly swine) *Brachyspira* species include the 16S rRNA gene (137), the 23S rRNA gene (9, 162), and the *nox* gene (127, 163).

Another recent adjunct to diagnosis has been the development of a fluorescent *in situ* hybridization (FISH) technique. This uses fluorescent oligonucleotide probes specific for sequences present in the 16S or 23S rRNA of different *Brachyspira* species to visualize spirochetes associated with the mucosa in formalin-fixed tissues (11, 78). Recently this technique has been further modified so that visualized spirochetes are isolated by laser capture microdissection, subjected to direct 16S rRNA gene PCR and the subsequent DNA sequence analysed (84). The advantage of these techniques is that they provide simultaneous identification and localization of the spirochetes associated with the intestinal mucosa. They should prove particularly useful in investigating aspects of the pathogenesis of AIS.

Strain Typing

Typing of individual *Brachyspira* species strains can provide important epidemiologic information to help devise control measures. Early studies used MLEE to differentiate intestinal spirochete isolates into species and strains (94, 101, 136), but this technique is not particularly good for discriminating all strains, and is time-consuming. Pulsed field gel electrophoresis now is the most commonly used strain typing technique for *B. pilosicoli, B. intermedia* and *B. hyodysenteriae*, and gives better strain discrimination than MLEE (4, 6, 125, 151, 173).

PCR on Feces

Recently, a two-step nested duplex PCR has been described for detection of *B. intermedia* and *B. pilosicoli* in DNA extracted directly from washed chicken feces (126). The first round of PCR amplifies genus-specific portions of the 16S rRNA and *nox* genes, whilst the second round uses a nested *B. pilosicoli*-specific 16S rRNA gene PCR and a *B. intermedia* specific *nox* PCR. Washing removes potential PCR inhibitors, and a two-step amplification procedure compensates for any loss of sensitivity associated with this washing step. This assay is rapid and should enhance diagnostic capacity for AIS. It could be further improved, and modified to include a *B. alvinipiulli*-specific PCR in the second round of amplifications.

Serology

Several serologic tests have been developed and used to determine exposure of swine to *B. hyodysenteriae*. Such tests have not used species-specific antigens and often have had low specificity and/or sensitivity (88). They include enzyme-linked immunosorbent assays, plate and microagglutination tests, agar gel diffusion, passive hemolysis assays, and indirect fluorescent antibody tests (56). An agar gel diffusion test has been used to identify evidence of intestinal spirochete colonizations of birds (148). The test does not, however, distinguish between different spirochete species and is relatively insensitive.

Differential Diagnosis

Spirochetes identified in fecal specimens from poultry should be distinguished from other helical bacteria including *Campylobacter, Arcobacter, Helicobacter,* and *Spirillum*. Many helical bacteria can be apathogenic indigenous flora of the gastrointestinal tract of birds. Wet droppings have a number of known causes, and these may interact in a multifactorial way to result in severe problems. In cases of chronic diarrhea or pasty vents, nutritional problems such as excess dietary salt, fats, or raw soybean meal should be investigated. Increased urinary output due to excessive drinking, kidney damage, and incorrect amounts of calcium and electrolytes in the diet can result in wet litter, as can water spillage. Other infectious causes of chronic diarrhea include enteric salmonellosis, colibacillosis, coccidiosis and histomoniasis.

In rheas and geese, intestinal spirochetes causing a necrotizing typhlitis must be distinguished from other potential causes including *Salmonella*, especially group B serotypes, *Clostridium difficile, C. perfringens, C. sordelli*, and *Histomonas meleagridis* (28, 102, 133). Furthermore, cecal lesions of eastern equine en-

cephalitis virus (EEEV) infection could be confused with severe AIS, but EEEV also produces copious small intestinal hemorrhages and necrosis and widespread petechiation and necrosis in visceral organs (174).

Intervention Strategies

Biosecurity

In farms that do not have AIS, strict biosecurity measures should be in place to prevent entry. There should be good physical containment (security fencing) around the farm, and bird-proof netting around openings in the houses. Entry of personnel should be restricted, preferably with shower-in and shower-out facilties. Replacement hens should only be obtained from sources known to be free of AIS. The food and water supply should be free of contamination. In particular, the water supply should be protected from fecal contamination from feral waterfowl.

Management Procedures in Flocks with AIS

Farms with AIS should practice the same precautions as outlined previously, but in addition they should decrease contact with potentially infectious feces by raising hens off floors, frequently changing litter and removing manure, implementing good rodent and insect control programs, minimizing dietary and molting stress, and providing high-quality feed ingredients whilst avoiding ingredients that enhance spirochete colonization (e.g., wheat). To prevent transmission between flocks on a site, and particularly from older to younger flocks, clean coveralls and boots, and disinfectant boot-dips should be provided at the entry into each house.

In the case of rheas, it is best to avoid raising them on swine farms. Visiting other rhea farms should be discouraged. Proper cleaning and disinfection of clothing, shoes, and equipment should be done before returning to the home flock following visits to rhea shows, rhea farms, or swine operations. All introductions of new rhea stocks should follow a minimum 60 days of quarantine and take place after 2–3 negative cloacal cultures for *B. hyodysenteriae*. Birds should be segregated into age groups, and strict biosecurity measures should be implemented to minimize potential transmission of *B. hyodysenteriae* from asymptomatic adolescent or adult birds to susceptible rhea chicks.

Vaccination

No vaccines are available to prevent AIS. Commercial bacterins and vaccines have been used to help control swine dysentery, but these have either provided inconsistent protection (53, 57) or even had deleterious consequences (116). Experimental vaccines using live attenuated strains of *B. hyodysenteriae* (70, 129, 139), recombinant proteins (90) or DNA (27) have all been developed, but have not yet reached commercial production.

Antimicrobial Treatment

Introduction

The authors are not aware of any chemotherapeutic compound that has been approved and registered for the treatment or prevention of AIS. Nevertheless, compounds used to treat or prevent swine dysentery and/or porcine colonic spirochetosis should have similar efficacy for treatment of AIS (48, 56).

In Vitro *Testing of Antimicrobials*

There are only two publications on *in vitro* antimicrobial susceptibility testing of intestinal spirochetes from birds. The first US study examined two isolates of *B. pilosicoli* and two of *B. alvinipulli* from chickens, and three isolates of *B. hyodysenteriae* and one of uncertain identity from rheas (165). The isolates were tested in agar dilution for their susceptible to 11 antimicrobial agents that are commonly available to commercial poultry producers or have been successfully used to treat *Brachyspira* species infections in swine. All 8 isolates were susceptible to tiamulin, lincomycin and carbadox, resistant to streptomycin, and gave strain dependant results for chlortetracycline, oxytetracycline, tylosin, bacitracin, erythromycin, neomycin, and penicillin.

A second larger study investigated susceptibilities of predominantly Australian isolates *B. intermedia* (n=25) and *B. pilosicoli* (n=17) from chickens (59). These were tested in agar dilution against four concentrations each of the antimicrobials tiamulin, lincomycin, tylosin, metronidazole, tetracycline and ampicillin. Isolates of both species generally were susceptible to tiamulin, lincomycin, metronidazole and tetracycline. The *B. intermedia* isolates tended to be less susceptible to tiamulin and more susceptible to lincomycin, tylosin and ampicillin than the *B. pilosicoli* isolates. Although not classified as resistant, four isolates of *B. intermedia* had an elevated MIC range for tiamulin (1–4 mg/L), 11 isolates of *B. intermedia* and five of *B. pilosicoli* had an elevated MIC range for lincomycin (10–50 mg/L), one isolate of *B. pilosicoli* had an elevated MIC range for tetracycline (10–20 mg/L), and one isolate of *B. intermedia* and five of *B. pilosicoli* had an elevated MIC range for ampicillin (10–50 mg/L). A clear lack of susceptibility to tylosin (MIC >4 mg/L) was seen in 11 isolates each of *B. intermedia* and *B. pilosicoli*, and to ampicillin (MIC >32 mg/L) in two isolates of *B. pilosicoli*.

These *in vitro* data suggest that drugs such as tiamulin, lincomycin and metronidazole should prove useful in the treatment of AIS, regardless of the *Brachyspira* species involved. Nevertheless it is recommended that *in vitro* susceptibility testing be undertaken on several representative isolates before antimicrobial therapy is contemplated. To avoid possible toxicity, tiamulin should not be used in combination with ionophores (e.g., monensin, salinomycin and narasin).

In Vivo *Treatment with Antimicrobials*

Treatment of laying hens with some antimicrobials is problematic because of the withdrawal times needed to avoid residues being present in the eggs. In addition, drugs such as the nitroimidazoles are not available for use in food producing animals in many legislative areas, most notable in the European Union and the US, because they are genotoxic (43). Finally, as previously stated, no antimicrobials have been specifically registered for the treatment of AIS in hens. Nevertheless, several reports are available on the outcome of antimicrobial treatment of flocks with AIS, as well as of treatment of individual experimentally infected hens.

In a study on a UK laying hen unit with AIS, treatment of immature hens with 125 ppm dimetridazole in-feed for 10 days resulted in improved condition and egg production, and spirochetes were not isolated at postmortem (46).

In the Netherlands, in-water treatment of infected broiler breeder flocks with 120 ppm Ridzol S™ (a 5-nitroimidazole) for 6 days resulted in a sometimes temporary increase in egg production (132). Lasting effects required early treatment, whilst late treatment did not improve production. Reinfection of birds in some flocks may have resulted from contact with infected litter or from ineffective treatment of parts of a flock. Longer intervals between medications were suggested to increase the numbers of spirochetes shed in the feces.

In an Australian study, two houses each of 8,000 40-week-old broiler breeder hens with AIS were treated with antimicrobials in the water (142). House 1 received lincospectin at 50 mg per bird per day for 7 days, whilst house 2 received tiamulin at 25mg/kg body weight for 5 days. Treatment with lincospectin resulted in slimy feces persisting for several weeks. Hens in the lincospectin-treated house remained negative for spirochetes for 3 months, after which 30% of fecal samples were spirochete positive. Three weeks after tiamulin treatment approximately 30% of fecal samples from the house again became spirochete positive, increasing to 80% after another 3 months. Both houses were then water medicated with oxytetracycline at 60 mg/kg for 4 days. This removed the low level of infection from house 1, but only reduced the prevalence from 80% to 60% in house 2. Subsequently the prevalence in house 2 built up to 70% after 4 weeks. It was assumed that reinfection occurred either from the environment of the houses or from birds that had not received adequate medication to remove the infection. Effective control may require regular treatments with courses of antimicrobials, for example given at 1–2 month intervals, together with thorough house cleaning and implementation of strict biosecurity measures to prevent spread of infection between houses.

In a recent UK study, three flocks of approximately 12,000 laying hens on a multi-age site were found infected with *B. pilosicoli* (20). In-water treatment with tiamulin at 12.5 mg/kg body weight for 3 days resulted in increased egg production and reduced mortality.

In laying hens experimentally infected with *B. intermedia,* both zinc bacitracin (ZnB) at 50 ppm in the food and 256 pp of a dietary enzyme designed to hydrolyse the non-starch polysaccharides in wheat (Avizyme® 1302) resulted in less colonization (55). In a subsequent experiment, 100 ppm ZnB inhibited colonization with *B. intermedia*, whilst hens treated with tiamulin at 25 mg/kg body weight for 5 days became spirochete negative and maintained egg production, although they later became reinfected (54). The use of ZnB is not necessarily recommended for the control of AIS, as 50 ppm in the food resulted in an increased susceptibility of laying hens to infection with *B. pilosicoli* (71). Treatment of broiler breeder hens with either tiamulin at 25 mg/kg body weight for 5 days or with lincomycin at 20 mg/kg for 5 days removed experimental infection with *B. pilosicoli* (145).

Taken together, these studies suggest that treatment with tia-

mulin, lincomycin/lincospectin, dimetronidazole or even chlortetracycline should assist with control of AIS in adult hens.

For rheas with severe AIS, treatment with dimetridazole (25–50 mg/kg body weight once or twice daily), lincomycin (25 mg/kg twice daily), or erythromycin (15–25 mg/kg once daily) for 5–7 days has been successful in reducing illness and deaths (60).

Introduction

Tuberculosis of poultry, often termed avian mycobacteriosis, avian tuberculosis, avian TB or TB, is a contagious disease caused by *Mycobacterium avium*. Avian tuberculosis is a chronic infection. Persistence in a flock, once established, induces unthriftiness, decreased egg production, and finally causes death. Although tuberculosis in commercial poultry in the United States is rarely diagnosed, tuberculosis still occurs sporadically in backyard poultry and game birds, and it remains an important problem in captive exotic birds.

Public Health Significance

The literature contains a number of instances in which it was claimed that *M. avium* was responsible for a tuberculous infection in humans. In the United States, the first case of avian tuberculosis in humans (with adequate proof) was published in 1930 (30).

With a decline in the incidence of tuberculosis due to *M. tuberculosis* in humans, increasing interest has been directed toward other mycobacteria, i.e., *M. avium* (27, 117, 131). Moreover, *M. avium* infections have been common in patients with acquired immune deficiency syndrome (AIDS) (22, 28, 58, 128). In the United States, *M. avium* serovars 1, 4, and 8 are isolated most frequently from AIDS patients, and serovars 4, 8, 9, 16, and 19 are isolated most frequently from non-AIDS patients (28). *M. avium* serovar 1 commonly is isolated from wild birds as well as AIDS patients (39, 49). Based on pulse-field gel electrophoresis, *M. avium* isolates recovered from humans and animals have some relatedness, but the human isolates are more closely related to pig isolates rather than those from birds (10, 31). *M. avium* serovar 2, the organism most frequently isolated from chickens, is rarely isolated from humans. Thus, it would appear that most human *M. avium* infections would more likely be due to human-to-human contact rather than bird-to-human contact.

History

Tuberculosis in chickens was first described in 1884 (20). Initially, Koch (60) maintained that tubercle bacilli were a single species irrespective of host. However, Rivolta and later Maffucci (67) showed that the microorganism of tuberculosis in chickens was dissimilar to that of bovine tuberculosis. Eventually, Koch (61) declared that tuberculosis of poultry was unlike tuberculosis of humans and that the disease in humans was dissimilar to that of cattle.

Cases of avian tuberculosis in domestic poultry have declined with the development of integrated commercial poultry farming. Cases in chickens and turkeys are predominantly in hobby flocks. The occurrence of avian tuberculosis in birds in zoo aviaries has become an important disease with increasing economic costs. Certain species of exotic birds have increased in value as they near extinction, thereby increasing the significance of mortalities from avian tuberculosis. Management problems concerning control of the disease are magnified, because exotic species are often maintained for years. The ability of the *M. avium* to survive in the soil and the lack of adequate procedures for cleaning and disinfecting contaminated premises have become a major obstacle to the elimination of avian tuberculosis from zoologic collections. This is made more complex by the lack of efficacious vaccines or suitable drug-treatment regimens.

Etiology

The most common cause of avian tuberculosis in chickens in the United States is *M. avium* serovars 1 and 2 (110). In Europe, *M. avium* serovar 3 has been isolated from wild birds (74, 77) and in Japan serotype 9 (*M. avium* subspecies *hominissuis*) has also

been isolated from painted quail (75, 99); however, neither of these organisms has been isolated from domestic birds in the United States (91), with the exception of a single imported White-headed tree duck (*Dendrocygna viduata*) from which serotype 3 was isolated (119). The subspecies (sbsps) classification of bacteria belonging to *M. avium* in recent years has further been clarified with the advent of molecular techniques. This classification has further elucidated correlation of certain characteristics such as host predilection and pathogenicity to particular subspecies. Historically the determination of the etiological agent involved isolation, biochemical typing, and determination of polar glycolipid surface antigen type by agglutination. Newer methods of classification have allowed *M. avium* serovars 1, 2 and 3 to be reclassified as *M. avium* sbsps *avium*. *M. avium* sbsps *avium* may further be identified as *M. avium* IS*1245+* and IS*901*[+] or *M. avium* IS*1245* RFLP "bird type", or combination of these (4, 24, 79, 81, 99). This has allowed the proposed delineation of *M. avium* sbsps *avium* into *M. avium* sbsps avium and *M. avium* sbsps hominissuis depending on their molecular classification (24, 79, 98, 134). *M. avium* sbsps *avium* is known to be virulent for chickens (4, 24, 71, 79, 122). For the purposes of this text, the agent of avian tuberculosis in poultry will be referred to as *M. avium.*

Growth Requirements and Colony Morphology

In contrast to *M. tuberculosis* and *M. bovis* (102), *M. avium* grows at temperatures ranging from 25–45°C, although the most favorable temperature range is 39–45°C. *M. avium* is aerobic. However, for primary isolation, growth is enhanced by an atmosphere of 5–10% carbon dioxide (113).

Special media (113) designed for culturing tubercle bacilli is desirable for isolation from field materials. Colonies are larger if the medium contains glycerin. Some subspecies of *M. avium* such as *paratuberculosis* and *sylvaticum* require mycobactin as a growth factor for initial and subsequent growth (69). On media containing whole egg or egg yolk and incubated at 37.5–40°C, small, slightly raised, discrete, grayish white colonies form in 10 days to 3 weeks. If the inoculum has abundant bacteria, colonies will be numerous and coalesce. Colonies are hemispheric and do not penetrate the medium. They gradually change from grayish white to light ocher and become darker as the age of the culture increases. In one instance, bright yellow colonies have been described (56).

Subcultures on solid media result in growth within 6–8 days and reach maximal development in 3–4 weeks. Such cultures usually appear moist and unctuous; the surface eventually becomes roughened. The colonies are creamy or sticky and are readily removable from the underlying medium. In liquid media, growth occurs at the bottom of the tube as well as at the liquid surface. Recently, three culture media were evaluated to determine the best media to use when culturing tissue and fecal samples from *M. avium* infected Japanese quail. Modified Herrold egg yolk with mycobactin, Lowenstein-Jensen, and Lowenstein-Jensen with cycloheximide, nalidixic acid and lincomycin were evaluated. Lowenstein-Jensen media (without additives) provided more positive cultures, had greater numbers of colonies on

positive tubes and had shorter incubation times than the other media (106).

A definite relationship appears to exist between the type of colony and virulence (6). *M avium* with smooth transparent (SMT) colonies were virulent for chickens; in contrast, variants with smooth-domed (SMD) or smooth-opaque (SMO) or rough colonies (RG) were avirulent regardless of source (6, 108). Colony morphology is transient and variable and other colony morphologies have been observed although with lesser frequency (86). These different colony morphologies also vary in their ability to stimulate oxygen radicals, to multiply within the cells, and their capacity to up- or down- regulate cytokines/chemokines (8, 53, 86, 96). Differences in colony morphology are mostly due to the presence in SMT or the absence in RG of glycopeptidolipids. Glycopeptidolipids seem to limit macrophage response and may be key virulence factors (8).

The most characteristic morphologic feature of *M. avium* is its acid-fastness. The organisms are bacillary in morphology; but club-like, curved, and crooked forms are also seen in some preparations. Cords are not formed. Branching infrequently occurs. Most of the bacteria have rounded ends and vary in length from 1–3 mm. Spores are not produced, and the organisms are nonmotile. Spherical or conical granules occur anywhere within the cytoplasm.

Biochemical Properties

There appears to be no significant biochemical differences between *M. avium* and *M. intracellulare*. The *M. avium* and *M. intracellulare* group (MAIG), however, do have features that separate them from other species or groups of mycobacteria (26).

MAIG does not produce niacin, does not hydrolyze Tween-80, is peroxidase-negative, produces catalase, does not have urease or arylsulfatase, and does not reduce nitrate; there are variations in these features, particularly in the results of tests for arylsulfatase. MAIG lack most amidases except for pyrazinamidase and nicotinamidase. Detailed listings of the biochemical features of MAIG and related microorganisms are available (89, 113).

Further identification of mycobacterial cultures may be performed using high-performance liquid chromatography (HPLC) for the identification of mycolic acids (21) or through the use of molecular tests such as 16S rRNA, *hsp65* and *groEL2* sequencing, as well as polymerase chain reaction (PCR) detection of IS elements (65, 125).

Disease in poultry is mostly attributed to one subspecies, namely *M. avium* sbps *avium*. However, in pet and wild birds, speciation of mycobacterium isolates is warranted as infection has been reported with several subspecies of *M. avium* and species of *Mycobacterium* including *M. tuberculosis, M. bovis, M. fortuitum,* and *M. genavense* (6, 9, 10, 14, 28, 34, 45, 46, 47, 55, 56, 57, 69, 84, 101).

Sensitivity to Antituberculosis Drugs

Generally, *M. avium* is more resistant to the commonly used antituberculosis drugs as compared to *M. tuberculosis* and *M. bovis* (26). However, synergistic effects of antimycobacterial drug combinations (i.e., ethambutol and rifampicin) on *M. avium*

complex have been reported (45). This generalized increase in resistance is attributed to its lipid rich cell wall (63, 80). This is further proven by the correlation between colony phenotype and the extent of antimicrobial resistance. Transparent colonies are always more resistant than their opaque counterparts (51, 85). The ability to bind the lipoprotein Congo red further demonstrates the association of resistance in *M. avium* and its cell wall: white colonies, which do not bind lipoprotein, are more resistant than red colonies (16, 80).

In approximately 50 strains of *M. avium* from chickens and swine and 11 from humans, in egg yolk agar, most strains will grow in the presence of 10 mg, but not in 50 mg, of streptomycin/mL, in more than 10 mg of *p*-aminosalicylic acid/mL, and in more than 40 mg isoniazid/mL medium. On the same kind of medium, *M. avium* is relatively resistant to ethambutol, thionamide, viomycin, and pyrazinamide. The inhibitory concentration is variable, depending on the medium and procedure (35).

Strain Classification

M. avium belongs to the slow growing nontuberculous bacteria group and together with *M. intracellulare* form the *Mycobacterium avium* complex (MAC). MAC organisms' reservoir is the environment. All members of the MAC have been isolated from animals. Strains of *M. avium* have traditionally been identified by serologic procedures (90). A numbering scheme was developed on the basis of the production of similar polar glycolipid surface antigens for reporting MAC serotypes or serovars (133). Serological typing allows for the recognition of at least 28 serovars of *M. avium* (serotypes 1 to 6) and *M. intracellulare* serotypes 7, 12 to 20, and 22 to 28) (129). *M. avium* can be further subdivided into *M. avium* sbsps *paratuberculosis* isolated from ruminants and free ranging birds (2, 11), *M. avium* sbsps *silvaticum* isolated from wood pigeons and other exotic birds, and *M. avium* sbsps *avium* isolated from birds and other domestic animals (25, 68). While *Mycobacterium avium* sbsps *paratuberculosis* has been recovered by culture from wild birds it has only been shown to cause lesions in one crow in spite of testing over 250 birds (5, 19). In 2002 Mijs (73) and collaborators suggested the *M. avium* sbsps *avium* can be further subdivided based on phenotypic and genotypic grounds into *M. avium* sbsps *avium* for isolates originating from birds (serovars 1, 2 and 3) and *M. avium* sbsps *hominissuis* (serovars 4, 6, 8 to 11, and 21) for isolates recovered from humans and animals (1, 25, 37, 68, 107). Serovars 1 and 2 occur mainly in animals, whereas 4 to 20 are commonly found in humans (111). Some serovars of *M. avium* found in swine (serovars 4 and 8) have also been isolated from humans (132). Serovars 1 and 2 are most commonly isolated from chickens, and serovar 3 is recovered sporadically from wild birds (74, 77). Distinguishing serovars provides a means for studying origin and distribution of specific strains. This typing method is simple and can be conducted in microtiter plates (118). However, not all isolates can be reliably serotyped using this method as some are untypable (13). In the past few years it has been demonstrated that a combination of molecular techniques is by far a more accurate method of classifying *M. avium* isolates. Strains are identified based on the presence or absence of insertion elements (IS) and are further subdivided by restriction fragment length polymorphisms

(RFLP). All *M. avium* sbsps *avium* are of the genotype IS*1245*[+], IS*901*[+], IS*1311*[+], and have the IS*1245* RFLP unique 3 band pattern called "bird type" for those isolates from birds which correspond to serovars 1, 2 and 3. *M. avium* sbsps *sylvaticum* has the same genotype except that the IS*1245* RFLP differs in band sizes (23, 24, 79, 81, 99). The presence of IS*901*[+] in isolates has been associated with virulence for birds (79). Molecular techniques with more accurate strain classification allow better epidemiologic study of these organisms (24, 25, 48, 62, 79, 98, 105). With future progress of molecular tools newer and more discriminatory typing methods for this dynamic group of organisms will emerge (125).

Pathobiology and Epidemiology

Incidence and Distribution

Avian tuberculosis in chickens is caused by *M. avium* serovars 1, 2, and 3, is worldwide in distribution, but occurs most frequently in the North Temperate Zone (121). As stated previously, avian tuberculosis is diagnosed rarely in commercial poultry. It has been diagnosed in small flocks from 30–400 chickens in Canada (76), and in relatively small free-range commercial flocks of 2000 chickens in Australia (37) and in a commercial egg laying flock in Spain (38). Historical evidence has shown that the highest incidence of infection in the United States was found in flocks of the north central states—North Dakota, South Dakota, Kansas, Nebraska, Minnesota, Iowa, Missouri, Wisconsin, Illinois, Michigan, Indiana, and Ohio. Incidence of the disease in western and southern states is low. The explanation for this is not entirely obvious, although there are several possible contributing factors such as climate, flock management, and duration of infection. The necessity of keeping birds closely confined during winter provides favorable conditions for the spread of the disease.

The difficulty of tuberculin-testing all chickens in the United States, or even a majority of the flocks, makes it impossible to obtain exact data on the incidence of *M. avium* infection of chickens. Slaughter data maintained in the United States by the National Agricultural Statistics Service for the years 1995 through 2005 revealed that avian tuberculosis was the cause for the condemnation of young chickens only in 1997 and 1998 at a rate of 7.5 and 6.2 birds per 10,000,000 birds slaughtered, respectively. In mature chickens during the same period, avian tuberculosis was diagnosed during 1996, 1999, 2000, 2001, 2002, 2003, 2004, and 2005 at a rate of 2.1, 1870, 1630, 14.6, 0.59, 2.4, 18.4, and no birds per 10,000,000 slaughtered, respectively. Avian tuberculosis was diagnosed in mature turkeys only in 2003 at a rate of 0.04 per 10,000,000 turkeys (64, 83). Because visual inspection alone is used to derive these numbers, this figure may represent an under- or overestimation of the true incidence. The diagnosis at inspection was most likely based only on emaciation and the presence of granulomas (11).

From 1985 to 2001, a midwestern animal diagnostic laboratory (Fulton, unpublished data) received 6,059 avian submissions involving 15,097 birds. Only 27 (0.45%) cases involving 36 (0.24%) animals were diagnosed with tuberculosis. Of these cases, only 3 (0.05%) cases (4 animals) were chickens from hobby flocks; 2 cases were in peafowl; and 1 case each in pigeons, doves,

quail, and partridges. By far, the largest group represented was exotic captive birds (parrots, toucans, budgerigars, and finches). Three different zoos had diagnoses of avian tuberculosis in such species as penguins, a crane, a duck, an ostrich, and toucans. No cases were seen in commercial chickens or turkeys.

Avian tuberculosis also occurs in some Latin American countries such as Brazil, Uruguay, Venezuela, and Argentina.

Overall, there has been significant reduction in the prevalence of avian tuberculosis due in part to the changes in poultry husbandry. Increasing emphasis has been placed on the desirability of maintaining all-pullet flocks, rather than older hens.

Historical information from the 1960s reports infection of animals by *Mycobacterium avium* in certain European countries. It is said to be rare in Finland (127), but not uncommon in Norway (33) and Denmark (2); *Mycobacterium avium* infection occurs in Germany (71, 93) and Great Britain (66). In Australia, avian tuberculosis is unknown in Queensland and West Australia but occurs in other states. In South Africa, the incidence in poultry is low (59). Infections probably occur in domestic and wild fowl in other countries, but the incidence and distribution cannot be determined because bacteriologic studies are not universally done. In Kenya, avian tuberculosis has been reported in lesser flamingoes (18). Historical prevalence of tuberculosis in animals may be found in Thoen *et al.* (122) and Thorel *et al.* (123).

Natural and Experimental Hosts

Birds

All species of birds can be infected with *M. avium*. Generally speaking, domesticated fowl or captive wild birds are affected more frequently than those living in a wild state. Avian tuberculosis has been reported in domesticated or captive-raised ducks, geese, swans, peafowl, pheasants, quail, partridge, pigeons, doves, turkeys, birds of prey, and other captive and/or wild birds. Pet birds including parrots, cockatoos, budgerigars, finches, flycatchers, and canaries have been infected (30, 34, 78, 94, 97).

Although uncommon, infections and disease may be expected to develop in wild birds in contact with farm premises where avian tuberculosis is prevalent in chickens. Pheasants seem to be unusually susceptible to infection by *M. avium* (97). The disease has also been observed in sparrows, crows, barn owls, cowbirds, blackbirds, eastern sparrow hawks, starlings, wood pigeons, Canada goose, wild turkey (36), American bald eagle (44), painted quail (75) and sandhill and whooping cranes.

Avian tuberculosis has been reported in ostriches, emus, and rheas housed in zoologic parks. Recently, avian tuberculosis was diagnosed in a 3-year-old female emu in a commercial flock (95).

Avian tuberculosis, although reported (43), is not common in turkeys and usually is contracted from infected chickens. Avian tuberculosis has been reported in wild birds and is reviewed elsewhere (9, 30, 34, 50, 54, 70, 91).

Avian tuberculosis is more common among birds in many zoologic gardens than in domestic fowl (74). Infections usually result from *M. avium* serovar 1 or serovar 2 (116). Tuberculosis in psittacine birds may also be due to *M. tuberculosis* or *M. bovis* (1, 47, 78). Recently, it was found that during a 9-year period of identification of *Mycobacterium* sp. infected pet birds in

Table 23.5. Comparative pathogenicity of *Mycobacterium avium* for certain mammals.

Animal	Susceptibility
Cat	Highly resistant
Cattle	Infection occurs; usually localized
Deer	Infection reported
Dog	Highly resistant
Goat	Assumed to be relatively resistant
Guinea pig	Relatively resistant
Hamster	Susceptible (intratesticular)
Horse	Infection reported
Llamas	Susceptible
Marsupial	Infection reported
Mink	Readily infected
Monkey	Susceptible
Mouse	Relatively resistant
Rabbit	Readily infected
Rat	Relatively resistant
Sheep	Moderately susceptible
Swine	Readily infected

Switzerland that *M. genavense* (71.8%) was the predominant species followed by *M. avium* complex (16.7%), *M. fortuitum* (4.2%), *M. tuberculosis* (4.2%), and *M. gordonae* (2.2%) and *M. nonchromogenicum* (2.2%) (46). In other studies (82), *M. genavense* is a common isolate of zoological collections. Luckily, *M. genavense* may be differentiated from *M. avium* by polymerase chain reaction with restriction enzyme digestion (72).

Mammals
M. avium can infect and cause disease in some domesticated mammals, but lesions usually are localized (33, 34, 40, 66, 112). Microorganisms may multiply in tissue for a considerable period and induce sensitivity to tuberculin. Disseminated tuberculosis caused by *M. avium* has been reported in rabbits and swine (111).

Although spontaneous infection of mammals may not be of comparable severity to that developed in fowl, it is possible to produce extensive changes in many species of mammals by introducing the infective agent artificially. The relative pathogenicity of *M. avium* for many of the domesticated mammals is summarized in Table 23.5.

In the United States and Europe, *M. avium* serovar 2 is the most common cause of tuberculous lesions in swine (52, 109, 130). Tuberculosis will remain an unnecessary economic burden on the swine industry until it is eliminated from chickens and other barnyard fowl. There has been a gradual but definite decrease of tuberculosis in swine in the United States (114). Reasons for the decrease may be the lower incidence of avian tuberculosis in poultry as a result of the increasing practice of maintaining one-age flocks and a change to confinement rearing of swine. In the past when pork prices were high, pork production would expand by using vacant farm buildings (outdated chicken houses). With the advent of contract pork production, a market no longer exists for swine raised in this fashion.

Age of Host Commonly Affected
Avian tuberculosis appears to be less prevalent in young fowl not because the younger birds are more resistant to infection, but because in older birds the disease has had a greater opportunity to become established through a longer period of exposure. Although tuberculosis lesions are usually less severe in young chickens than adult birds, extensive or generalized avian tuberculosis in young chickens has been observed. Such birds are an important source of dissemination of virulent tubercle bacilli and must be considered a source to other fowl and susceptible mammals.

Tuberculosis causes important death losses in captive wild birds of zoo aviaries (74). The significance of these findings is emphasized by reports of disease in valuable endangered species. Numerous reports are also available on tuberculosis in pet birds (1, 12, 46, 78, 95, 100, 126).

Transmission
The tremendous number of tubercle bacilli exuded from ulcerated tuberculous lesions of the intestine in poultry creates a constant source of virulent bacteria. Although other sources of infection exist, none equals infective fecal material in the importance for dissemination of avian tuberculosis. Fecal discharges may also contain tubercle bacilli from lesions of the liver and mucosa of the gallbladder expelled through the common bile duct. The respiratory tract is also a potential source of infection, especially if lesions occur in tracheal and bronchial mucosa.

The contaminated environment, especially soil and litter, is the most important source for the transmission of the bacilli to uninfected animals. The longer the premises have been occupied by infected birds and the more concentrated the poultry population, the more prevalent the infection is likely to be.

M. avium may persist in soil for up to 4 years (92). *M. avium* bacilli remained viable in carcasses buried 3-feet deep for 27 months. Virulent strains of *M. avium* have been found to survive in sawdust for 168 days at 20°C and 244 days at 37°C (93).

M. avium has been isolated from eggs of naturally infected chickens, but hatched chicks failed to develop avian tuberculosis (30, 32, 34, 92). *M. avium* does not survive in eggs after 6 minutes of boiling, and in preparation of scrambled eggs, 2 minutes of frying was sufficient to kill the bacteria.

M. avium can be disseminated in carcasses of tuberculous fowl and offal from chickens dressed for food. Cannibalism might play a part in transmission.

Dissemination of *M. avium* on shoes and equipment used in the care and maintenance of infected poultry (crates and feed sacks) can be involved in transfer from diseased to healthy flocks.

Wild birds such as sparrows, starlings, and pigeons may be infected with *M. avium* and may spread *M. avium* to poultry flocks. Although not very likely, swine may have ulcerative intestinal lesions from *M. avium* and, thus, constitute a source of infection for other animals and birds.

Clinical Signs
Clinical signs are not pathognomonic. In advanced infections, the bird will be less lively than its pen mates, will fatigue easily, and may be depressed. Although appetite usually remains good, pro-

gressive and striking loss of weight commonly occurs, evident as atrophy of breast muscles with a prominent keel. In extreme cases, the body fat eventually disappears, and the face of the affected bird appears smaller than normal.

Feathers assume a dull and ruffled appearance. Comb, wattle, and earlobes often appear pale and thinner than normal and have a dry epidermis. Occasionally, the comb and wattles have a bluish discoloration. Icterus, indicative of advanced hepatic damage, may be noted.

Even when the disease is severe, the temperature of the affected bird remains within the normal range. In many instances, the bird reveals a unilateral lameness and walks with a peculiar jerky hopping gait. Lesions may rupture and discharge fluid with caseous material. Paralysis from tuberculous arthritis can sometimes occur.

With advanced emaciation, nodular masses can be palpated along the intestine. However, the hepatomegaly that many tuberculous birds possess may make this procedure difficult or impossible. Intestinal nodules may be ulcerative, resulting in severe diarrhea.

Affected birds may die within a few months or live for many, depending on severity or extent of the disease. A bird may die suddenly as a consequence of hemorrhage from the rupture of the affected liver or spleen.

In a flock situation, clinical signs may vary between infected birds. Two clinical syndromes were described in an infected commercial flock of laying hens. One group had good body condition, continued to lay eggs but had nodular masses in the infraorbital sinuses, liver, and intestines. Another group within the same flock was emaciated, did not lay eggs, lacked sinus lesions, and had numerous nodular masses in internal organs (38).

Pathology

Gross

Lesions are seen most frequently in liver, spleen, intestines, and bone marrow. Some organs, such as heart, ovaries, testes, and skin, are affected infrequently and cannot be considered organs of predilection. For turkeys, ducks, and pigeons, lesions predominate in the liver and spleen but occur also in many other organs (34).

Lesions of avian tuberculosis in chickens are characterized by pinpoint to several centimeter, irregular grayish yellow or grayish white nodules in spleen, liver, and intestine (Fig. 23.18A, B, D). Involvement of liver and spleen results in enlargement, which can result in fatal hemorrhage from rupture. Large nodules have an irregular knobby contour, with smaller nodules present over the capsular surface of affected organs. Lesions near the surface in such organs as liver and spleen are easily enucleated from adjacent tissues. Nodules are firm but can be incised easily. Mineralization is rare. On cross-section, a nodule may contain a variable number of small yellowish foci or a single soft yellowish caseous center surrounded by a fibrous capsule. The capsule continuity may be interrupted by small circumscribed necrotic foci. The fibrous capsule is of variable thickness and consistency, depending on the size and duration of the lesion. It is barely discernible or apparently absent in small lesions and measures 1–2 mm in thickness in larger nodules. Intestines may have white

firm nodules that bulge from the serosal surface. Involvement of lungs is usually less severe than that of liver or spleen.

Granuloma formation is frequent within bone marrow (Figs. 23.18C and 23.19). Infection of bone marrow probably occurs very early in the course of the disease and results from the bacteremia.

Microscopic

The basic lesion of *M. avium* infection consists of multiple granulomas with a central caseous necrosis. Granulomas consist of the accumulation of large number of macrophages with abundant cytoplasm (epithelioid macrophages). Epithelioid macrophage populations expand within the granuloma and fuse near the periphery to form multinucleate giant cells. In larger nodules, the central area of the granuloma may have coagulative or caseous necrosis. In large nodules, only the multinucleate giant cells may persist as a mantle around the necrotic core. Immediately peripheral to the multinucleate giant cells is a collection of both epithelioid and histiocytic macrophages (Fig. 23.20). A fibrous capsule consisting of fibrocytes and minute blood vessels also occurs near the outer portion of the peripheral area. Acid-fast bacilli are numerous in the central or necrotic zone of the tubercle but can be found in large numbers in the epithelioid zone adjacent and distal to multinucleate giant cells (Fig. 23.21).

The outermost region of the granulomas is encapsulated by fi-

brous connective tissue, macrophages, some lymphocytes, and an occasional granulocyte. Calcification of the tubercle rarely occurs in fowl. Amyloid deposition in the surrounding parenchymal elements has been reported in liver, spleen, and kidney.

Microscopically, lesions of avian tuberculosis in turkeys vary considerably but are similar to avian tuberculosis of chickens. In other instances, lesions are diffuse, with extensive destruction of surrounding parenchyma. Cytoplasmic masses or large giant cells may be numerous, and large numbers of granulocytes are commonly present. Some lesions become circumscribed by a broad, dense zone of fibrous connective tissue.

Pathogenesis of the Infectious Process

Ingestion of the bacillus results in intestinal infection and eventual bacillemia. Bacillemia allows for the transfer of bacilli from the intestine to the liver directly. The bacillemia, which probably occurs intermittently and perhaps early in most instances, also provides for a generalized distribution of lesions. No tissue, with the possible exception of the central nervous system, appears to be exempt from infection.

Cheville *et al.* (17) studied experimental *M. avium* infection in chickens. The disease course in young chicks lasted for 30 days after intravenous challenge. Single acid fast bacilli were first found 5 days postinfection in cells of periarterial lymphoid sheaths of the spleen without other histologic evidence of infection. Many bacilli were found within aggregated histiocytic macrophages of the sheath 10 days postchallenge. By day 14,

miliary tubercles were found within lymphoid sheaths. Delayed type hypersensitivity (DTH), as judged by wattle thickness, first occurred 2 days postinfection and increased in intensity as the disease progressed. This response decreased as the disease became more severe. The disease process was divided into 3 periods, a latency period, a lesion development period, and a cachexia period. The latency period occurred for the first 7 days of the infection. During this period, there were no microscopic lesions, but DTH reactions appeared and increased in intensity with time. The lesion development period occurred from days 8–17 postinfection. Bacilli multiplied in lymphoid sheaths during this time. Serum antibody titers developed; the thymus atrophied; and small tubercles with few bacilli developed. Cachexia lasted from day 18 until death. During this period, massive tubercles with large numbers of bacilli developed; there was lymphoid atrophy; DTH disappeared; and amyloid was deposited at the periphery of tubercles. In addition to lymphocyte-intact chickens, these studies also used both bursectomized and thymectomized chicks. There was very little difference in the pathogenesis between lymphocyte-intact and -depleted chicks.

The capacity of *M. avium* to produce progressive disease may be related to cell wall constituents and certain complex lipids present in the cell wall, such as cord factor, sulfur-containing glycolipids (sulfatides), or strongly acidic lipids (88, 115). *M. tuberculosis* and *M. avium* prevent fusion of phagosomes (the vacuole where they reside intracellularly) with lysosome and maturation of the resulting phagolysosome (103). It appears, however, that the effect of the aforementioned components alone or together on phagosome-lysosome fusion cannot account for virulence. DTH develops following exposure to mycobacteria; once activated,

macrophages demonstrate an increased capacity to kill intracellular *M. avium*. The DTH responses are mediated by lymphocytes, which release lymphokines that act to attract, immobilize, and activate blood-borne mononuclear cells at the site where virulent bacilli or their products exist. Tumor necrosis factor, alone or in combination with interleukin-2, but not γ interferon, has been associated with macrophage killing of *M. avium* serovar 1 (7). The DTH contributes to accelerated tubercle formation and is, in part, responsible for cell-mediated immunity in tuberculosis. Activated macrophages that lack sufficient subcellular microbicidal components to kill virulent tubercle bacilli are destroyed by the intracellular growth of the organism, and a lesion develops. A combination of toxic lipids and factors released by virulent *M. avium* may 1) cause disruption of the phagosome, 2) inhibit phagolysosome formation, 3) interfere with the release of hydrolytic enzymes from the attached lysosomes, and/or 4) inactivate lysosomal enzymes released into the cytoplasmic vacuole. Toxic oxygen metabolites are not responsible for killing activated macrophages. However, the significance of hydrogen peroxide, activated oxygen radical(s), and nitric oxide in resistant macrophages of birds exposed to virulent *M. avium* remains to be elucidated (115). More recently, *M. avium* has been shown to induce caspase-1 activity in macrophages and may serve as a mechanism for its pathogenicity (96).

Diagnosis

A presumptive diagnosis of avian tuberculosis in fowl usually can be made based on gross lesions (15). Demonstration of acid-fast bacilli in smears or histologic sections of liver, spleen, or other organs strengthens the diagnosis and is sufficient for most diagnostic cases. Inoculation of suitable media to isolate and identify the causative agent confirms the diagnosis of avian tuberculosis and allows speciation of the causative agent (57). In live, suspected infected birds, fecal smears for culture, staining, and/or PCR may be attempted but these tests are not reliable due to intermittent or no fecal shedding of bacilli. (124) Fecal positivity increases as the disease course progresses (106). Polymerase chain reaction has been used to detect mycobacteria including *M. avium* and *M. genavense* in formalin-fixed tissue which may further aid diagnostic considerations (41).

Tuberculin Test

When administered properly, the tuberculin test provides a satisfactory procedure for determining presence of avian tuberculosis in a flock. The technique involves intradermal injection of the wattle with 0.03–0.05 mL of a U.S. Department of Agriculture (USDA) supplied purified protein derivative tuberculin prepared from *M. avium* in a manner previously described (3). The injection site then is monitored for a reaction. A more complete methodology and interpretation has been reported elsewhere (112). Tuberculin testing in poultry may reveal a false-negative result twice during the course of infection: once during early infection and again during late infection, when there is immune system exhaustion or anergy. This test is also unreliable in some bird species (104).

Serology
Enzyme-linked Immunosorbent Assay
Enzyme-linked immunosorbent assay (ELISA) has detected mycobacterial antibodies in sera of chickens experimentally inoculated with *M. avium* serovar 2, but false-positives may be common (120). ELISA is less specific than the tuberculin test.

Rapid Agglutination Test
A whole-blood agglutination test has been described for diagnosis of avian tuberculosis in fowl (55). The agglutination test has been more useful for detecting infected birds in a diseased flock; however occurrence of false-positive agglutination reactions in healthy birds is a drawback (42).

Differential Diagnosis
The most expedient way to diagnose the disease is by necropsy. Granulomas are rather characteristic, but other conditions must be differentiated. These include coligranulomas (Hjarre's disease), pullorum disease, other *Salmonella* infections, *Staphylococcus* infection, fowl cholera, aspergillosis, and neoplasia. Presence of numerous acid-fast bacilli in lesions is significant. When available, culture and identification of *M. avium* is helpful but not essential for a diagnosis.

Intervention Strategies
Management Procedures
In backyard poultry and captive birds, the tuberculin test should be used to detect avian tuberculosis. Removal of chickens that react reduces environmental contamination and subsequent infections. The whole-blood agglutination test also may serve to detect infected birds and may be more reliable. However, if the residual flock is permitted to occupy the same contaminated premises, contaminated soil may be a continuing source for infection. Furthermore, neither the tuberculin nor the agglutination tests can be depended upon for detection of every tuberculous fowl. As long as one infected bird remains in a flock, dissemination of the disease to healthy fowl is possible. Consequently, termination of the entire flock and repopulation on noninfected soil may be the best approach to control avian tuberculosis.

Procedures for establishing and maintaining avian tuberculosis-free backyard flocks should include the following: 1) Abandon old equipment and establish other facilities on new soil. Ordinarily, it has been impractical to render an infected environment satisfactorily safe by disinfection. 2) Provide proper fencing or other measures to prevent unrestricted movement of chickens, thus preventing exposure from previously infected premises. 3) Eliminate the old flock, burning carcasses of birds that show lesions of tuberculosis. 4) Establish a new flock in the new environment from avian tuberculosis-free stock. If chickens in a clean flock are prevented access to an infected environment and are protected against accidental exposure to an infected environment and accidental exposure to *M. avium*, it is reasonable to believe that they will remain free from avian tuberculosis.

Recommendations for control of avian tuberculosis in exotic birds include the following: 1) Prevent contact with tuberculous

birds; premises and housing previously used by them are to be avoided. 2) Quarantine additions to the aviary for 60 days and retest with avian tuberculin.

Vaccination

Use of experimental vaccines containing inactivated and/or live mycobacteria for protecting chickens against tuberculosis has been evaluated (87). The best results were obtained in chickens vaccinated with live *M. intracellulare* serovar 6 (*M. avium* serovar 6) given orally. These fowl showed 70% protection after intramuscular (IM) challenge with *M. avium*. Encouraging results were also reported in chickens after combined IM vaccination with inactivated plus live *M. intracellulare* serovar 7 and serovar Darden (*M. avium* serovars 7 and 19). Recently, vaccination of chickens using various fractions of a homologous strain of *M. avium* for vaccine production and challenge revealed that the number of lesions and bacilli per gram of liver were decreased; it did not however prevent infection (29).

Treatment

Treatment with antituberculosis drugs is impractical and is rarely done to treat domestic backyard poultry. However, combinations of antituberculosis drugs have been used to treat certain exotic birds maintained in captivity (126). Clinical remission was observed in 3 birds that received a combination of isoniazid (30 mg/kg), ethambutol (30 mg/kg), and rifampicin (45 mg/kg). The recommended duration of therapy was 18 months, provided that there were no adverse side effects. Additional investigations are needed to develop suitable regimens for the treatment of tuberculosis in various exotic birds.

Other Bacterial Diseases

H. John Barnes and Lisa K. Nolan

Miscellaneous and Sporadic Bacterial Infections

A number of surveys of bacteria isolated from poultry have been done, which often include a variety of unusual bacteria of low incidence. For example, bacteriologic examination of clinically ill broilers within 2 weeks of processing resulted in 132 isolates. The majority of these were various species of staphylococci and *E. coli*, but *Corynebacterium, Stomatococcus, Micrococcus, Lactobacillus, Moraxella, Proteus, Acinetobacter, Pseudomonas,* and *Yersinia* were also isolated (12). Similarly, microbial surveys of eggs, dead embryos, chicks with omphalitis and yolk sac infections, and chick mortality often reveal a diversity of unusual bacteria, generally in low incidence that are found in the environment and are not normally associated with disease. This is especially true for commercially raised ratites (48, 143). As the significance of the isolates that are recovered infrequently in surveys is unknown or not considered significant, they have not been covered in detail in this review. Bacteria recovered from environmental sampling and organisms considered to be normal flora also have not been included.

Interest in achieving and maintaining intestinal homeostasis in meat-producing birds has led to methods to quantify microbial populations by molecular methods (36, 217, 270). Organisms identified in these studies generally are not discussed in this review.

Acinetobacter

Acinetobacter is a nonfermentative, strictly aerobic, small, gram-negative coccobacillus in the family Moraxellaceae (181). It is a common organism in poultry environments and has been recovered from the eyes of normal ducks (55) and respiratory tracts of healthy chickens (7). It is occasionally recovered from dead-in-shell embryos and weak chicks (130, 155, 220). *A. lwoffi* and *A. calcoaceticus* were isolated from outbreaks of septicemia in hens. Mortality was approximately 15%, and there was multifocal necrosis and green discoloration of the liver (89, 132). Turkeys are also affected as *Acinetobacter* has occasionally been isolated from dead-in-shell embryos and weak poults, respiratory disease, septicemia, and inflamed joints of turkeys (91). Other clinical presentations include pigeons with arthritis (85) and ducks with arthritis, septicemia, or airsacculitis (33, 262).

Actinobacillus/Gallibacterium

Bacteria previously identified as *Actinobacillus salpingitidis*, avian *Pasteurella haemolytica*-like, or *P. anatis* have been reclassified and placed into a new genus *Gallibacterium* (59). The organisms may colonize avian hosts and cause no clinical disease, or cause septicemia, respiratory disease, severe conjunctivitis, or salpingitis (73, 93, 159, 173, 180, 236). Chickens, ducks, geese, and ostriches have been affected. Field isolates from septic laying hens and a well-characterized strain of *G. anatis* were pathogenic for pullets and layers following inoculation (38, 237, 238). Mortality was higher in birds inoculated intravenously compared to those inoculated intraperitoneally, and lesions were more severe in birds that had been experimentally immunosuppressed before exposure (38).

Atypical *A. lignieresii*, currently identified as taxon 2 and taxon 3, was isolated from lesions of salpingitis in egg-laying ducks and geese. Isolation of these organisms from the cloaca and penis of normal geese suggests that salpingitis probably results from an ascending infection (35). A similar conclusion was reached about the role of *Actinobacillus* in goose venereal disease (see below) (161). Severe conjunctivitis resulting in blindness in a free-living Canada goose was caused by *A. suis* (159).

Actinomyces/Arcanobacterium (Corynebacterium)

A chronic, disseminated granulomatous disease of turkeys in Canada suspected to be actinomycosis has been observed sporadically since 1955 (219). Serious outbreaks of osteomyelitis involving the proximal tibia, thoracic vertebra, and/or proximal tibiotarsi caused by *Arcanobacterium* (*Actinomyces*) *pyogenes* in commercial male turkey flocks resulted in considerable economic loss (41). Lame birds in 20 affected flocks averaged 20% (range, 5–50%), age averaged 16-weeks (range, 12–20 weeks), and weekly mortality averaged 2.8% (range, 0.5–10.5%). Hen flocks were not affected (19). Club-shaped, pleomorphic, gram-positive bacilli in smears of lesions provided a rapid diagnosis (41). Biochemical and serologic evaluation of isolates from 9 flocks indicated they were either identical or very closely related. An agar-gel precipitin test was highly effective at detecting antibodies (19). Treatment of an affected flock with penicillin in the feed (100 g/ton) resulted in a gradual improvement in the flock after 8–10 days on medication. Osteomyelitis was reproduced in 15-week-old male turkeys inoculated intravenously with a representative isolate.

Septicemia, visceral lesions, cutaneous abscesses, mortality of nearly 14%, and a decrease in egg production of over 27% occurred in caged layers infected with *A. pyogenes*. Portal of entry was through skin lesions caused by poor caging (71).

A. pyogenes was isolated from abnormal kidneys of broilers, but attempts to reproduce renal lesions with the isolates were not successful (228).

Aegyptianella

Aegyptianella are obligate intracellular organisms in the family Anaplasmataceae and are most closely related to *Anaplasma* spp. (208). They cause the tick-borne disease aegyptianellosis (105). The disease has been identified in a variety of birds in-

cluding chickens, turkeys, and guinea fowl. Affected birds experience increased mortality and develop severe anemia, which can predispose them to ascites and right ventricular heart failure (121). Aegyptianellosis occurs mainly in free-ranging poultry and wild birds that are infested with fowl ticks in the genus *Argas*. With the exception of wild turkeys in the Rio Grande area of Texas (51) and an Amazon parrot imported into England from South America (197), the organism has only been identified in Europe, Asia, and Africa. Diagnosis depends on identifying the typical organism in erythrocytes of infected birds (105). Treatment with tetracyclines and supportive care are generally effective (105). Prevention is the same as that for spirochetosis (see *Borrelia* below).

Aerobacter

Aerobacter has been recovered occasionally from dead embryos (131). Twenty percent mortality occurred in a flock of turkeys infected with *Aerobacter (Klebsiella) aerogenes*. Affected poults had enlarged mottled livers, swollen kidneys, and visceral urate deposits ("gout"). Intramuscular injections of 15–20 mg/kg polymyxin B produced transient coma-like signs but were successful in stopping the disease (110).

Aeromonas

Aeromonas is commonly found in aquatic environments and animals. It is a frequent intestinal inhabitant of poultry that can easily contaminate carcasses during processing. Intestinal colonization is dependent on the O-antigen lipopolysaccharide of the organism (168). *Aeromonas* has public health significance as a potential cause of food-borne illness because of the production of cytotoxins (23).

Aeromonas hydrophila, either alone or in combination with other organisms, can cause localized and systemic infections in avian species including poultry (101, 223). High numbers were found in chickens with watery mucoid feces (87). *Aeromonas* was recovered from turkeys experiencing severe diarrhea. Inflammation and hemorrhage of the intestinal mucosa were characteristic findings in affected poults. Experimental inoculation of chicks with the turkey isolate caused significant mortality (97). *Aeromonas* was among the organisms identified from cellulitis lesions in turkey carcasses at processing (189). *A. hydrophila* has been isolated from ducks with salpingitis (35), septicemia (154), airsacculitis (262), and granulomatous inflammation of salt glands (137). A bacterin prepared from 3 strains that caused high mortality in experimentally inoculated ducklings successfully controlled losses in commercial duck flocks (154). *A. formicans* has been isolated infrequently from arthritic lesions in ducks at processing (33). *Aeromonas* and *E. coli* were the most frequently isolated bacteria from geese with necrotic inflammation of the phallus (see Goose Venereal Disease below) (163).

Aeromonas is among environmental bacteria that can be recovered from dead-in-shell embryos and weak chicks (155). Microbial contamination of ostrich eggs by *Aeromonas* was associated with reduced hatchability (80).

Arcobacter

Bacteria in the genus *Arcobacter* previously were classified as campylobacters (see chapter 18) to which they are closely related. *Arcobacter* differ from campylobacter in their ability to grow aerobically and at 15°C (191). *Arcobacter* species have public health significance as a cause of food-borne illness, but produce no recognized clinical disease in experimentally exposed chickens or turkeys (150). Usually it is isolated from carcasses or retail meat, however, the organism has been recovered from cloacal swabs of chickens and from the ceca of ducks (10, 129, 207, 264). Special procedures and media can be used to selectively isolate the organism (119). Molecular methods have been developed to rapidly detect, speciate, and genotype organisms. Ducks are more frequently affected than chickens or turkeys, but a high rate of broiler carcass contamination has been identified (11).

Bacillus

Bacillus spp. occasionally have been associated with embryo mortality and yolk sac infections in chickens (42, 58, 253), turkeys (43), ducks (25, 220), and ostriches (79, 80). *Bacillus* spp. and *E. coli* were the most commonly cultured bacteria from reproductive disorders of hens (104). *B. cereus*, an organism that can cause food-borne illness in people, infected turkey hens following artificial insemination and was found in 25% of their unhatched eggs. The prevalence fell to 4% after the infection was controlled (43). Certain strains of *Bacillus* interfere with intestinal colonization of enteric pathogens and have value as probiotics (18, 142).

Keratinases (subtilisins) produced by *B. licheniformis* have the ability to degrade feathers (90). Feather degradation is associated with focal ulcerative dermatitis of turkey breast skin but a correlation between keratinase exposure and lesion formation has not been investigated (22).

Bacteroides

Bacteroides spp. are anaerobic, non-sporeforming, gram-negative rods that are normally found in high numbers in the lower digestive tract, especially ceca, of poultry. They are rarely associated with disease. *B. fragilis* occasionally has been isolated from the oviduct of laying hens experiencing salpingitis (34). *Bacteroides* also has been associated with inflammation of the phallus and multifocal liver necrosis in geese (see Goose Venereal Disease below) (29, 76).

Bilophila

Bilophila is commonly found in the large intestine of animals, including human beings, and has been associated with appendicitis and localized inflammatory lesions. Examination of lower intestinal contents from broiler chickens in the southeastern US did not find an association between malabsorption syndrome and the bacterium (166).
23.22. *Borrelia anserina* in blood film during the acute stage of infection. Giemsa, ×1200.

23.23. *Borrelia anserina* in plasma from infected chicken during terminal stages of spirochetosis. Note the agglomeration of organisms. Dark-field, ×480.

Borrelia

Borrelia anserina causes a tick-borne, non-relapsing borreliosis (spirochetosis) in avian species including chickens, turkeys, pheasants, geese, and ducks. The disease is usually an acute septicemia characterized by variable morbidity and high mortality, but may also be mild when birds are infected with low virulent strains (20, 227). Birds also can develop asymptomatic infections with *B. burgdorferi*, the cause of Lyme disease in people, and serve as hosts for ticks capable of spreading the spirochete to mammals (64, 99, 133, 160).

Occurrence of spirochetosis corresponds with the subtropical and tropical distribution of fowl ticks in the genus *Argas*, which serve as both the reservoir and primary vector. Attempts to transmit *B. anserina* with *Amblyomma cajennense* were unsuccessful (144). Occasional outbreaks have been identified in the southwestern United States in chickens, turkeys, and pheasants (70). Extensively reared free-range flocks are more likely to be affected than confined flocks, and indigenous breeds of chickens are generally more resistant than exotic breeds (203). In addition to ticks and other biting arthropods (mosquitoes, mites), infection can result from cannibalism, scavenging on carcasses, multiple use of syringes and needles, or ingestion of infective blood, droppings, or infected ticks. Virulent strains are capable of penetrating unbroken skin. *B. anserina* is not resistant outside of the host. Recovered birds are not carriers; organisms disappear from tissues at or shortly after they disappear from the circulation (20).

Borrelia anserina is a highly motile, helical bacterium (Fig. 23.22) that stains well with aniline dyes, Romanowsky-type stains, and silver impregnation. Spirochetes can be readily identified in wet smears of blood or tissues by dark-field or phase microscopy (Fig. 23.23).

Birds infected with virulent strains of *B. anserina* are visibly sick, with cyanosis or pallor of the comb and wattles, ruffled feathers, dehydration, inactivity, and anorexia. There is a marked elevation in body temperature that begins shortly after infection and a rapid loss of body weight. Affected birds pass fluid, green droppings containing excess bile and urates, and have increased water consumption. Late in the disease, birds develop paresis or paralysis, become anemic, and are somnolent to comatose. Body temperatures are subnormal just prior to death. Birds recovering from the disease are often emaciated and have temporary residual weakness or paralysis of one or both limbs (20). Infection with low virulent strains may be mild or inapparent (70).
Marked enlargement and mottling of the spleen is typical of spirochetosis (Fig. 23.24) but may not be evident if birds are infected with low virulent strains (70) or early in the disease. Livers often are enlarged and contain small hemorrhages, pale foci, or marginal infarcts. Kidneys are swollen and pale with excess urates distending the ureters. Green, mucoid intestinal contents are usually present, and there often are variable amounts of hemorrhage, especially at the proventriculus-ventriculus junction. Fibrinous pericarditis occurs infrequently. Extensive hemorrhage and muscle necrosis have been reported in naturally infected pheasants (20).

Splenic lesions result from macrophage and lymphoid hyperplasia, erythrophagocytosis, and hemosiderin deposition. Multifocal necrosis and hyalinization of white pulp and/or extensive hemorrhage may be present in some birds. The liver is congested with increased periportal infiltrates of mixed lymphocytes, hemocytoblasts, and phagocytic cells with vacuolated cytoplasm. Erythrophagocytosis and hemosiderin are seen in Kupffer cells. Extramedullary hematopoiesis may be present. Lymphoplasmacytic infiltrates occur in kidneys and intestinal lamina propria of some birds. Occasionally, there is a mild to moderate lymphocytic meningoencephalitis (16, 20).

Spirochetosis can be diagnosed by finding characteristic lesions in birds with signs consistent with the disease. Larval ticks on the birds, evidence of tick bites, or presence of ticks in
23.24.   An enlarged, mottled spleen is characteristic of spirochetosis caused by highly virulent strains of *Borrelia anserina* in chickens. Low virulence strains may not produce splenic lesions, and they may appear differently in other avian species depending on the amount of necrosis and hemorrhage. A few serosal hemorrhages on the proventriculus also can be seen in this bird.

the bird's environment increases the likelihood of spirochetosis. The disease is confirmed by demonstrating *B. anserina* or its antigens in affected birds or by seroconversion following recovery. Dark-field microscopy is the method of choice for identifying spirochetes in blood (21). In tissue sections, spirochetes can be demonstrated by silver impregnation staining procedures (70).

Borrelia cannot be cultured on routine bacteriologic media but will grow in chick embryos following yolk sac inoculation or in susceptible chicks (21). It can be grown in liquid medium but loses virulence (152). Bursectomy or dexamethasone treatment of chicks may be necessary for low virulent strains to grow to detectable numbers (78). Strains are usually maintained in ticks, day-old chicks, chicken or turkey embryos, or by cryopreservation at –70°C in 5% glycerol or dimethylsulfoxide added to infective blood (21, 145). Several serologic methods have been used to detect antibodies in immune birds including serum plate agglutination, slide agglutination, spirochete immobilization, agar gel precipitin, and indirect fluorescent antibody tests. Spirochetal antibodies readily can be detected in yolk of eggs from immune hens (21).

Arsenicals and most antibiotics, including penicillin, chloramphenicol, kanamycin, streptomycin, tylosin, and tetracyclines, are effective in treating infected birds. Intramuscular injections of penicillin at 20,000 IU/bird given three times in 24 hr or 20 mg oxytetracycline given daily for two days represent current treatment regimens (20).

Active immunity follows recovery or immunization. Immunity is serotype-specific; infection with other *B. anserina* serotypes can occur in recovered or vaccinated birds. An autogenous or polyvalent vaccine containing multiple serotypes may be necessary to provide full protection (254). Controlled infection fol-

lowed by antibiotic treatment 3 days later also has been used to induce active immunity. Passive maternal immunity provides protection for 5–6 weeks and hyperimmune serum protects birds against challenge for up to 3 weeks (20). Antibodies prepared against an outer surface lipoprotein provide passive homologous but not heterologous protection (213).

Preventing fowl tick infestation is the best method to control spirochetosis in endemic areas. Young chickens in dense poultry areas during the summer were more likely to be infested with fowl ticks (222). Adult ticks can remain alive without feeding and carry the spirochete for as long as 3 years (20).

Citrobacter

Citrobacter is a genus in the Enterobacteriaceae family. The organism commonly colonizes mucous membranes of the respiratory and digestive tracts of normal birds, but can be an opportunistic pathogen. *Citrobacter* is one of many environmental bacteria that are occasionally isolated from unhatched eggs, weak chicks, and yolk sac infections (155, 253). It has been isolated from the liver of two-week-old turkey poults with respiratory disease (91). Antimicrobial testing of 37 isolates from diseased or dead turkey poults between one and 35 days of age indicated sensitivity (MIC_{50}<1μg/ml) to enrofloxacin, ceftiofur, gentamicin, and trimethoprim/sufadiazine (212). *C. freundii* infrequently has been isolated from young ducks with salpingitis (35).

Coenonia

Coenonia is a recently described genus that contains a single species, *C. anatine*, previously identified as taxon 1502. It is a *Riemerella anatipestifer*-like bacterium that causes a similar exudative septicemia in ducks and geese (252).

Coryneform Bacteria

A gram-positive rod with characteristics of *Erysipelothrix*, *Lactobacillus*, and *Listeria* was isolated from an outbreak of polyarthritis in chickens (174). *Corynebacterium* sp. accounted for 18% of the 132 isolates from blood samples, livers, and hock joints of clinically ill commercial broilers within 2 weeks of processing (12).

Enterobacter/Pantoea

Enterobacter is a normal inhabitant of the avian digestive tract (30). Similar to other gram-negative bacteria in the Enterobacteriaceae family, it can infect eggs and young birds causing embryo loss, omphalitis, yolk sac infections, and mortality in young birds (91, 136, 155, 212, 253, 263). *Enterobacter* was isolated infrequently from turkeys with cellulitis (189). Organisms formerly identified in the *E. agglomerans* complex have been placed in a new genus, *Pantoea*.

Eubacterium (see Liver Granulomas and Related Granulomatous Diseases below)

Flavobacterium

Flavobacterium is a dominant proteolytic bacterium in the upper respiratory tract of chickens and turkeys (47) that is rarely associated with clinical disease. It has been recovered from ducks with arthritis (33), an adult goose with salpingitis (35), chickens, a pigeon, and finch with septicemia and/or arthritis (250), and unhatched eggs and weak chicks (155). Heavy, pure cultures of *F. meningosepticum* were obtained from a 5-week-old ostrich chick that failed to grow and thrive and had airsacculitis, pneumonia, and thymic atrophy/hypoplasia (148).

Gaffkya (see *Peptostreptococcus*)

Gallibacterium (see *Actinobacillus/Gallibacterium*)

Hafnia

Hafnia are gram-negative rods in the family Enterobacteriaceae that are similar to *Salmonella. H. alvei* infrequently has been identified as a cause of septicemia in pullets and laying hens (50, 204). Infections were characterized by loss of appetite, diarrhea, opisthotonus, decreased egg production, and increased mortality. Scattered pale foci in the liver, hepatomegaly, splenomegaly, and catarrhal to hemorrhagic enteritis were seen on necropsy. Microscopically, degeneration, multifocal necrosis, and inflammation of the liver, lymphocytic depletion and necrosis of the spleen, and intestinal hyperemia, hemorrhage, and catarrhal enteritis were identified. Gram-negative bacteria were numerous within lesions, occurring frequently as intravascular emboli. Septicemia was reproduced following oral and intraperitoneal inoculation of pullets and hens. *Hafnia* can be identified by biochemical tests and a bacteriophage test. Specific diagnostic procedures are required to avoid misdiagnosis due to similarities between this organism and *Salmonella* species.

Helicobacter

A distinct group of bacteria, previously identified as *Campylobacter*-like organisms (see chapter 18), has been placed into the genus *Helicobacter* based on their phenotypic characteristics and 16s rRNA sequences (191). Helicobacters infecting poultry represent emerging pathogens that cause food-borne illness in people and possibly enteric and hepatic disease in poultry (9, 72).

Helicobacter pullorum, a species in the urease-negative, enterohepatic group of helicobacters, has been isolated from ceca of normal broilers, livers and intestines of layers with lesions characteristic of "vibrionic hepatitis," and people with gastroenteritis, bacteremia, and liver disease (45, 46, 229, 230, 242). The organism has been found infecting chickens in Europe and Australia (53, 169). It produces a distinct cytolethal-distending factor, which may be a significant virulence factor (54). Helicobacters can be cultured using procedures for isolating campylobacters; however, they are inhibited by polymyxin B, which was used in some older media formulations. A polymerase chain reaction to detect the organism has been developed (45, 98, 229). A multiplex PCR is useful for identifying and differentiating *Arcobacter, Campylobacter*, and *Helicobacter* (183). Specific identification requires a combination of phenotypic and genotypic analyses (98, 167, 191, 231).

Helicobacter canadensis, a species closely related to *H. pullorum*, infects geese and has been identified from people with diarrhea (258). Two additional *Helicobacter* species, *H. anseris* and *H. brantae,* were recently described infecting resident Canada geese in Boston. Although suspected to be possible human pathogens, they have not been implicated in human disease. Environmental contamination of parks by feces from geese infected with these organisms is potentially a public health concern. Another avian species (*H. pamatensis*) has been described from a tern (83) and other unnamed, distinct strains have been isolated from avian species (221).

Klebsiella

Klebsiella is an environmental contaminant that occasionally causes embryo mortality, yolk sac infections, and mortality in young chickens, turkeys, and ostriches (130, 136, 155, 192, 199, 212, 214, 253, 263). *Klebsiella* was found to be a contaminant of semen from Rhode Island red cockerels (15). Hygienic handling of semen, hatching eggs, and hatchery sanitation are necessary to prevent these losses (15, 214).

The organism has been associated with cutaneous, respiratory, ocular, systemic, and reproductive diseases of poultry. *Klebsiella* were among aerobic bacteria isolated from turkeys with cellulitis (102). Concurrent infection of young turkeys with *K. pneumoniae* increased the severity of respiratory disease resulting from *Bordetella avium* and *Chlamydiophila psittaci* infections (114). *Klebsiella* was isolated from turkey flocks with adenoviral inclusion body tracheitis that experienced respiratory disease and increased mortality. An outbreak of ocular disease caused by *Klebsiella* affected a flock of 4-week-old chickens (157). *Klebsiella* and *Staphylococcus aureus* were isolated from a septicemic disease of 20-week-old layers experiencing increased mortality. Mortality and clinical disease occurred following oral inoculation of young chicks with three *Klebsiella* biotypes. Chicks inoculated with *K. pneumoniae* had the highest mortality (81). *Klebsiella* has been infrequently isolated from reproductive diseases including salpingitis and oophoritis in hens (27, 224). Localized and systemic infections with *Klebsiella* occur in young ostriches causing "ostrich fading chick syndrome," an often-fatal disease of birds less than 3 weeks of age (243). Hydroponically grown alfalfa sprouts being fed to the birds were heavily contaminated with the organism and believed to be the source of infection (263).

Antimicrobial testing of 100 isolates from diseased or dead turkey poults between one and 35 days of age indicated sensitivity (MIC_{50} <1μg/ml) to enrofloxacin, ceftiofur, gentamicin, and trimethoprim/sufadiazine (212). Isolates (n = 22) from culled or moribund broiler chicks up to 2 weeks of age were most susceptible to ceftiofur and ciprofloxacin (136). Greater than 80% of isolates from ostriches were sensitive (MIC_{90}) to amikacin, ciprofloxacin, enrofloxacin, gentamicin, and trimethoprim/sulfamethoxazole (263).

Lactococcus

Lactococcus lactis was isolated from lungs, liver, and spleen of 5 diseased birds from over 3000 waterfowl that died in southwestern Spain. Although these were free-living waterfowl, infections in domestic waterfowl would be likely. *Lactococcus* needs to be distinguished from *Streptococcus* and *Enterococcus* (106).

Lawsonia

Lawsonia intracellularis is an obligate, intracellular, *Campylobacter*-like organism that causes proliferative enteropathy in a variety of animals, especially pigs, horses, and hamsters (147). Among avian species the disease has been reported in young ostriches and emus (66, 151). Infection of ratites was associated with increased mortality, poor growth, diarrheal disease, tenesmus, and rectal prolapse. Affected intestinal mucosa was thickened and rugose. Enterocyte proliferation, crypt changes, and infiltration of the mucosa with mixed inflammatory cells were seen microscopically. Intraepithelial, comma-shaped bacteria were visible with Warthin-Starry silver staining in the apices of enterocytes, which were identified as *L. intracellularis* by specific immunofluorescence. Affected birds responded to a 10-day course of chlortetracycline (50 mg/kg body wt) (151). Chickens were not susceptible to experimental *Lawsonia* exposure (62). Furthermore, the organism was not found in normal chickens or ones with malabsorption syndrome in the southeastern US (166). Genomic analysis of organisms from several animal species including ostriches showed they were closely related (65).

Listeria

Outbreaks of listeriosis caused by *L. monocytogenes* occur sporadically in chickens, turkeys, waterfowl, pigeons, and other avian species (107, 108, 139, 153). Young birds are most susceptible (26). The organism is important because of its ability to cause human infections following contact with infected birds (107) or consumption of contaminated poultry or poultry products, especially those that are precooked and "ready-to-eat" (74). Intestinal colonization of poultry and presence of *L. monocytogenes* in feces represent potential sources of the organism for listeriosis in ruminants (84).

Septicemic and encephalitic forms of listeriosis are recognized in birds. Emaciation and diarrhea characterize birds with septicemia. Neurological signs including depression, incoordination, ataxia, torticollis, and opisthotonos are seen in the encephalitic form (67, 69). Torticollis is especially common in affected birds. In the septicemic form, there is splenomegaly, multifocal hepatic necrosis, myocardial necrosis, and pericarditis. Myocardial degeneration, necrosis, and inflammation are often extensive (153, 200). Ascites and petechial hemorrhages in liver, heart, spleen, kidneys, and brain were seen in affected broilers (256). Salpingitis developed in hens following the acute systemic phase of the infection (135).

Birds with the encephalitic form may have visible inflammatory foci in the brain stem but usually lack gross lesions (67, 69,

107, 139, 256). Microscopically, gliosis and satellitosis in the cerebellum and hemorrhages, fibrin thrombi, and abscesses containing gram-positive bacteria are present in the midbrain, cerebellum, and medulla oblongata of birds with encephalitic listeriosis. Lesions tend to be most severe in the medulla oblongata (67, 139).

The organism is commonly found in feces and soil in temperate areas of the world. Infection can follow inhalation, ingestion, or wound contamination. An outbreak of listeriosis occurred in broilers shortly after beak trimming (256). Cold, wet conditions causing excessively moist litter were associated with an outbreak of encephalitic listeriosis and the organism was isolated from litter, water, and soil samples (67). In another outbreak, the poultry house had been flooded 10 days before onset of the disease, and conditions were hot and humid (139).

Listeria can be readily isolated and does not require special procedures (68, 181) except it may be difficult to recover from birds with the encephalitic form of the disease. However, direct culture of brain stem was positive in four of five samples collected in an outbreak of encephalitic listeriosis (69). Chicken embryos are readily infected and can be used for isolation. *L. monocytogenes* is the only species that has been implicated in poultry disease and it needs to be differentiated from other species of *Listeria* (68). There are 16 serotypes; most human and animal infections are cause by serotypes 1 and 4 (68). Demonstrating antigen in fixed tissues that have lesions of a septicemic disease is useful for confirming a diagnosis of listeriosis when culture is not possible (200). A comprehensive review of diagnostic methods for identifying *Listeria* has been published (94).

Chickens (26) and turkeys (39) are relatively resistant to experimental infection. Inoculation of younger birds and exposure to high numbers of organisms are more likely to result in colonization following oral challenge (14). Experimental air sac inoculation of day-old turkey poults with *L. monocytogenes* resulted in dose-related levels of mortality and joint infections demonstrating the feasibility of aerogenous infection. Lesions in birds that died were consistent with those that have been reported for the septicemic form of the disease (124). The organism was not shed in the eggs of heavily inoculated laying hens (164). *L. monocytogenes* has been used to study macrophage function in retrovirus infection (75) and cell-mediated responses in susceptible and resistant chickens exposed to Marek's disease virus (49).

Prevention of listeriosis depends on identifying and eliminating sources of infection. Based on the history of published outbreaks, avoiding wet conditions would seem prudent even though the risk for developing listeriosis has not been proved. The organism is often resistant to most commonly used antibiotics. High levels of tetracyclines are usually recommended for treatment. Widespread use of antibiotics in feed may have had prophylactic value in listeriosis prevention in poultry (108).

Long-Segmented Filamentous Organisms (LSFOs)

LSFOs are gram-positive, anaerobic, spore-forming bacteria that are commonly found in the jejunum and ileum of poultry and a

number of other animals. Microscopically, they can be seen embedded in the apical cytoplasm of enterocytes, displacing microvilli (268). In turkeys, LSFOs are 0.6 to 1.1μm wide and up to 13.5μm long (6). Chickens are refractory to infection with LSFOs isolated from mice even following corticosteroid treatment, suggesting that there are different types or species of LSFOs and rodents are not a likely source of infection for poultry (5). However, analysis of 16S rRNA from LSFOs infecting rats, mice, and chickens indicated they were similar and distantly related to clostridia. A provisional name, *Candidatus arthromitus,* has been proposed (225).

Often LSFOs are markedly increased in young chickens, turkeys, and quail with gastrointestinal diseases, especially during cold periods (103). While most frequently found in ill birds, LSFOs may not be pathogens, but rather they overgrow when conditions are altered because of enteric disease. The organisms stimulate mucosal immunity following phagocytosis and processing by infected enterocytes (268). In mice they provide protection against pathogen colonization and increase small intestinal transit time (226). High numbers of LSFOs were present in the jejunum of poults with experimental stunting syndrome (6), but subsequent studies using filtered inocula showed they were not the cause of the disease (218). However, depressed growth (11–14%) occurred when poults were inoculated with two isolates of filamentous bacteria (178). Presence of LSFOs has been associated with decreased carotenoid levels and skin pigmentation in chickens (4). Virginiamycin is partially effective in controlling the organisms and improving serum carotenoid levels (3).

Moraxella

Moraxella has been occasionally isolated from turkeys with respiratory disease (91). *M. osloensis* caused a cholera-like disease in commercial turkeys. Affected birds had at least one consolidated, pneumonic lung, multiple hemorrhages and inflammation of serous membranes, and abnormal spleens and livers. The organism could be distinguished from *Pasteurella multocida* by its growth on eosin-methylene blue and MacConkey agars. The disease was reproduced in experimentally inoculated turkeys (88). *Moraxella* sp. also has been recovered from salpingitis in layers (34) and from dead-in-shell embryos or weak chicks (155). An ostrich developed granulomatous conjunctivitis from which *M. phenylpyruvica* was isolated (109).

Mycobacterium avium subsp. paratuberculosis

Natural infections of poultry with *Mycobacterium avium* subsp. *paratuberculosis* have not been reported, but chickens are susceptible to experimental infection (247, 249) and develop an immune response following exposure to the organism (60). A related mycobacterial strain that causes a chronic intestinal disease of wood pigeons (*Columba palumbus*) in Europe (245, 248) produces lesions consistent with paratuberculosis in experimentally inoculated calves (63, 244). Both the wood pigeon strain and *M. avium* subsp. *paratuberculosis* may have significant public health importance, as they have been associated with Crohn's disease and sarcoidosis in people (165).

Neisseria

Diplococci consistent with *Neisseria* can cause pneumonia in young ostriches (122). Gram-negative, nonfermentative, *Neisseria*-like bacteria, that have a phenotype distinct from similar bacteria in the respiratory tract of chickens and turkeys, have been isolated from tracheas and lungs of birds in flocks with respiratory disease. The organism does not grow on MacConkey agar and is nonhemolytic, oxidase-positive, and catalase-positive. Turkeys were more frequently affected than chickens. Ages of infected birds ranged from 5 weeks to 3 years. Usually other bacteria or viruses were identified in affected flocks. Its role in respiratory disease is unknown (57). *Neisseria* are also commonly identified in goose venereal disease (see below).

Nocardia

Nocardia are branching, gram-positive filamentous bacteria that typically cause granulomatous lesions, especially in the respiratory system. The organism has rarely been isolated from poultry even though chickens are susceptible to experimental infection following oral or intraperitoneal inoculation (188).

Oerskovia

Oerskovia are similar to *Nocardia* and infrequently cause opportunistic infections in people and animals. The organism was isolated, along with α-hemolytic staphylococcus, from a clinically ill pigeon that had a large granulomatous mass at the base of the heart adjacent to the esophagus and trachea. Colonies of gram-positive bacilli were present within granulomas (265).

Pantoea (see *Enterobacter/Pantoea*)

Pelistega

Pelistega europaea is a newly described bacterium associated with respiratory disease in pigeons. Taxonomically it is most closely related to *Taylorella equigenitalis*, the cause of contagious equine metritis (251).

Peptostreptococcus

Young turkey poults with diarrhea often have high numbers of a large coccus in the liquid cecal contents that is typically arranged in tetrads (61). The bacterium has been referred to as *Gaffkya anaerobius*, but the genus *Gaffkya* is no longer valid. *G. anaerobius* has been transferred to the genus *Peptostreptococcus*. Genomically, peptostreptococci are more closely related to clostridia than streptococci (181). Gram-positive, anaerobic cocci, including *Peptostreptococcus*, account for up to 30% of normal cecal microbes (24). The role of the organism in diarrheal disease remains to be determined.

Planococcus

Planococcus is a halophilic, motile, gram-positive coccus that is unrelated to other cocci and is normally associated with marine environments. Pure cultures of *P. halophilus* were obtained from livers of 43-week-old layers with multifocal hepatic necrosis. Mortality of nearly 6% occurred in the flock during the month after onset of the disease. The isolate was resistant to most antimicrobials. However, it was susceptible to streptomycin, which was added to feed at 5 g/kg. Feed, specifically fishmeal and marine byproducts, was considered to be the most likely source of the organism. High ambient temperatures (up to 46°C) during the outbreak were thought to be a contributing factor (1).

Plesiomonas

Plesiomonas is closely related to *Aeromonas* and shares many of its characteristics. It is commonly found in fresh water environments and primarily infects aquatic birds (125) although it has been recovered from the livers of turkeys with histomoniasis (257).

Proteus

Proteus is a genus in the family Enterobacteriaceae that inhabits the lower intestinal tract. The organism is capable of penetrating the eggshell, which is facilitated by fecal contamination. Experimental inoculation of fertile eggs resulted in 100% embryonic mortality (44). Temperature influences egg penetration and survival within the egg (2).

   Proteus occasionally causes embryonic death, yolk sac infections, and mortality in young chickens, turkeys, and ducks (25, 130, 155, 192, 199, 210, 212, 214, 253). Experimental inoculation with an isolate from ducklings failed to cause disease (210). *Proteus* also can be a contaminant of artificially collected semen (15).

   Septicemia due to *Proteus* has occurred in quail (171, 211), pheasants infected with apathogenic avian influenza virus (241), and broilers suspected of having immunologic deficiency (201). *Proteus* has been recovered occasionally from a low percent of salpingitis and oophoritis lesions in layers (27, 34, 224) and has been associated with respiratory disease in chickens (156, 240, 269). An isolate from chickens with respiratory disease caused 50% mortality in experimentally inoculated 4-week-old chickens (156). *P. mirabilis* was isolated from the lung, trachea, and kidney of chickens experiencing respiratory signs, diarrhea, paralysis, and high mortality. The disease was reproduced with isolates of the organism (269). *Proteus* was isolated infrequently from turkeys with cellulitis (102, 189) and white leghorn pullets with necrotic dermatitis that seroconverted to reticuloendotheliosis virus (120). In waterfowl *Proteus* can occasionally produce arthritis, salpingitis, airsacculitis, septicemia (33, 35, 262), and granulomatous inflammation of salt glands (137).

   Antimicrobial testing of 19 *Proteus* isolates from diseased or dead turkey poults between one and 35 days of age indicated sensitivity (MIC$_{50}$ <1μg/ml) to enrofloxacin and ceftiofur (212).

Pseudomonas

Pseudomonas can cause localized or systemic diseases in young and growing poultry, invade fertile eggs causing death of embryos and newly hatched birds, and reduce shelf life of contaminated meat. The organisms are ubiquitous, often associated with soil, water, and humid environments. For a review of earlier literature on *P. aeruginosa* infections in domestic animals, see (158).

   Pseudomonas aeruginosa is a motile, gram-negative, non-spore-forming rod measuring 1.5–3 × 0.5–0.8 μm, occurring singly or in short chains. The organism is a strict aerobe that grows readily on common bacteriologic media, usually producing a water-soluble green pigment composed of fluorescein and pyocyanin. A characteristic fruity odor can often be recognized. Detailed methods to characterize and differentiate pseudomonads have been published (181).

   Pseudomonas is generally considered to be an opportunist that produces respiratory infections, sinusitis (91), keratitis and keratoconjunctivitis (138, 184), or septicemia and its sequelae when introduced into tissues of susceptible birds. Above normal mortality in young birds due to omphalitis and yolk sac infections acquired in the hatchery have been described (260). Chickens (17, 82, 140, 170, 184, 205, 260), turkeys (13, 102, 111, 126, 184), ducks (33, 137, 184, 210, 262), pheasants (118), ostriches (123, 175, 194, 263), geese (234), and a variety of pet and captive birds have been affected. Although birds of any age may be infected, young birds are most susceptible, as are severely stressed or immunodeficient birds. Concurrent infections with viruses and other bacteria, especially mycoplasmas, are common and may enhance susceptibility to *Pseudomonas* (198, 201, 234). Morbidity and mortality are usually 2–10% but can be much higher, approaching 100%.

   Pseudomonas aeruginosa is the most common pseudomonad causing infections. Virulence is variable among isolates. Mortality following yolk sac inoculation of chicks ranged from 0–90% (260). Isolates examined in another study were highly virulent causing 50–100% mortality in experimentally inoculated 4-week-old chickens (156). *P. fluorescens* caused death of turkey embryos following dipping of eggs in contaminated antibiotic solution (22), and it has been associated with multi-causal respiratory disease of chickens (156) and turkeys (114). *P. stutzeri* was isolated from chickens with respiratory disease but produced only low mortality in experimentally inoculated chickens (156). Pseudomonads are capable of digesting eggshell cuticle if the humidity is high (37). Chickens are susceptible to melioidosis (*Burkholderia [Pseudomonas] pseudomallei*), but naturally occurring disease in poultry has not been described (255).

   Mortality characterizes most *Pseudomonas* infections. Death usually occurs rapidly; often within 24–72 hours following infection. Clinical signs vary depending on whether infections are localized or systemic, but may include anorexia, stunting, lassitude, lameness, incoordination, ataxia, swelling of head, wattles, and sinuses, swelling of hock joints or foot pads, respiratory distress, diarrhea, and conjunctivitis (82, 111, 138, 140, 179). Torticollis, indistinguishable from fowl cholera, occurs following

23.25. Panophthalmitis with corneal perforation in an 18-day-old turkey poult. A heavy pure growth of *Pseudomonas aeruginosa* was obtained on culture, and intralesional bacteria were present in tissues on histopathology. (Tahseen Abdul-Aziz)

23.26. Subcutaneous lesions in the upper neck area of chicks following the use of a Marek's disease vaccine contaminated by *Pseudomonas*. (Laddie Munger)

Pseudomonas inoculation of turkeys via the eustachian tube (190). Infections of the nasal glands in ducks resulted in granulomatous adenitis (137).

Lesions are consistent with clinical findings and include subcutaneous edema and fibrin, occasionally with hemorrhage, exudate in affected joints, inflammation of serous membranes mimicking lesions of colisepticemia (airsacculitis, pericarditis, perihepatitis), pneumonia, swelling and necrotic foci in liver, spleen, kidney, and brain, conjunctivitis, sinusitis, and occasionally keratitis (82, 111, 138, 156, 179, 184). Chicks that survived yolk sac inoculation had retained, inflamed yolk sacs when examined 14 days postinoculation (260). Unilateral panophthalmitis characterized by corneal perforation and phacolysis occurred in young turkeys with ocular *Pseudomonas* infection (Fig. 23.25). The rapidly progressive destruction of the eye may be related to proteases produced by the organism (13). Large numbers of bacteria, often in and around affected blood vessels within most tissues, including brain, are typically seen microscopically in acute lesions. Heterophilic exudate in the pharynx and pulmonary foci were present in respiratory infections of pheasants (118). A similar case characterized by pseudodiptheretic membranes and granulomatous lesions in the respiratory and upper digestive tract occurred in a group of young ostriches experiencing high mortality. Intralesional *P. aeruginosa* colonies were identified by immunohistochemistry and the infection was confirmed by culture (175). *Pseudomonas* was isolated infrequently from adult hens with salpingitis and oophoritis (27, 224), from turkeys with cellulitis (102, 189), from geese with venereal disease (see below), and was the most common bacterium recovered from abnormal joints of broiler chickens in a study of leg weakness (40).

Pseudomonas is among a variety of bacteria often recovered from dead embryos and sick newly hatched chickens, turkeys, pheasants, ducks, and ostriches (44, 80, 130, 155, 192, 210, 253). With the exception of a respiratory outbreak in pheasants attributed to exploding contaminated eggs in the incubator, presence
of *P. aeruginosa* in embryos is not considered a source of infection for older birds. Severe outbreaks have followed injection of large numbers of birds with contaminated vaccines (Fig. 23.26) (170, 246) and antibiotic solutions (52, 266). In these cases, contamination resulted from poor hygiene during mixing and handling, not from the products themselves. Contact with infected birds (179) and intense, continuous broiler production with different ages being raised at the same facility (82) can result in spread of *Pseudomonas* infection. In some outbreaks, the source of the organism and how it spread could not be determined.

Diagnosis requires isolation and identification of the organism. Various methods including serologic, phage, and aeruginocine typing methods are available (209) and may be useful in epidemiologic studies.

Prevention and control are based on identifying and eliminating the source of the organism. Good hygiene, especially in hatcheries and when birds are injected, is fundamental to *Pseudomonas* control. Cleaning and disinfection of equipment and use of sterile techniques in preparing vaccines and injectables will control *Pseudomonas* infections resulting from inoculation (52). Sensitivity of isolates to hatchery disinfectants needs to be determined (267). A commercial quaternary ammonium disinfectant was ineffective at achieving total kill of high concentrations (10^9) of *P. aeruginosa* that had been isolated from chicks with omphalitis. It was generally effective when numbers of organisms were low (10^3) and had a variable effect on intermediate concentrations (10^6). Potentiation of the disinfectant with EDTA substantially improved its efficacy when tested *in vitro* (259). Use of either quaternary ammonium with or without EDTA reduced airborne bacteria at hatching and did not have an adverse affect on hatchability or livability (261). Reduction of stress and prevention of other viral and bacterial infections will aid in reducing susceptibility to *Pseudomonas*.

Antibiotics can be useful in reducing losses if initiated early in

the disease, but because of the organism's resistance to many antimicrobials (140, 156, 193, 195, 205, 209, 260), sensitivity testing is essential. Antimicrobial testing of 31 isolates from diseased or dead turkey poults between one and 35 days of age indicated sensitivity (MIC_{50} <1μg/ml) only to enrofloxacin (212). In contrast, greater than 80% of isolates from ostriches were sensitive (MIC_{90}) to amikacin, ciprofloxacin, enrofloxacin, and gentamicin (263). Supplemental vitamin A and potassium permanganate in the water were helpful adjuncts to antibiotic therapy in controlling conjunctivitis (138).

Rothia

Rothia species are aerobic actinomycetes that have been associated with chronic infections, most notably tooth decay, in human beings and animals. They are closely related to *Actinomyces. Rothia* was the only bacterium isolated from osteomyelitis and joint lesions in four lame or recumbent tom turkeys in an affected flock. Intravenous inoculation of unaffected turkeys reproduced the clinical signs and lesions from which the organism was reisolated (22).

Streptobacillus

Streptobacillus moniliformis, a gram-negative, often beaded, nonbranching, filamentous bacterium, can infect turkeys, usually following rat bites or exposure to infected rats. Polyarthritis and synovitis occur in infected birds; other tissues are usually normal. The disease can be reproduced in turkeys following experimental inoculation of the organism by intravenous, subcutaneous, and footpad routes, but not by oral administration. Chickens are not susceptible. Diagnosis requires isolation and identification of the organism. Infection can be prevented through rodent control (100, 172).

Streptomyces

Normally a free-living soil organism, *Streptomyces* was isolated in pure culture from nonviable ratite eggs. Large gray-white plaques were present between the eggshell and shell membrane and the dead embryos were congested, had abnormal discolored yolk, and had multiple white foci in the liver. Washing and disinfecting of the egg was believed to have contributed to the infection (263).

Suttonella

Unique gram-negative rods isolated from passerine birds experiencing episodes of mortality in Great Britain were described as a new species, *Suttonella ornithocola* (92, 134). The organism has not been associated with disease in poultry.

Vibrio

Non-O1 *V. cholerae* has been isolated from geese that died following weight loss and lassitude of 2–3 days duration (216), from nasal cavities of apparently healthy ducks (32), and from tissues of ducks with airsacculitis or septicemia (262). Individuals working with ill birds that have contact with coastal waters and shellfish need to be aware that birds can be a source of human infection (216). Conjunctivitis caused by *V. cholerae* NAG, a potential human pathogen, occurred in ducklings (31). The organism was also isolated from the intestines, and water where the ducks were being kept. Exposure of the domesticated ducks was believed to have come from free-living birds. Both O1 and non-O1 *V. cholerae* have been frequently isolated from feces of aquatic birds and their environments (187).

Historically, a cholera-like disease has been reported in poultry and zoo birds caused by *V. metschnikovii (metschnicovii)*, and campylobacters have been implicated as the cause of hepatitis in chickens (see Chapter 18) (196). *V. metschnikovii* is still occasionally isolated from diseased chickens (149) and waterfowl (115). An outbreak of vibrionic hepatitis in a layer flock caused an 89% decrease in egg production and 10% increase in mortality. Lesions included hydropericardium, ascites, and an enlarged, discolored liver that contained multiple gray to yellow necrotic foci. Chlortetracycline was effective in controlling the disease (215).

Vibrio alginolyticus is a dominant proteolytic bacterium in the upper respiratory tract of chickens and turkeys. It does not cause disease but may enhance pathogenicity of avian influenza viruses by providing a mechanism for cleavage of the virus hemagglutinin (47).

Diseases Caused by or Associated with Bacteria

Beak Necrosis

A gram-positive bacterium with affinity for keratin was associated with beak necrosis that affected nearly half of the birds in a flock of 1-year-old broiler breeder hens and caused approximately 10% mortality (56). Feeding fine feed (mash) predisposes birds to oral and beak lesions although the exact mechanism of how lesions develop is unknown. Oral lesions resolve rapidly after birds are put on pelleted feed (95). Injury to the epidermis occurs initially followed by necrosis, ulceration, and bacterial growth. Affected birds have decreased leukocytes and anemia (96). Beak deformity, loss of the distal end of the mandible, and osteomyelitis occur in severely affected birds. Weight loss and mortality result from impaired feeding (86). Use of 40-mm grids over feeders to restrict male access to feed resulted in a higher occurrence of oral and beak lesions (116). Males are more often affected than females (86). Visibly affected birds need to be culled for welfare reasons. In one study, beak lesions were the major cause for culling of male broiler breeders (117).

Goose Venereal Disease

An infectious venereal disease of uncertain etiology characterized by inflammation of the penis and cloaca of ganders in breeding flocks was first described in Hungary (239). Subsequently, the disease has affected flocks in Europe, Russia, and the Middle East. Initially, the base of the phallus becomes

swollen and inflamed, with the process extending to the cloaca. Later, there is necrosis, ulceration, and eventually considerable scarring of the mucosa, often making reproduction impossible. Similar lesions may develop in the cloaca of hens following breeding. Morbidity ranges from 20 to 100%, and newly introduced birds readily contract the disease. Increased infertility and gander mortality of approximately 5% are flock problems resulting from the disease (232).

A variety of bacteria, especially *Neisseria* and *Mycoplasma* spp. and *Candida albicans*, affecting the phallus of ganders and cloaca of hens has been associated with the disease (29, 162, 232, 233). The normal phallus microflora of unaffected ganders has been established (161) and is similar, with the exception of *Mycoplasma* and *Candida albicans*, to that of affected ganders (29). Use of antimicrobials effective against mycoplasmas substantially reduces the severity of the disease (77). A similar disease attributed to *C. albicans* spread through goose flocks in Israel (28). Dramatic improvement followed treatment with mycostatin and antibiotics. Vaccination with ethanol-inactivated fungus provided good control of the disease (141). A phycomycete, *Mucor janssenii*, found in one flock of affected ganders reproduced a similar disease in experimentally inoculated birds (163). Exposure of SPF Muscovy ducks and geese to isolates alone and in various combinations produced only mild clinical signs and lesions except in a female contaminated by an affected gander and inoculated with *C. albicans*. Trauma is considered to be a likely initiating factor followed by infection with bacteria and fungi (162).

It is recommended that ganders be examined at each breeding season and affected birds removed from the flock. Artificial insemination can be used in affected flocks to improve fertility (29).

Intracellular Infection in Ducks

Mortality in Muscovy ducks (*Cairina moschata*) caused by an intracellular organism primarily affecting endothelial cells in the lungs was initially attributed to *Haemoproteus* infection (127). However, subsequent examination of additional cases revealed that the organism was not a protozoan, but probably a bacterium capable of forming spores or an unidentified microorganism. Muscovy ducks are most susceptible and can contract the infection from asymptomatic infected Pekin ducks. Experimental transmission is possible using blood from an infected duck.

Lungs of affected ducks are dark red-purple, slightly edematous, and firm. Microscopically, air capillaries are obliterated because of marked swelling of endothelial cells, which are often packed with intracellular organisms, and interlobular septa are widened and contain inflammatory cells and edema. In tissue sections, organisms stain poorly with hematoxylin and eosin but are readily demonstrated with periodic-acid-Schiff or silver stains (128, 202).

Liver Granulomas and Related Granulomatous Disorders

Granulomas are occasionally seen in livers of turkeys and, less frequently, chickens at processing. Affected livers and carcasses are condemned. The incidence in individual flocks may reach 50%.

Granulomas are focal or multifocal, single to coalescing lesions that are grossly visible as firm, lobulated, roughly spherical, pale yellow to white masses ranging in size from a few millimeters to several centimeters. Advanced lesions have a rough appearance and may be "gritty" when cut. Bile stasis of adjacent normal hepatic tissue is often marked. Liver granulomas are caused by a variety of infectious and parasitic agents. *E. coli, Eubacterium*, and other bacteria are among the more common etiologic agents (235). Similar granulomas are occasionally seen in the spleen and rarely in other tissues of affected birds.

Microscopically, lesions are typical avian heterophilic granulomas (176) that contain a central caseous mass covered by a layer of multinucleated giant cells, which is confluent except in areas where the process is still active. Surrounding the caseated center is a more diffuse zone of heterophils, macrophages, fibroblasts, and lymphocytes. Heterophils can be seen migrating through the layer of giant cells and are especially numerous in areas where giant cells are absent or discontinuous. Diffuse and focal lymphocytic foci form the outermost layer of the lesion. Fibrosis may be extensive in chronic lesions. Bacteria generally are not visible unless special stains are used. Tangles of filamentous organisms can usually be seen with silver stains such as Warthin-Starry or Dieterle and gram-positive filamentous or coccoid organisms may be seen with Gram's stain (8, 146, 177).

A variety of bacteria have been isolated from the lesions including *Actinomyces* (219), *Catenabacterium, Corynebacterium, Eubacterium, Propionibacterium, Enterococcus (Streptococcus)*, and *Staphylococcus* (146, 177). Liver granulomas occurred after intravenous inoculation of turkeys with a *Catenabacterium* spp. that had been isolated from a naturally infected turkey. Chickens, peafowl, guinea pigs, rabbits, hamsters, and mice did not develop lesions (177). Granulomatous lesions in liver and spleen were reproduced experimentally by inoculating turkeys with *Eubacterium tortuosum* (8, 112) even though the organism is part of the normal cecal flora (112). Co-inoculation with other bacteria, including a virulent strain of *E. faecalis* or *S. epidermidis*, increased the likelihood of liver lesions. Often, mucosal ulcers in the lower intestinal tract can be found in affected birds suggesting liver lesions develop from bacteria carried to the liver from the intestine via the bloodstream (8, 112, 146, 177).

Liver granulomas also occur in chickens but much less frequently. Gram-positive, filamentous bacteria morphologically and tinctorially distinct from *Eubacterium*, long-segmented filamentous organisms, *Actinomyces*, and *Nocardia* were present in sporadic cases of visceral granulomas in broiler chickens at processing in the United States (113). Lesions also occurred in the spleen, cecum, and mesentery of some birds.

In 7–8-week-old turkeys, pyogranulomatous typhlitis and hepatitis characterized by cecal cores and rupture was associated with *E. coli,* and concurrent coccidia and hemorrhagic enteritis virus infections. Excess condemnations for granulomatous lesions did not occur when the flock was processed (178).

Larvae of intestinal helminths also can cause hepatic foci ("white-spotted livers") in turkeys and chickens that need to be differentiated from bacterial granulomas. Only a low percentage of hepatic foci in turkey livers at processing yielded bacteria;

E. coli and *Salmonella* spp. were most commonly recovered (185). Foci were associated with migration of *Ascaridia* larvae. Exposing turkey poults to *A. dissimilis* ova reproduced the lesions (186). No causative organism initially was identified in granulomatous lesions in ceca and livers of older chickens from small flocks in Canada (182), but subsequently, larvae of the cecal worm, *Heterakis gallinarum*, were found to be associated with the lesions (206).

Chapter 24

Avian Chlamydiosis (Psittacosis, Ornithosis)

Arthur A. Andersen and Daisy Vanrompay

Introduction

Definition and Synonyms

Avian chlamydiosis is caused by the bacterium *Chlamydophila psittaci*. Avian chlamydiosis in birds is usually systemic and occasionally fatal. Clinical signs vary greatly in severity and depend on the species and age of the bird and the strain of chlamydia. Avian chlamydiosis can produce lethargy, hyperthermia, abnormal excretions, nasal and ocular discharges, and reduced egg production. Mortality ranges up to 30%. In pet birds, the most frequent clinical signs are anorexia and weight loss, diarrhea, yellowish droppings, sinusitis, and respiratory distress (64). Many birds, especially older psittacine birds, may show no clinical signs; nevertheless, they will often shed chlamydiae for extended periods. Necropsy of infected birds often will reveal spleen and liver enlargement, fibrinous air sacculitis, pericarditis, and peritonitis (72, 89, 101).

This chapter primarily covers avian chlamydiosis as it occurs in birds raised commercially for meat and egg production—turkeys, ducks, and pigeons. It should be noted that the disease in pet birds is quite similar, and the disease characteristics, transmission, and diagnosis are essentially the same. A summary of the disease and control procedures for chlamydiosis in companion birds was recently published (84) and is on the American Veterinary Medical Association (AVMA) and Centers for Disease Control and Prevention (CDC) Web sites.

The disease in birds and humans originally was called psittacosis or parrot fever (65) as it was first recognized in psittacine birds and in humans associated with psittacine birds. Ornithosis was a term introduced in 1941 by Meyer (63) to differentiate the disease in or contracted from domestic and wild fowl from the disease in or contracted from psittacine birds. The two syndromes are currently considered to be the same (69). Their earlier separation was based on the assumption that in man ornithosis was a milder disease than psittacosis. However, the disease in man contracted from turkeys often is more severe than that contracted from psittacine birds.

Public Health Significance

Avian strains of *C. psittaci* can infect humans, and precautions should be taken when handling infected birds or contaminated materials. Human infections are common following handling or processing of infected turkeys or ducks. Most infections are through inhalation of infectious aerosols; thus, processing plant employees are especially at risk, as are farm workers and poultry

inspectors at processing plants. Personnel who are employed to further process turkey meat have also become infected. Chickens, pigeons, pheasants, quail, and partridges also may pose public health threats, mainly to their producers.

In humans, the incubation period of avian chlamydiosis is usually 5–14 days; however, longer periods are known (84). Infections vary from inapparent to severe systemic disease with pneumonia. Because the disease is rarely fatal in properly treated patients, awareness of the danger and early diagnosis are important. Infected humans typically develop headache, chills, malaise, and myalgia, with or without signs of respiratory involvement. Although pulmonary involvement is common, auscultatory findings may appear normal or underestimate the extent of involvement. A human chlamydial strain (*C. pneumonia* strain TWAR) produces similar disease symptoms in humans (33, 34). The recommended therapy for it is the same as for the avian strain, so a differential diagnosis is not required.

History

Avian chlamydiosis gained world prominence during a pandemic in 1929–1930 that involved at least 12 countries. In the United States, the disease was attributed to the importation of green Amazon parrots from South America. In 1931, strict regulations were placed on the importation of parrots from tropical countries. During this time, Leventhal, Cole, and Lillie independently observed very small basophilic bodies in the tissues of infected birds and humans and suggested that they were the causative agent. The etiological relationship between basophilic bodies and disease was soon established conclusively by Bedson and Bland (cited in 61).

During the next 20 years, it became clear that chlamydiae were not limited to psittacine birds, were widespread in almost all avian species, and that chlamydiae from other avian species were transmissible to humans. In 1939, chlamydiae were isolated from two pigeons sent to the diagnostic laboratory in South Africa by a pigeon fancier who was losing a few birds from his flocks. Isolates were soon recovered from racing and carrier pigeons in California, and infections in two humans in New York were attributed to contact with feral pigeons. In 1942, serological evidence showed that ducks and turkeys could be infected naturally. Within 3 years, human infections due to contact with ducks were reported in California and New York. However, it was not until the early 1950s that isolates were made both from turkeys and from humans in contact with the turkeys (61). The list of avian

species in which naturally occurring chlamydial infections were identified increased rapidly until today more than 400 species of birds belonging to more than 21 orders have been reported.

During the 1960s, the incidence of severe epidemics in poultry in the United States and Europe declined, although occasional outbreaks and serologic evidence show that avian chlamydiaosis is a continuing threat both to birds and to humans in contact with them. Outbreaks in turkeys were reported in the United States during the 1980s (40, 67) and more recently in Europe (81, 104). An increase in the number of outbreaks due to chlamydia in ducks has been reported in recent years. Human infections were associated with a number of these outbreaks (11, 15, 32, 50, 57, 59, 66).

Etiology

Classification

The specific genus and species will be used when referring to species and strains. The members of the order Chlamydiales are obligate, intracellular gram-negative bacteria infecting both humans and animals. Rapid and easy identification of these bacteria is essential for taxonomic, epidemiological, and clinical determinations. The family Chlamydiaceae was recently reclassified into two genera, *Chlamydia* and *Chlamydophila* (25). The two genera, *Chlamydia* and *Chlamydophila,* correspond to the former *C. trachomatis* and *C. psittaci*, respectively. Under the new classification, *Chlamydia* includes 3 species (*C. trachomatis, C. muridarum,* and *C. suis*), and *Chlamydophila* includes 6 species (*C. psittaci, C. abortus, C. felis, C. caviae, C. pneumoniae,* and *C. pecorum*). DNA sequence analysis of phylogenetic markers (the ribosomal intergenic spacer and the domain I of the 23S rRNA gene) provides a rapid and reproducible method for identifying, grouping, and classifying chlamydial strains (25, 27, 80). For continuity with the old classification, the terms chlamydiosis, chlamydiae, etc., are used as generic terms and refer to the diseases caused by all members of the genera *Chlamydia* and *Chlamydophila.*

Morphology and Staining

The three morphologically distinct forms of *Chlamydophila* are termed elementary body (EB), reticulate body (RB), and intermediate body (IB) (Fig. 24.1). The EB is a small, electron-dense, spherical body, about 0.2–0.3 mm in diameter, which rivals mycoplasma for the smallest of the prokaryotes. The EB is the infectious form of the organism, which attaches to the target epithelial cell and gains entry. The EBs are characterized by a highly electron-dense nucleoid, located at the periphery of the EB and clearly separated from an electron-dense cytoplasm. Following entry into the host cell, the EB expands in size to form the RB, which is the intracellular metabolically active form. It is larger than the EB, measuring approximately 0.5–2.0 mm in diameter. The RB divides by binary fission and thereafter matures into new EBs. During this maturation, morphologically intermediate forms (IB), measuring about 0.3–1.0 mm in diameter, can be observed inside the host cell. The IB has a central electron-dense core with radially arranged individual nucleoid fibers surround-
24.1. Transmission electron photomicrograph of a *C. psittaci* inclusion (INCLUS) in infected L929 cells. The various morphological forms of chlamydiae are present: elementary body (EB), reticulate body (RB), and intermediate body (IB). ×15,000

ing the core. Cytoplasmic granules are tightly packed at the periphery of the IB and are separated from the core by a translucent zone.

All chlamydiae are gram-negative, but the Gram stain is of no practical value in identifying chlamydiae. Chlamydiae are large enough to be seen either with a light microscope using special optics or with selective stains. In wet mounts of impression smears of infected tissues or exudates, intracellular chlamydiae are large enough to be seen at magnifications of 3800 or more in phase contrast microscopes (Fig. 24.2A). They are also readily seen by dark-field illumination (Fig. 24.2B). With either technique, however, they cannot be distinguished from contaminating intracellular mycoplasma organisms. When only bright-field optics are available, chlamydiae may be seen in touch impressions of infected tissues by staining them with Castaneda, Giemsa, Gimenez, Machiavello, or Stamp methods after appropriate fixation (2). They appear dark purple with Giemsa; blue with Castaneda; and red with Machiavello, Gimenez, and Stamp stains against contrasting backgrounds. The Gimenez method (31) is preferred for staining chlamydiae in touch impressions of yolk sacs of infected chicken embryos and has proved very useful in obtaining presumptive diagnoses in microscopic examination of touch impressions of diseased air sacs, spleens, and pericardia of naturally infected birds (Fig. 24.3).

Biochemical Properties

The RB is the intracellular, metabolically active form. Although DNA and RNA are both found in the EB and the RB, the ratio of RNA to DNA is greater in the RB. The RBs synthesize their own DNA, RNA, and protein, but some of their metabolic capabilities are limited when compared with free-living, colonizing bacteria. For example, they cannot complete the pentose cycle and do not use pyruvate by way of the tricarboxylic acid cycle. They can, however, catabolize pyruvic, aspartic, and glutamic acids, generating CO_2 and 2- and 4-carbon residues.

Antibiotic Susceptibility

Multiplication of all strains of chlamydiae (except for some *Chlamydia suis* strains and experimental mutants) is strongly inhibited by appropriate concentrations of tetracyclines, chloramphenicol, and erythromycin and less so by penicillin. Some strains are inhibited by D-cycloserine. All strains of *C. trachomatis* are inhibited by sodium sulfadiazine. By varied mechanisms tetracyclines, chloramphenicol, and erythromycin inhibit synthesis of protein on chlamydial ribosomes. Penicillin interferes with chlamydial cell wall synthesis, resulting in the interruption of RB

binary fission and, thus, the formation of abnormally large RBs that cannot mature into EBs. D-cycloserine acts similarly, but the drug's action can be reversed by the addition of alanine. Inhibition of multiplication by sodium sulfadiazine affects the organism's ability to produce folic acid; this inhibition can be reversed by the addition of *p*-aminobenzoic acid. Certain antibiotics have little or no effect on the growth of chlamydiae, and this fact can be useful in selecting for viable chlamydiae in suspensions containing contaminating bacteria. Concentrations of 1 mg/ml of streptomycin sulfate, vancomycin, and kanamycin sulfate may be used for this purpose. Chlamydiae are also unaffected by bacitracin, gentamicin, and neomycin.

Susceptibility to Chemical and Physical Agents

Chlamydiae are highly susceptible to chemicals that affect their lipid content or the integrity of their cell walls. Even in a milieu of tissue debris, they are inactivated rapidly by surface-active compounds, such as quaternary ammonium compounds and lipid solvents (84). They are somewhat less susceptible to dilute solutions of protein denaturants, acids, and alkalies (methanol, ethanol, ammonium or zinc sulfate, phenol, hydrochloric acid, or sodium hydroxide). Infectivity is destroyed within minutes, however, by exposure to common disinfectants such as benzalkonium chloride, alcoholic iodine solution, 70% ethanol, 3% hydrogen peroxide, and silver nitrate; but they are resistant to cresol compounds and lime. Dilute suspensions (20%) of infectious tissue homogenates are inactivated by incubation for 5 minutes at 56°C, 48 hours at 37°C, 12 days at 22°C, and 50 days at 4°C (73).

Infectious dense forms of the organisms in yolk sac membranes or mouse tissues may be preserved indefinitely at –20°C or below, although the initial freezing and subsequent thawing incurs a titer loss of 1–2 $\log_{10}$. Infectivity of the suspension is destroyed after 6 freeze-thaw cycles (73). Thin-walled, large forms of the organism are inactivated at –70°C.

Cell walls of the dense forms are disrupted by ultrasonication at frequencies above 100 KC or by treatment of intact organisms with sodium deoxycholate.

Antigenic Structure and Toxins

The number of proteins produced by chlamydiae is unknown, and only a limited number have been studied for their antigenic importance. The cystine-rich major outer membrane protein

(MOMP) has a molecular weight of 40 kDa and represents approximately 60% of the weight of the outer membrane. The MOMP is an immunodominant protein, and there is considerable evidence that antibodies to surface-accessible epitopes of MOMP have a protective role in immunity to chlamydial infection. The outer membrane protein A (*ompA*) gene (also referred to as *omp1* gene) encodes the MOMP. The *ompA* gene contains 5 conserved- and four variable-sequence regions, VS1 to VS4, which encode for the variable-protein domains VDI to VDIV. VDI, VDII, and VDIV especially protrude from the *C. psittaci* membrane. Epitope mapping has shown the presence of genus- and species-specific antigenic determinants within the conserved regions. However, species-specific antigenic determinants have also been found in the most conserved parts of VDIV. Serovar-specific antigenic determinants are located within VDI and VDII. Monoclonal antibodies (MAbs) to the highly immunoaccessible serovar-specific epitopes on the MOMP can passively neutralize chlamydial pathogenicity and infectivity. Monoclonal antibodies to genus-, species-, or serovar-specific epitopes on the MOMP are excellent tools for specific chlamydial diagnosis.

The chlamydial lipopolysaccharide (LPS) is also an essential constituent of the outer membrane and, like the MOMP, represents one of the major surface-exposed antigens of chlamydiae in both the EB and the RB. It has a molecular weight of 10 kDa and is chemically and serologically related to the LPS of gram-negative enterobacteriaceae. In fact, the chlamydial LPS contains several antigenic determinants cross-reacting with the LPS of enterobacterial Re mutants of *Salmonella* species and *Acinetobacter calcoaceticus* (17, 68). However, the chlamydial LPS contains in its saccharide moiety, a trisaccharide of 3-deoxy-D-manno-2-octulosonic acid (Kdo) of the sequence αKdo $(2 \rightarrow 8)$ -αKdo- $(2 \rightarrow 4)$ -aKdo. This antigenic epitope is shared only by all members of the genera *Chlamydia* and *Chlamydophila* and, thus, represents a Chlamydiaceae-specific antigen useful for specific diagnosis (18).

A chlamydial cystine-rich heat shock protein 60 (hsp60) has been described that is cross-reactive with other gram-negative bacteria such as *Escherichia coli, Neisseria gonorrhoeae*, and *Coxiella burnetii* (107). This is not surprising considering the fact that heat shock proteins are among the most conserved molecules in phylogeny. Thus, the presence of cross-reactive epitopes on the chlamydial outer membrane should be kept in mind when choosing or interpreting a specific diagnostic test. The chlamydial hsp60 has been associated with the hypersensitivity often seen in repeated chlamydial infections. It is thought to play a major role in scar formation and the sequelae seen in *C. trachomatis* infections of the eye and reproductive tract. Specific toxins are not yet identified in chlamydiae.

Strain Classification

Antigenicity, Genetic or Molecular

Chlamydophila psittaci includes 8 known serovars (serotypes) (Table 24.1) designated A to F, M56, and WC (5, 8, 103). Of the 8 known serotypes in the species *C. psittaci*, 6 are known to naturally infect birds. These serotypes are distinct from those associated with chlamydiosis in mammals. Each avian serotype ap-

Table 24.1.   *Chlamydophila psittaci* serotypes.

Serotype	Representative chlamydial strain	Host association
A	VS1	Psittacine
B	CP3	Pigeons, doves
C	GR9	Ducks, geese
D	NJ1	Turkeys
E	MN	Pigeons, turkeys
F	VS225	Psittacine
M56	M56	Muskrat, snowshoe hare
WC	WC	Cattle

pears to be associated with a different group or order of birds (8, 103). Serovar A is endemic among psittacine birds and causes sporadic zoonotic disease in pet bird owners. Serovar B is endemic in pigeons but also has been isolated from other bird species. Serovar B strains are potentially hazardous to pigeon fanciers, although these strains seem to be less pathogenic to humans in comparison with serovar A strains. Water fowl most frequently seem to be infected with serovar C strains, although serovar C has also been isolated from a turkey (CT1) and a partridge (Par1). Serovar D is highly virulent and is often associated with turkeys but has also been isolated from egrets and seagulls. Veterinarians and poultry workers are especially at risk of becoming infected with serovar D strains. Serovar E (also known as Cal-10, MP, or MN) was first isolated during an outbreak of pneumonia in humans during the early 1930s (28). Later on, serovar E isolates were obtained from a variety of bird species including ducks, pigeons, ostriches, and rheas. Serovar F is represented by the psittacine isolate VS225. The M56 serovar was isolated during an outbreak in muskrats and hares (85). The WC serovar was isolated during an outbreak of enteritis in cattle (71).

All Chlamydiaceae are recognized by monoclonal antibodies (MAbs) that detect the LPS αKdo $(2 \rightarrow 8)$ -αKdo- $(2 \rightarrow 4)$ -αKdo. A multiplex-PCR test that targets the MOMP gene, tRNA-gly, and 23S rRNA also recognizes all Chlamydiaceae (25). *Chlamydia* species have a common antigenic epitope in variable segment 4 of the MOMP: NPTI, TLNPTI, LNPTIA, or LNPTI. Monoclonal antibodies should recognize this epitope in *Chlamydia*, to the exclusion of *Chlamydophila*. However, DNA sequencing is the most reliable way to distinguish *Chlamydia* and *Chlamydophila*. Sequencing of the PCR amplified Chlamydiaceae 16S–23S rRNA intergenic spacer allows the identification of Chlamydiaceae genera (25).

Species within *Chlamydia* and *Chlamydophila* are distinguished by either serology, restriction fragment length polymorphism (RFLP), or at least partial DNA sequence analysis of any one of 8 genetic loci: MOMP, GroEL, 60 kDa cysteine-rich protein, small cysteine-rich lipoprotein, KDO-transferase, 16S rRNA, 23S rRNA, or the 16S–23S intergenic spacer (19). The 8 known *C. psittaci* serovars (A to F, M56, and WC) can be distinguished by use of a panel of serovar-specific monoclonal antibodies in a micro-immunofluorescence test (5, 8). However,

serotyping can be performed only in specialized laboratories because serovar-specific MAbs are not commercially available. Genotyping by *AluI* restriction fragment length polymorphism (RFLP) analysis of the *ompA* gene, encoding the MOMP, was introduced in 1995 (83). RFLP analysis of the *ompA* gene of all known *C. psittaci* serovars revealed corresponding restriction patterns or genotypes (5, 96). More recently, *ompA* genotyping by real-time PCR using genotype-specific probes has been described, allowing the detection of an additional variant described as genotype E/B (29). Genotyping of avian *C. psittaci* strains is very convenient, as it is a rapid, powerful technique that can be used directly on clinical samples. The method of choice will depend on the laboratory, as either analysis can be used to classify the avian *C. psittaci* isolates.

Pathogenicity

Based on natural pathogenicity for domestic fowl, strains of *C. psittaci* isolated from birds fall into two general categories: 1) Highly virulent strains that cause acute epidemics in which 5–30% of affected birds die and 2) less virulent strains that cause slowly progressive epidemics. Strains of both high and low virulence appear to have equal ability to spread rapidly through a flock, as evidenced by serologic test results. Highly virulent strains are isolated most often from turkeys and occasionally from clinically normal wild birds. The isolates serotyped from some of the earlier outbreaks with high mortality have been of serotype D (8, 105). These strains are also labeled "toxigenic," because in natural and experimental hosts they produce rapidly fatal disease with lesions characterized by extensive vascular congestion and inflammation of vital organs. Toxigenic strains have a broad spectrum of pathogenicity for laboratory animals and can cause serious human infections (some fatal) in poultry handlers and laboratory research workers. Strains of low virulence cause slowly progressive epidemics with a mortality rate of less than 5% when uncomplicated by secondary bacterial or parasitic infection. Strains of this category are routinely isolated from pigeons and ducks and occasionally from turkeys, sparrows, and other wild birds. The turkey isolates from outbreaks with low mortality have been of serotype B or E. Birds infected with these strains usually do not develop the severe vascular damage typical in birds infected with the virulent toxigenic strains, nor do they have the severe clinical signs (89).

Chlamydiosis in pigeons, ducks, and some psittacine birds often is accompanied by concurrent infection with salmonellae. In such cases, the mortality rate among birds is high, and chlamydiae are shed in very large numbers; susceptible hosts in the immediate environment of the infected birds are exposed to doses that can result in clinical disease.

Developmental Cycle

A unique biphasic developmental cycle in which chlamydiae alternate between the infectious elementary body (EB) and the vegetative reticulate body (RB) distinguishes chlamydiae from other intracellular bacteria. The EB is metabolically inert and resistant to the hostile extracellular environment, whereas the RB divides intracellularly and cannot survive outside the host cell.
24.4. Buffalo green monkey (BGM) cell culture, 1 hour after inoculation with the *C. psittaci* Texas Turkey serovar D strain showing an elementary body (EB) attached to the side of a host cell microvillus.
24.5. BGM cell culture, 1 hour after inoculation with the *C. psittaci* Texas Turkey serovar D strain showing an internalized elementary body (EB) within a membrane-lined vacuole. Notice the mitochondria (M) in the vicinity of the inclusion.

The initial event in the infectious process begins with attachment of *C. psittaci* EBs to microvilli at the apical surface of a susceptible columnar epithelial cell (51) (Fig. 24.4). The EB travels down the microvillus and locates in indentions of the eukaryotic plasma membrane, some of which resemble coated pits. The bases of micropilli represent areas of active transport of extracellular materials into the cells and, therefore, might assist rapid and efficient entry of EBs. After 1–3 hours, the EBs are internalized in invaginations of the plasma membrane (Fig. 24.5). Uptake of *C. psittaci* is an endocytic mechanism, involving microfilament-dependent and/or independent processes. The *C. psittaci*-containing endocytic vesicles or vacuoles escape interaction with
24.6. BGM cell culture, 18 hours after inoculation with the *C. psittaci* 89/1326 serovar B strain isolated from the spleen of a pigeon. Note the chlamydial vacuole near the nucleus (N) of the BGM cell with dividing reticulate bodies (RB) characterized by the "hour-glass" profiles (H).
24.7. BGM cell culture, 52 hours after inoculation with the *C. psittaci* 92/1293 serovar D strain, isolated from the lungs, the spleen, and the cloaca of turkeys. Note the large inclusion and the elementary bodies (EB) apparently "escaping" from the inclusion. Also notice the mitochondria (M) lining the inclusion.

lysosomes and proceed in about 8–12 hours to the cbn nuclear area, where EBs are converted to RBs. Conversion to RBs primarily involves reduction of disulfide bond cross-linking among the outer membrane proteins altering the EB cell wall. Synthesis of DNA, RNA, and proteins is initiated, permitting growth and binary fission of the RBs. Binary fission is characterized by the appearance of typical "hour-glass" profiles inside the vacuole (Fig. 24.6). The enlarging vacuole is also termed an "inclusion." *C. psittaci* microorganisms do not always remain within the inclusion throughout their intracellular development. In some cases and in apparent correlation with high pathogenicity of strains, the inclusion membrane seems to degrade during the active multiplication, liberating the bacteria into the cytoplasm of the host cell (97). About 30 hours after internalization of the EB, the first RBs are reorganized into newly formed EBs. At about 48–50 hours, the developing chlamydial inclusion may contain anywhere from 100–500 progeny, depending on the characteristics of the *C. psittaci* strain (Fig. 24.7). With most *C. psittaci* strains, the host cell has undergone severe degenerative changes, and microorganisms are released by lysis (Fig. 24.8). Exocytosis of the inclusion, followed by a "healing" or closing of the open-cavern structures where the inclusion had existed, has been reported (90). Persistent infections may occur with EBs remaining inside the host cell cytoplasm.

Pathobiology and Epidemiology

Incidence and Distribution

Avian chlamydiosis occurs worldwide, with the incidence and distribution varying greatly with the species of bird and the serotype of the chlamydial organism. Psittacine birds harbor primarily one serotype of chlamydia that is endemic, and many psittacine birds are chronically infected. When under stress,
24.8 BGM cell culture, 50 hours after inoculation with the *C. psittaci* Texas turkey serovar D strain showing lysis of an infected BGM cell. Note the presence of reticulate bodies (RB), intermediate bodies (IB), and elementary bodies (EB).

chronically infected birds may become clinically ill or shed the organism. At these times, humans may become infected. The economic losses and the human infections usually follow a sporadic pattern; however, there are reports of outbreaks following the introduction of infected birds into pet stores or into homes. In recent years, antibiotics have been used extensively to control the spread of the disease in birds and to reduce the risk to humans. The pattern in pigeons appears to be similar, with at least two different serotypes being involved.

The disease pattern in turkeys appears to be changing. His-

torically, most outbreaks were explosive and occurred in free-ranging birds, but outbreaks now have been seen in confinement birds (104). Serotype D (virulent turkey) is usually found when death losses are high, whereas serotype B (pigeon) is less virulent (8). In these outbreaks chlamydia was usually thought to be introduced from the outside. However, recent studies on turkeys in Belgium and France showed that low virulent strains (serotypes A, B, E, and F) are widely distributed in commercial turkeys and may be endemic. Serology indicated that chlamydial activity is common, even though clinical signs are not seen. The chlamydial activity was usually seen prior to or during avian pneumovirus (APV) or ornithobacterium rhinotracheale (ORT) infections, indicating that chlamydia is part of the respiratory disease complex (92).

Information on the incidence and epidemiology of chlamydia in domestic ducks is limited. In the United States, it has not been a significant problem. In Europe, there have been a number of outbreaks, some of which have occurred in recent years (15, 57). Isolates from only a few European outbreaks have been serotyped, and these all have been of serotype C (103). This serotype also has been recovered from geese and swans.

Chlamydial strains from mammals are not a problem for poultry. Recent advances in serotyping using monoclonal antibodies and in strain identification using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) demonstrate that the strains occurring naturally in birds are distinct from those in mammals (7, 8). Attempts to infect birds with mammalian strains usually result in aborted or asymptomatic infections (53, 89). Avian strains will infect humans and may produce a severe pneumonia; however, secondary spread among humans rarely occurs (84).

Natural and Experimental Hosts

In addition to the naturally occurring chlamydial infections in domesticated birds, chlamydiae or chlamydial antibodies have been found in more than 400 wild avian species (1, 54). Common reservoirs of chlamydiae in the United States include wild and feral birds such as sea gulls, ducks, herons, egrets, pigeons, blackbirds, grackles, house sparrows, and killdeer, all of which freely intermingle with domestic birds. Highly virulent strains of *C. psittaci* can be carried by and excreted in large numbers by sea gulls and egrets without any apparent effect on these hosts.

Experimental hosts of avian chlamydiae can include virtually any species of bird, but it is thought that species vary in susceptibility. The length of time shedding and the numbers of chlamydiae shed may vary considerably depending upon the avian species. Antibody production as a consequence of a chlamydial infection also may vary.

Mammalian laboratory hosts used for avian chlamydiae are principally mice and occasionally guinea pigs. Both of these hosts can have naturally occurring chlamydial infections. Investigators using these animals should determine the chlamydial status of the breeding stock. Rabbits are refractory to clinical disease caused by avian chlamydiae, but they may be used to produce polyclonal antibodies (105).

Younger domestic birds generally are more susceptible than older birds to infection, clinical disease, and mortality. Infection in old turkeys, such as spent breeder hens, can go unnoticed unless birds are subjected to stressful conditions such as shipment to market on crowded trucks. Turkey toms may have a higher mortality rate than turkey hens.

Transmission, Carriers, and Vectors

The development of methods to readily serotype *C. psittaci* and to genetically characterize isolates is increasing the understanding of the epidemiology of the disease in birds. It is apparent that certain serovars of *C. psittaci* are usually associated with specific types of birds (e.g., serovar A with psittacine birds) and that some of these serovars have a parasite-like relationship with the host. That is, infection with *C. psittaci* will result in an inapparently infected carrier that under certain conditions such as stress will shed the organism. *C. psittaci* carrier status has been recognized in pigeons and psittacine birds and likely occurs with other birds. Shed chlamydiae recovered from psittacine birds is almost always serovar A and, from pigeons and doves, serovar B or E (8, 21, 103).

In turkeys, serovars associated with disease are not endemic but are introduced from feral birds. Isolates from large chlamydial outbreaks in turkeys are generally serovar B or serovar D (8, 103). Serovar B is common in pigeons and has been isolated from clinically normal pigeons and recovered from a number of turkey outbreaks with low mortality. Serovar D, usually found in high mortality outbreaks, has never been consistently associated with any avian species but turkeys; however, because of the methods used to raise turkeys and the time between outbreaks, it is doubtful that it is endemic in the turkey population. Most likely, another species of bird serves as the reservoir and transmission to turkeys occurs during commingling. The source or reservoir of serovar D is not known.

Chlamydial isolates of serovar C have been isolated from ducks and swans in Europe (100). Too few isolates have been serotyped to determine whether it is primarily a strain from ducks and other anseriformes. It is notable that this serovar has not been identified from other birds. In recent years, a few chlamydial isolates have been made from fatal cases in ratites. These isolates usually have been of serovar E, indicating that the ratites may be contracting it from pigeons or doves (4, 35).

Transmission of chlamydiae is probably by inhalation or ingestion of contaminated material. Large numbers of chlamydiae can be found in respiratory tract exudate and fecal material of infected birds. The importance of the respiratory exudate has become more apparent: In turkeys, the lateral nasal glands become infected early and remain infected for more than 60 days (89). Choanal/oropharyngeal swabs are more consistent for isolation of the agent than fecal swabs, especially during early stages of infection (6). Direct aerosol transmission through aerosolization of respiratory exudate must be considered as the primary method of transmission during outbreaks.

The role of arthropods in the transmission of chlamydiae is uncertain. Mites from turkey nests can contain chlamydiae (22), and during an epidemic in turkeys in South Carolina, simulid flies were suspected as a possible method of transfer (70).

Vertical transmission through the egg has been described for ducks, chickens, turkeys, and a number of wild birds (58, 100, 106). Its occurrence appears to be fairly low; however, it could serve as a method of introducing chlamydia into a flock.

Incubation Period, Clinical Signs, Morbidity and Mortality, Pathology and Pathogenesis
Turkeys

Page *et al.* (72) examined the pathogenesis of a *C. psittaci* infection in commercial turkeys after inoculation by aerosol or by the oral route with serovar D strain (8). Page determined the quantitative distribution of the organisms in tissues by isolation. Vanrompay *et al.* (98) studied the pathogenesis of *C. psittaci* serovars A, B, and D strains in specific-pathogen-free turkeys by immunodetection, which allowed the precise determination of the tissue and cell tropism. In this study, turkeys were aerosol infected as this most likely represents the natural route of infection as demonstrated by Page (72). From these studies, the following pathogenic sequence of events can be deduced for all three serovars investigated. In turkeys infected by aerosol, the primary site of replication is the upper respiratory tract, where epithelial cells become infected. Subsequently, epithelial cells of the lower respiratory tract and macrophages throughout the respiratory tract become infected. Then, intense replication occurs in the respiratory tract. At the same time, chlamydiae can be demonstrated in plasma and monocytes, indicating septicemia, and chlamydiae appear in epithelial cells and macrophages of various tissues throughout the body.

In turkeys, an experimental infection with a serovar B strain induced much milder clinical signs and lesions than infection with serovar A or D strains (101). Serovar B strain had a longer incubation period, took longer to reach maximum titers in the tissues, and had shorter periods during which the organism was found in the tissues.

The incubation period of chlamydiosis in naturally infected birds varies, depending upon the number of chlamydiae inhaled and the virulence or pathogenicity of the infecting strain for that host species. Experimentally, definitive disease signs in young turkeys receiving a virulent strain may be evident in 5–10 days. In birds naturally exposed to smaller doses or in older birds, the period may be longer. Strains of lower virulence, which cause less severe signs, may have longer incubation periods. Clinical signs may not be noticeable until 2–8 weeks after exposure.

Signs of chlamydiosis in turkeys infected with virulent strains are cachexia, anorexia, elevated body temperature, conjunctivitis, and respiratory distress. The birds excrete yellow-green, gelatinous droppings. Egg production of severely affected hens declines rapidly to 10–20% and may temporarily cease or remain at a very low rate until complete recovery. Disease signs in a flock infected with strains of low virulence are usually anorexia and loose, green droppings in some birds, with less effect on egg production.

At the peak of disease in a flock infected with a virulent strain, 50–80% of the birds will show clinical signs, and morbidity from less virulent strains is only 5–20%. Mortality caused by virulent chlamydia ranges from 10–30% and is only 1–4% with less virulent strains.

The less virulent strains cause gross lesions, which are similar to those caused by virulent strains, only less severe and extensive. In overwhelming infections with virulent strains, lungs show diffuse congestion, and the pleural cavity may contain fibrinous exudate. In fatal cases, a dark transudate may fill the thoracic cavity. The pericardial membrane is thickened, congested, and coated with fibrinous exudate. The heart may be enlarged, and its surface may be covered with thick fibrin plaques or encrusted with yellowish, flaky exudate. Severe damage to the lungs and heart undoubtedly is a major cause of death. The liver is enlarged and discolored and may be coated with thick fibrin. Air sacs are thickened and heavily coated with fibrinous exudate. The spleen is enlarged, dark, and soft and may be covered with gray-white spots representing areas of focal cellular proliferation. The peritoneal serosa and mesentery show vascular congestion and may be coated with foamy, white fibrinous exudate. All of these exudates contain large numbers of mononuclear cells in which numerous micro colonies of chlamydial RBs may be seen. Fibrinous exudates, found on all organs and tissues of the thoracic and peritoneal cavities, reflect vascular damage as well as increasing inflammatory response caused by the continued multiplication of the organisms.

In birds that survive infection with a strain of low virulence, the lungs may not be seriously affected. However, multiplication of organisms on the epicardium may result in the formation of one or more fibrin plaques.

Histopathologic changes in conventional turkeys of various ages injected intratracheally with the virulent Texas turkey (TT) strain of *C. psittaci* were first described by Beasley *et al.* (14). They observed both necrotizing and proliferative changes comparable to those caused by other chlamydial strains in other species (with the exception of focal necrosis of the liver, which is prominent in parrots and mice). Specific cellular changes and corresponding organ damage were decidedly more severe and extensive in young turkeys than in older ones. A majority of the birds examined had tracheitis characterized by extensive infiltration of mononuclear cells, lymphocytes, and heterophils in the lamina propria and submucosa. Cilia were absent in severely affected areas. This extensive tracheal damage is not necessarily characteristic of naturally infected birds and may be a result of intratracheal inoculation of large numbers of organisms. Epithelioid pneumonitis in varying degrees was found in 80–100% of 10-week-old birds but less often (10–20%) in mature birds. Lungs of severely affected birds were congested and had extensive infiltration of the tertiary bronchi and respiratory tubules with large mononuclear cells and fibrin. There was necrosis of individual cells and large areas of tissue; the parenchyma and stroma were equally affected. Fibrinous to fibrino-purulent inflammatory exudates were present on respiratory and peritoneal surfaces and on the epicardium in a majority of infected turkeys. The pericardium and epicardium were thickened by swelling of congested vessels and an inflammatory exudate containing fibrin, large mononuclear cells, and varying numbers of lymphocytes and heterophils. Myocarditis was observed in more than half the infected birds, but arteritis was present in only 8%. Hepatitis was present in more than 90% of the birds,

and in severely affected individuals, there was a diffuse dilation of sinusoids with infiltration of mononuclear cells, lymphocytes, and heterophils. Proliferated and swollen Kupffer cells were filled with debris, and a yellowish pigment thought to be hemosiderin. Necrotic hepatic cells were scattered throughout the organ with a few foci of necrosis. Acutely sick turkeys had a catarrhal enteritis. Spleens of a majority of birds were altered, with cellular proliferation and necrosis causing an enlarged and mottled appearance, which was more marked in younger than in older birds.

The organisms also caused orchitis and epididymitis, seeming to have an affinity for the active germinal epithelium (13). Fibrin and inflammatory cells appeared in association with the desquamated and necrotic epithelium, filling the seminiferous tubules with eosinophilic exudate. It was also observed that often the immediate cause of death in adult males was a rupture of testicular blood vessels followed by massive internal bleeding. The brains of 6 infected birds examined were without significant changes.

Vanrompay *et al.* (99) examined histopathologic changes in four groups of 20 specific-pathogen-free (SPF) turkeys, kept in isolation units and inoculated by aerosol. Turkeys were experimentally infected with strain 84/55 (*C. psittaci* serovar A), isolated from a parakeet, strain 92.1293 from a turkey (*C. psittaci* serovar D), the Texas Turkey strain (*C. psittaci* serovar D), or strain 89/1326 (*C. psittaci* serovar B) from a pigeon. All four strains of *C. psittaci* proved to be pathogenic for SPF turkeys. Turkeys showed conjunctivitis, sinusitis, rhinitis, keratitis, pneumonia, airsacculitis (Fig. 24.9A), pericarditis (Fig. 24.9B), hepatomegaly (Fig. 24.9C), splenomegaly, enteritis, congestion of the kidneys, and congestion of the ovaries or testes. Histopathologically, there were epithelial erosions and fibrin deposit in the conjunctivae (Fig. 24.10A), corneal ulceration, bronchopneumonia (Fig. 24.10B), fibrinous necrotizing airsacculitis (Fig. 24.10C), fibrinous pericarditis, interstitial nephritis, peritonitis, and catarrhal enteritis. The type and distribution of the lesions was similar for serovars A and D. The lesions produced after the serovar A infection, however, appeared more severe. For serovar B, in comparison with both other serovars, no lesions were observed in the small intestine, the pancreas, ovary, and testis.

Controlled dual infections in SPF turkeys demonstrated the pathogenic interplay between *C. psittaci*, APV, and *E. coli*. *E. coli* is a predisposing factor for the outcome of a *C. psittaci* infection. In its turn, *E. coli* can increase the severity of a *C. psittaci* infection and can reactivate a latent *C. psittaci* infection (91). An APV infection during the acute phase of a *C. psittaci* infection aggravates the severity of clinical signs, macroscopic lesions, pharyngeal APV excretion, and histological tracheal lesions. However, no clear interaction was established after APV infection in latently *C. psittaci*-infected turkeys (93).

Ducks and Geese
Chlamydiosis in domestic ducks is not an important disease in the United States, but it is important both economically and as a public health hazard in Europe. Chlamydiosis in ducks is usually a severe, debilitating, often fatal disease in which young ducks develop trembling, imbalanced gait, and cachexia. They become anorexic with green, watery intestinal contents. They develop a serous to purulent discharge from the eyes and nostrils causing the feathers on the head to become encrusted with exudate. As the disease progresses, the ducks become emaciated and die in convulsions. Morbidity ranges from 10–80%, and mortality varies from 0–30% depending on age and the presence of concurrent infection with salmonellae (87).

In recent years a number of outbreaks occurred in ducks in Europe and Australia in which the clinical signs in some outbreaks were minimal or absent (11, 15, 50, 57, 59, 66). Deaths and/or clinical signs were associated with stress of handling or with infection by other pathogens. Despite this change in pathogenicity, chlamydia in ducks has remained a public health problem.

Incidental to studies of chlamydiosis in ducks, several investigators have observed the disease in geese and have isolated *C. psittaci* from diseased tissues (87). Clinical disease and necropsy findings were similar to those in ducks.

Pigeons
The incubation period for chlamydiosis in pigeons is not known. Infection is endemic and is believed to be perpetuated primarily by a parent-to-nestling transmission cycle (20, 62).

Signs of uncomplicated chlamydiosis in pigeons are variable, but those that develop acute disease are anorexic, unthrifty, and diarrhetic. Some develop conjunctivitis, swollen eyelids, and rhinitis (Fig. 24.11). Respiratory difficulty is accompanied by rattling sounds. As disease progresses, birds become weak and emaciated. Recovered birds become carriers without signs of disease. Some birds progress through an infection showing no signs or, at the most, transient diarrhea before becoming carriers. Salmonellosis or trichomoniasis exacerbates the illness in chlamydia-infected carrier birds, inducing signs and lesions of acute disease. Serologic surveys indicate that infection rates in pigeons of 30–90%, and active infection rates, as measured by isolation, of 20% are common (61, 74, 82).

Gross lesions of uncomplicated chlamydiosis in pigeons are fibrinous exudates on thickened air sacs, the peritoneal serosa, and occasionally the epicardium. The liver is usually swollen, soft, and discolored. The spleen may be enlarged, soft, and dark. Greater than normal amounts of urates are seen in cloacal contents if catarrhal enteritis occurs. In less severe infections, only the liver or air sacs are involved. Some heavily infected shedders have no lesions (72, 74).

Chickens
Epidemiologic and laboratory evidence indicates that chickens are relatively resistant to disease caused by *C. psittaci*. Acute infection progresses to disease and mortality only in young birds, and the incidence of actual epidemics is very low. Experimentally, even young birds are resistant to many strains of *C. psittaci*. In acute cases, chickens have fibrinous pericarditis and hepatomegaly. Most natural infections in chickens are inapparent and transient; however, clinical cases with conjunctivitis, pericarditis, perihepatitis, and airsacculitis have been reported (10, 12).
24.11. Pigeons with no signs of chlamydial infection (top); moderate chlamydial conjunctivitis (middle); and severe chlamydial conjunctivitis (bottom).

Pheasants, Quail, and Partridges

Chlamydiosis has been reported in farm-raised pheasants, quail, and partridges. The clinical signs and lesions are similar to those seen in other birds. Morbidity and mortality can be very high, especially in young birds. Human infections have been reported (23, 40, 61, 87).

Immunity

Immunity to chlamydia is generally poor and short-lived. As birds become older, however, they become more resistant to clinical disease, even though infection may occur. Indeed, some birds, notably pigeons, are refractory to disease-producing infection even with highly virulent strains.

In turkeys, a moderate degree of resistance to organ damage is present by 15 weeks of age (13), and this resistence increases with further aging. The role active immunity has in preventing reinfection of naturally or experimentally infected turkeys has not been determined. The progress of infection initiated by an oral dose of chlamydiae and then spread by natural means through a group of 19 turkeys was followed by isolation attempts from blood and clinical observations (72). At varying times over a period of 47 days, each bird developed chlamydemia, hyperthermia, and mild anorexia. The chlamydemia lasted up to 10 days in each bird but was followed by clinical normalcy and apparent resistance to further bloodstream infection in spite of environmental contamination sufficient to infect all unexposed birds.

In ducks, resistance and immunity have not been sufficiently studied. Pigeons are apparently resistant to many avian strains of *C. psittaci*, even the highly toxigenic ones, but they are very susceptible to isolates from pigeons and sparrows (61, 71).

Despite extensive studies, the important host defense mechanisms against *Chlamydia* remain incompletely defined. An ongoing controversy is the relative contribution of humoral versus cell-mediated immunity in the host resistance against chlamydiae. What is known is primarily from studies in guinea pigs and mice.

In guinea pigs, both humoral immunity and cell-mediated immunity are essential for clearing the infection and for resistance against reinfection with the *C. psittaci* guinea pig inclusion conjunctivitis (GPIC) strain, currently classified as *Chlamydophila caviae* (76, 78, 79). However, in the murine system, T-cell-mediated immunity is evidently the critical immune mechanism for controlling *C. trachomatis* genital infection (52, 75, 77, 88).

Diagnosis

The methods used to diagnose *C. psittaci* infections are 1) direct visualization of the agent in clinical specimens by staining techniques, 2) isolation of the agent from clinical specimens followed by identification of the isolated agent, 3) detection of specific chlamydial antigens or genes in clinical specimens, and 4) serological tests in which antibodies are measured, preferably by demonstrating rising titers in paired acute and convalescent sera.

Specimen Collection and Direct Examination

Samples must be collected aseptically, especially for isolation, as contaminant bacteria can interfere with test results. At necropsy, the tissues of choice are air sacs, spleen, pericardium, heart, liver, and kidney. From live birds, choanal/oropharyngeal swabs and cloacal swabs are the first choices (6, 9).

If the samples are for isolation, proper handling is necessary to prevent loss of infectivity of chlamydiae during shipment and

handling. A transport medium consisting of sucrose-phosphate-glutamate (SPG) developed for *Rickettsia* is satisfactory for chlamydiae. The medium as recommended for chlamydiae consists of SPG buffer (sucrose 74.6 g/liter; KH_2PO_4, 0.512 g/liter; K_2HPO_4, 1.237 g/liter; and L-glutamic acid 0.721 g/liter) and can be autoclaved or filtered (86). To this is added 10% fetal calf serum and antibiotics. The transport media can be used as a diluent for freezing of chlamydia. The samples should not be frozen if they can be processed in 2–3 days.

Direct Visualization by Staining

Chlamydiae can be detected in smears and paraffin-embedded tissue sections by a number of techniques. The Gimenez, modified Gimenez (PVK stain), and the Giemsa staining techniques are commonly used (2, 3). The chlamydial EBs in this test will appear red against a green background.

Immunohistochemical staining is another method for detection of chlamydiae in cytological and histological preparations. This technique is more sensitive than histochemical staining, but interpretation of the results requires experience. The use of immunohistochemical staining of formalin-fixed sections is gaining popularity.

Isolation

Isolation attempts may be made by the inoculation of properly processed specimens onto cell culture monolayers, into the yolk sac of embryonated chicken eggs, or into mice.

Cell Cultures

Cell cultures are the most convenient method for isolating the avian strains of *C. psittaci*. McCoy, HeLa, Vero, L929, and BGM are the most commonly used cell lines, although a number of other cell cultures can be used. Standard tissue culture media and procedures, with a few modifications, are used. The laboratory equipment and supplies must be suitable to 1) stain and examine for chlamydial inclusions by direct immunofluorescence (IF) or other appropriate staining techniques, 2) permit centrifugation of the inoculum into the cell monolayer at 37°C or as near as possible, 3) permit staining and examination at two to three times during a passage, 4) permit blind passage at 3–4 days, and 5) provide protection of humans against possible infection. Small flat bottom vials (1 dram shell vials) or 24-well multi-well culture plates with 12 mm diameter glass cover slips will meet these requirements and are often used (2, 3, 43).

Suppression of cell division may be required to increase availability of nutrients for the growth of the chlamydiae and to permit longer observation of the infected cell cultures. The host cells can be suppressed by irradiation or by cytotoxic chemicals. Cytotoxic chemicals include 5-iodo-2-deoxygiodine, cytochalasin B, cycloheximide, and emetine hydrochloride (47). Cycloheximide is the most commonly used and is added to medium at a rate of 0.5–2.0 mg/ml at the time of inoculation of the monolayer. The effects of these drugs on replication of the chlamydiae can be variable; however, they appear to have no effect or a possible enhancing effect on the growth of the avian chlamydial strains.

Centrifugation of the inoculum onto the cell monolayer is often used to enhance the rate of infection. Centrifugation is routinely done at 500–1500 / g for 30–90 minutes. Temperatures near 37°C are preferred.

Tissue culture monolayers are fixed (with methyl alcohol, acetone, or an acetone-methyl alcohol mixture, depending on the staining technique and the cell culture vessel) and then stained and examined for inclusions on day 2 or 3 post-infection. The preferred method to demonstrate the chlamydial inclusion is the direct or indirect immunofluorescence staining using monoclonal antibodies against the genus-specific epitope on the chlamydial LPS or the MOMP (2, 3). The inclusion can also be demonstrated by cytological staining techniques, especially Gimenez, Stamp, Macchiavello's or Giemsa.

Chicken Embryo Inoculation

Fertile chicken eggs incubated 6 or 7 days at 39°C are inoculated with 0.2–0.5 ml/embryo via the yolk sac. Eggs for this use must be from chickens that are chlamydia free and that are not consuming chlamydiastatic antibiotics in their feed. Vascular congestion in the yolk sac is the predominant lesion seen in embryos dying from *C. psittaci* infection. The yolk sacs are harvested from embryos that die from 3–10 days after inoculation. If no embryos die, one or two blind passages should be performed. Yolk sac touch impressions are prepared for cytological staining or for direct or indirect immunofluorescence staining. The yolk sac harvest can also be used to inoculate onto tissue culture monolayers followed by identification of the chlamydial inclusions by the appropriate cytological or immunofluorescence stainings.

Detection of Specific Chlamydial Antigens

Tests that detect chlamydial antigen, as opposed to viable chlamydiae, have several advantages over isolation techniques. Antigen detection systems identify both viable and nonviable chlamydiae as well as soluble antigens in secretions or excretions. At present, direct immunofluorescence (IF), enzyme-linked immunosorbent assay (ELISA), and immunochromatography (IC) are available as rapid diagnostic tests for demonstrating chlamydial antigen. Most available tests use a monoclonal antibody (MAb) against the genus-specific epitope on the chlamydial LPS or against the species-specific epitope on the chlamydial MOMP and were originally developed for the detection of *C. trachomatis* or *C. pneumoniae* in human specimens. Some of these LPS-based tests have been evaluated for the detection of *C. psittaci* in avian specimens (16, 30, 55, 56, 102). The following conclusions can be drawn from these studies. The current rapid antigen detection methods are of relatively low cost and easy to perform, do not require rigorous maintenance of refrigeration for specimen shipment, and provide results much faster than culture. Of the antigen-detection tests evaluated in birds, at present the IMAGEN™ IF test seems to be the most specific and sensitive direct antigen detection test. However, IF is a diagnostic procedure with a sensitivity and specificity depending on the expertise of the observer. In general, the current generation of rapid diagnostic tests is not recommended for demonstrating *C. psittaci* in the individual bird because of shortcomings in sensitivity or specificity.

Detection of Specific Chlamydial Genes

C. psittaci-specific genes can be detected by both amplified and nonamplified nucleic acid-based detection methods. The polymerase chain reaction (PCR), as the most commonly used amplified nucleic acid-based detection method, focuses on the amplification of a portion of the *ompA* gene encoding the chlamydial MOMP or the 16S rRNA gene (26, 48, 49, 60).

Advantages of PCR for diagnosing chlamydiosis in birds are 1) easy, noninvasive sample collection methods, 2) simple transport and storage requirements, as viable chlamydiae are not needed, 3) avoidance of taking multiple samples as sometimes is recommended when using direct antigen detection tests, for instance ELISA, 4) rapid results, 5) high sensitivity, and 6) high specificity. In addition, production of targeted DNA fragments permits restriction endonuclease mapping of polymorphisms of the amplification product, thus facilitating species and strain differentiation (5, 24, 83, 96).

The main disadvantage of PCR is the risk of cross-contamination, necessitating strict operating procedures. False-negatives can occur through nucleic acid mutations in genes used as detection markers. Furthermore, positive PCR may sometimes reflect a carrier status. In those cases, quantitative PCR or serology may be helpful to confirm the clinical diagnosis of chlamydiosis.

Avian *C. psittaci* DNA amplification assays are performed only in specialized laboratories. Currently, PCR is used only in birds that are highly valued both monetarily and as companion animals. In the future, simplified cost-effective commercial PCR assays are likely to become available for routine chlamydial diagnosis in birds.

Serology

A diagnosis of chlamydiosis can be made by serology. This generally requires a four-fold increase in antibody titer on paired sera or a high number of positive titers in a flock. The complement fixation test is the standard and is used by most laboratories. Newer serological tests are available, some of which only detect IgM and are better indicators of current infection. Most of these tests require further evaluation by other laboratories before they can be recommended. For more information on the advantages of the various serological tests, the reader is referred to the following reviews and papers covering the tests (2, 3, 41).

Complement fixation (CF) is a widely used method for detecting anti-chlamydial antibodies. This is partly because the immunodominant carbohydrate-containing antigen of chlamydia readily induces complement-fixing antibodies. Such antibodies are no indication of immunity to reinfection with chlamydiae. They are useful, however, in detecting chlamydial infection, especially in a flock of birds. Generally, higher titers (≥64 in poultry) are indicative of a current or recent infection. If low titers are obtained, it may be necessary to retest in about 10–14 days to detect any change in titer. A 4-fold or greater increase is considered to be diagnostic of a current chlamydial infection.

The direct and modified direct complement fixation procedures are the most commonly used to detect antibody in birds (43, 44, 45, 46). Both are relatively sensitive and can be performed using antigen prepared from cell culture-propagated chlamydiae. The modified direct procedure involves the addition of fresh chicken sera to the complement. This increases the sensitivity of the CF procedure so that it can be used to test sera from avian species whose antibodies do not normally fix guinea pig complement (42, 44).

The latex agglutination (LA) and elementary body agglutination (EBA) methods were developed for use with psittacine bird sera. However, the LA test is useful for screening turkey serum for antibodies and for testing pigeon and dove sera (39). Its usefulness for testing sera of ducks and geese is not known. The LA method predominantly detects IgG but will detect IgM (38). Its main disadvantage is that it is not as sensitive as direct CF, which detects only IgG activity in avian serum (38), nor as sensitive as the more recently described elementary body agglutination (EBA) test, which detects only IgM activity (36, 37). The EBA test has been evaluated and is currently being used for detecting antibody activity in various types of birds.

The indirect micro-immunofluorescence (IMIF) and indirect immunofluorescence (IFI) tests have been used extensively for serotyping of *C. trachomatis* in humans and more recently for identifying whether an immune response in humans is to *C. trachomatis*, *C. pneumonia*, or *C. psittaci*. The principles of the tests are similar in that both are an indirect IF test: the IFI test detecting reactions to inclusions in infected cell culture and the IMIF test detecting the EBs attached to a microscope slide. A recent report compared these tests to the CF and the ELISA for measuring antibody in pigeon sera and found the IFI and IMIF tests to be highly specific and efficient (82). The tests are used in serotyping avian isolates (8, 103) and have potential as a serological test. Older serological methods that are not widely used (e.g., rapid plate [or slide] and capillary tube agglutination, indirect CF inhibition, passive hemagglutination, immunodiffusion, and others) are described elsewhere (41). Newer methods such as indirect ELISA and indirect IF are being used, but they need to be thoroughly researched and evaluated to ascertain their usefulness.

Differential Diagnosis

Suspected chlamydiosis may have to be differentiated from pasteurellosis, particularly in turkeys, in which some signs and lesions may be similar. Pasteurellosis can be ruled out by appropriate culture procedures. Because of some similar signs and lesions, mycoplasmosis may need to be ruled out in turkeys suspected of having chlamydiosis. That can be accomplished by culturing and serologic testing for mycoplasmosis. Colibacillosis may mimic chlamydiosis to some extent; it can be excluded by the use of the appropriate coliform culturing procedures. Avian influenza may have to be ruled out in suspected chlamydiosis by virus isolation attempts and by serologic testing.

Intervention Strategies

Management Procedures

Ideally birds should be reared in confinement without any contact with potentially contaminated equipment or premises. Contact with potential reservoirs or vectors such as wild and feral

birds should also be prevented. General sanitation must be practiced diligently. Movement of people should be restricted so that visitors do not have free access to premises holding birds. This is easier to accomplish if birds are confined in houses.

Vaccination

Despite considerable efforts to develop an effective chlamydial vaccine, there have not been significant advances toward this goal. Thus, commercial chlamydial vaccines are not yet available.

Protective immunity to Chlamydiaceae is believed to be effected primarily through the action of CD4+ T helper type 1 (TH1) lymphocytes, CD8+ T lymphocytes, mononuclear phagocytes, and cytokines secreted by these cells. In addition, the role of local antibodies in mucosal secretions is not to be underestimated. The only protective chlamydial antigen that has been unambiguously identified is the major outer membrane protein (MOMP). However, attempts at chlamydial vaccine development based on a subunit design using MOMP have generally failed, probably because the immunogens did not induce the protective cellular and humoral immune responses elicited by native bacterial epitopes. In light of the current knowledge on protective chlamydial immunity, plasmid DNA expressing the MOMP of an avian *C. psittaci* serovar A strain has been tested for its ability to raise a protective immune response in SPF turkeys against challenge with the same serovar A strain. Good priming of T cell memory and protection against lung infection was observed (94, 95). Further studies are required to define the immune mechanism(s) for the protection observed.

Treatment

Treatments for poultry and pet birds have been reviewed (84, 100). Turkeys should be treated with chlortetracycline (CTC) at a concentration of 400 g/ton of pelleted feed. Care must be taken so that heat produced during the pelleting process does not destroy CTC and lower the concentration below an effective level. The CTC-medicated feed must be given for 2 weeks and then replaced by nonmedicated feed for 2 days prior to the birds being slaughtered for meat for human consumption. Calcium supplement should not be added to CTC-medicated pellets because calcium ions chelate CTC and diminish its effectiveness. It is recommended that all turkeys on an infected premise be treated and sent for slaughter: Reinfection can occur readily because resident wild birds may continue to harbor chlamydiae, or the treatment outlined may not rid all birds of chlamydia. In areas where chlamydiosis has been a problem, turkeys and ducks being marketed should be examined by a veterinarian and 1–2% should be tested serologically. It may be advisable also to attempt isolations on tissues from birds randomly selected from those tested serologically.

Essentially the same treatment methods are used to treat other fowl infected with *C. psittaci*. In other birds, salmonellosis may often be a complicating factor so it may be necessary to use a combination of antibiotics.

Pigeons should be treated with CTC-medicated feed, but the treatment may not be effective in eliminating the carrier state. Alternating periods of treatment with periods of no treatment may eventually clear the chronic infection (61).

State and Federal Regulations

State regulatory agencies may impose quarantine on intrastate movement of diseased flocks and may require antibiotic treatment of the flock prior to slaughter. Because regulations may vary from state to state, the appropriate public health and/or animal health agencies should be consulted as necessary.

According to USDA regulations, movement of poultry, carcasses, or offal from any premise is prohibited where the existence of chlamydiosis has been proved by isolation of a chlamydial agent. The Animal and Plant Health Inspection Service of the USDA and the U.S. Department of Health and Human Services forbid interstate movement of birds from infected flocks, but there is no restriction on movement of eggs from such flocks.

III Fungal Diseases

Chapter 25
Fungal Infections

Bruce R. Charlton, R. P. Chin, and H. John Barnes

Introduction

Few fungal species are common pathogens in avian species, and these belong to the grouping of Eumycota (mycelial forms), as opposed to the Myxomycota (plasmodial forms) of the Kingdom Fungi. Fungi are unicellular or multicellular heterotrophic eukaryotes that derive nutrition by absorption; reproduce by asexual means, sexual means, or both; and possess cell walls. The Eumycota are composed of 5 phyla, or divisions. Four divisions are differentiated by the morphology of sexual structures; the fifth, Fungi Imperfecti (Deuteromycota), is distinguished by the lack of evidence of a sexual phase (1).

Classification of fungi historically has been based on morphologic characteristics of the sexual form (teleomorph) and asexual form (anamorph), with the teleomorph state assuming precedence in nomenclature, under the umbrella of Kingdom Plantae. The result is at times confusing, or even crosswise of common sense, as for instance, the nomenclature applied to aspergilli. The genus *Aspergillus* belongs to the division Deuteromycota, which is composed entirely of anamorphs; however, some aspergilli also have teleomorphs, and so by definition, they belong to a separate division and are assigned to a different genus as well. For example, *Aspergillus fisherianus* the anamorph becomes *Neosartorya fischerianus* the teleomorph by meitotic reproduction of ascospores (division Ascomycota). In addition, reproductive patterns aside, synonyms have been applied lavishly to certain fungal species and diseases over time. An attempt is made in this chapter to present taxonomy that conforms to the International Code of Botanical Nomenclature (Tokyo Code).

Mycoses are relatively uncommon diseases but are often devastating to the host supporting the fungal infection. The ability of fungi to infect animals is incidental to their maintenance. Propagation and dissemination occur as a result of their saprobic lifestyle; infection is a dead end, with the exception of dermatophytoses, because mycoses are not contagious.

The chapter is organized like the previous edition. The first focus is aspergillosis, followed by other fungal infections representing the less common mycoses. Aspergillosis is by far the most commonly encountered mycosis of birds and is an economically important respiratory disease of poultry. Candidiasis is the principal fungal infection of the digestive tract of poultry. Dermatophytosis affects the integument and is the only contagious and zoonotic mycosis. Some rare fungal infections of poultry are briefly discussed; histoplasmosis and cryptococcosis are notable as public health hazards.

Aspergillosis

Introduction

Definition and Synonyms

Aspergillosis is defined as a disease caused by infection with the genus *Aspergillus*, which is composed of approximately 600 species (103). Manifestations of aspergillosis depend upon which organs or systems are involved and whether infection is localized or disseminated. Aspergillosis in birds is usually confined to the lower pulmonary system with florid lesions in air sacs and lungs.

In young poultry, the disease is referred to as brooder pneumonia. Other synonyms for avian aspergillosis include fungal or mycotic pneumonia, pneumonomycosis, bronchomycosis, and colloquialisms such as "asper" and "air sac." Less common manifestations relate to infections of the eye, brain, skin, joints, and viscera.

Economic Significance

The financial cost of aspergillosis is most readily apparent in turkey production where the disease primarily affects grow-out flocks. In Iowa, between 1985 and 1994, aspergillosis was reported in a yearly average of 8.3% of flocks ranging in age from 13–18 weeks (76). Mortality attributed to aspergillosis averaged 4.5%, placing it as the second most costly disease with an esti-

mated yearly loss of $5,260 per affected flock in Iowa—$338,000 annually statewide. In 2000, Iowa ranked ninth in turkey production in the United States with roughly a 3% share of national production (10). Assuming an even distribution of aspergillosis across the country, mortality losses from the disease results in financial losses of more than $11 million yearly nationwide. However, losses from carcass condemnations typically far outstrip mortality losses.

Public Health Significance

Aspergillosis is not a zoonotic or contagious disease. Allergic pneumonitis can develop in those with frequent exposure to moldy hay, compost, or other forms of decaying organic matter in which *Aspergillus* and other allergenic organisms thrive. Severely immunocompromised individuals are at risk for developing opportunistic infections, including aspergillosis.

History

Molds, likely belonging to the genus *Aspergillus,* were described in wild birds in the early 1800s occurring in such species as the Scaup duck, jay, and swans (6, 92). The first time that an *Aspergillus* was described in a lesion, however, was in 1842 when Rayer and Montagne (86) identified *A. candidus* from the air sac of a bullfinch. *Aspergillus fumigatus,* the most frequently observed agent of avian aspergillosis, was first found in the lungs of a bustard (*Otis tardaga*) in 1863, and the species name was attributed to Fresenius (18). He also applied the term *aspergillosis* to this respiratory disease. Interestingly, early investigators believed that fungi found in lesions of avian species were growing saprophytically on "morbid products" in the body (6). Aspergillosis is common in turkey poults, having been described by Lignieres and Petit (61). Hinshaw (43) described the disease in adult turkeys.

Etiology

Classification

The principal agent causing aspergillosis in poultry is *Aspergillus fumigatus*. Isolation of *A. flavus* is less common. Other species rarely isolated include *A. terreus, A. glaucus, A. nidulans, A. niger, A. amstelodami,* and *A. nigrescens*. Both *A. fumigatus* and *A. flavus* lack a sexual stage and require only one classification scheme: division Deuteromycota, class Deuteromycetes, order Moniliales, family Moniliaceae, genus *Aspergillus*. Alternate classification schemes for the genus appear to be equally valid (85).

A. fumigatus *Fresenius 1850*

Colony Morphology
The organism grows rapidly on Sabouraud dextrose, Czapek's solution, or potato dextrose agar (25–37°C) with colonies having a diameter of approximately 3–4 cm in 7 days. The flat colonies are white at first and then bluish green as conidia begin to mature, especially near the center of the colony. As the colony matures, the conidial masses become gray-green, and the colony edge re-
25.1. Conidiophore with flask-shaped vesicle, phialides, and columnar mass of chains of conidia of *Aspergillus fumigatus.* ×250.

mains white. The colony surface varies slightly among isolates being either smooth and velvety to slightly floccose or folded. The colony reverse is usually colorless. The description presented here includes the most typical characteristics of clinical isolates, but variations occur in colony color, morphology, and growth rate (60).

Microscopic Morphology and Staining
Hyphae measure 3–7 μm in diameter, have parallel sides, are septate, and branch dichotomously. The conidiophores, spore-bearing branches of *A. fumigatus,* are smooth, colorless to light green near the vesicle, up to 300 μm in length, and 5–8 μm in diameter (Fig. 25.1). The conidiophore gradually enlarges distally to form a flask-shaped vesicle. The vesicle is 20–30 μm in diameter with a single series of phialides (conidiogenous cells) over the distal half. The phialides (6–8 μm in length) are arranged upward paralleling the axis of the conidiophore. A distinctive feature of *A. fumigatus* is the development of columnar masses of chains of conidia arising from the vesicle. The conidial chains may attain a length of up to 400 μm. The conidia, green in mass, are echinulate, globose to subglobose, with a diameter of 2–3 μm.

Visualization of wet-mount specimens is aided with methylene blue or lactophenol cotton blue stains. Localization of fungal elements in embedded tissue sections is facilitated with periodic acid-Schiff or Gomori's methenamine silver stains.

A. flavus *Link 1809*

Colony Morphology
The organism grows very rapidly, obtaining a colony diameter of 6–7 cm in 10 days at 25°C on Sabouraud dextrose, Czapek's solution, or potato dextrose agar. Some isolates may be slower growing. The colonies begin as white, close-textured mycelium, turning yellowish to yellow-green with a white colony edge as

25.2. Conidophore with globose vesicle. Phialides and radiate chains of conidia of *Aspergillus flavus*. ×250.

conidia develop. Mature colonies may become somewhat olive-green. The colony may be furrowed radially or flat. Brownish to black-brown sclerotia (densely tangled mats of mycelia), which begin as white tufts of mycelium, may be more evident than conidial development in some isolates. Isolates vary considerably in color and number of sclerotia, if any are present. The colony reverse varies from colorless to pinkish drab to brownish in sclerotial strains. The conidial heads of *A. flavus* are radiate with the chains of conidia splitting to form loose columns.

Microscopic Morphology

The conidiophores (up to 100 μm long and 10–65 μm in diameter) of *A. flavus* are thick-walled, rough, and colorless. The vesicles, although more elongated when young, are globose to subglobose (10–65 μm in diameter) with phialides usually in 2 series (biseriate or 2-layered) on the entire surface of the vesicle (Fig. 25.2). Phialides may be one series (uniseriate), or, more rarely, each condition may be present in a single head. The conidia are globose to subglobose, echinulate, and between 3 and 6 μm in diameter (usually 3.5–4.5 μm).

Growth Requirements

The causative agents of aspergillosis are ubiquitous, due in part to their indifferent nutrient requirements. They commonly occur in soil, grains, and decaying plant matter. Growth is supported in virtually all laboratory media but is inhibited by cycloheximide. *Aspergillus fumigatus* grows well with chicken feather keratin as its sole carbon and nitrogen source (104) and can colonize fiberglass by using binding resins for nutrition (31). The optimum temperature for rapid culture of *A. fumigatus* is 40°C; however, few environments impede growth. The organism is thermotolerant, with growth occuring at temperatures as high as 55°C and survival maintained at temperatures up to 70°C (59). Growth also

occurs at air temperatures as low as 9°C and at relative humidity levels ranging from 11–96% (77). An oxygen tension as low as 0.5% will support growth and conidiation (40).

Biochemical Properties

Identification of fungal agents, including the aspergilli, are based primarily upon colony and microscopic morphology and growth characteristics; biochemical criteria are used infrequently as adjuncts to species identification. Analysis of isoenzyme patterns has been examined as a taxonomic tool. The only enzyme pattern common to all strains of *A. fumigatus* is that of glutamate dehydrogenase (59).

Susceptibility to Chemical and Physical Agents

Some species of the genus *Aspergillus* appear to be quite resistant to chemical agents and have been known to occur in sanitizing fluids, sulfuric acid, copper sulfate plating baths, and formalinized tissues for museum specimens (103). Phenolic disinfectants are commonly used fungicidal agents. Commercial preparations of enilconazole have been used to control aspergilli in the poultry house environment (88). Certain oils derived from spices, such as cinnamaldehyde, are inhibitory to *Aspergillus* growth (64).

Antigenic Structure and Toxins

Antigens

The aspergilli produce a range of antigenic molecules. The antigenic and allergenic properties of *A. fumigatus* extracts have long been recognized in the field of mammalian aspergillosis, but few reports have been made of the serologic responses of birds infected with *Aspergillus*. The qualitative and quantitative variability of the composition of the antigenic extracts, even between batches prepared in the same laboratory, and the multitude of antigens produced increase the difficulty in preparing standardized reagents (42, 59).

Antigens prepared from *A. fumigatus* and *A. flavus* have been used in the detection of antibodies in experimentally exposed turkey poults (78, 98) and chicks (115). The preparations used in the poult studies were culture filtrate antigens produced on either a neopeptone dialysate medium or on Dorsett's medium (117).

Allergic skin reactions in avian species against an alcoholic precipitate from a mycelial extract of *A. fumigatus* have been studied (5). Penguins showed severe and prolonged skin sensitivity, whereas pigeons and ducks were quite resistant. Zoo penguins frequently die from *A. fumigatus* infections.

Detection of the immunodominant galactofuranosyl residues of galactomannan (12), a major cell wall component of *A. fumigatus* (91), in sera or urine with immobilized monoclonal antibody (113) has proved useful in aiding early diagnosis of invasive pulmonary aspergillosis in humans. However, the antigen is not specific for *Aspergillus*, and the occurence of galactomannan in foods and antibiotics may lead to false-positive results (2). The applicability of using galactomannan antigenemia to diagnose aspergillosis in poultry is untested.

Monoclonal antibodies to a 106-kD cell wall antigen of *Asper-*

gillus species were developed for immunohistochemical examinations of archived paraffin-embedded tissues (48). The commercially available MAb-WF-AF-1 works well to identify *A. fumigatus* conidia and hyphal elements in experimentally infected turkey tissues.

Toxins

Aspergillus spp. are among the 3 most common mycotoxigenic genera. Aflatoxins, along with other mycotoxins, are discussed in detail in Chapter 33.

Numerous experimental studies have demonstrated that toxins consumed by poultry can interfere with resistance to various infections. A concept that is not well-recognized, however, is that the pathogenic species of *Aspergillus*, particularly *A. flavus* and *A. fumigatus,* produce toxins that could be involved in the pathogenesis of aspergillosis in poultry. Richard *et al.* (98) found no enhanced pathogenicity of aflatoxigenic strains of *A. flavus* in turkey poults. *A. fumigatus* conidia, however, caused approximately 50% mortality and induced antibodies in poults exposed by aerosol; whereas *A. flavus* conidia caused neither mortality nor antibody production. Some authors had considered previously that a toxin was involved in avian aspergillosis caused by *A. fumigatus* (110). Extensive necrotic lesions (98) and torticollis observed in turkey poults in the absence of brain lesions (99) were reasons for consideration of toxin involvement in aspergillosis caused by *A. fumigatus* (102).

Gliotoxin is one of several toxins produced by various isolates of *A. fumigatus*; it was found to be produced by most of the isolates obtained in an outbreak of aspergillosis of turkeys (93). Turkeys are quite sensitive to oral doses of the toxin. Gliotoxin also is immunosuppressive; it is cytotoxic to, and inhibits blastogenesis of, turkey peripheral blood lymphocytes (101). Richard and DeBey (95) reported the presence of gliotoxin in excess of 6 ppm in tissues of experimentally infected turkey poults, and higher concentrations of gliotoxin have since been found in turkey lung tissue of naturally occurring cases of aspergillosis (96). In a murine model of disseminated aspergillosis, animals infected with a nongliotoxin producing strain survived significantly longer than those infected with a gliotoxin producing strain of *A. fumigatus* (114). It is concluded that gliotoxin production contributes to the pathologic changes observed with aspergillosis.

Virulence Factors

Metabolites, which are necessary for the pathogenicity of *A. fumigatus*, have not been identified. A discussion of the organism's virulence factors requires consideration of its success as a saprobe, in addition to its role as an accidental, noncontagious pathogen. The ability to use a variety of substrates, the copious production of spores that are easily airborne, and the hydrophobicity of the conidia all contribute to its achievement as an ubiquitous saprobe. The widespread distribution of the organism ensures inhalation of conidia by susceptible hosts. The conidia are small enough, 2–3 µm in diameter, to bypass the physical barriers of the upper respiratory tract and are deposited deep in the pulmonary system. The accelerated growth rate of the fungus at temperatures found within piles of rotting vegetation coincides with the body temperature of homeotherms. *In vitro* growth of *A. fumigatus* is enhanced by the presence of hydrocortisone, the pharmaceutical equivalent of the endogenous stress-induced hormone cortisol (71). The occurrence of aspergillosis is a function of the inhaled dose of conidia and the susceptibility of the host.

A. fumigatus produces a number of proteolytic enzymes that can degrade host tissues, especially components of the extracellular matrix. The elastinolytic and collagenolytic enzymes are of particular interest; however, studies using knock-out mutants have not yet identified proteases, which play an essential role in the pathogenesis of pulmonary aspergillosis (59).

Pathogenesis and Epidemiology

Incidence and Distribution

Primarily two forms of aspergillosis occur in poultry. Acute aspergillosis usually is characterized by severe outbreaks in young birds and high morbidity and high mortality. Chronic aspergillosis occurs in adult breeder birds (particularly turkeys) or occasionally in birds in an adult flock or aviary. The incidence of chronic disease is not as great, but in commercial poultry flocks, there are significant economic losses when adult birds succumb to this disease. Aspergillosis appears to be more significant in confinement situations where stress factors may be involved or where moldy litter or grain is present.

Contaminated poultry litter is often the source of *Aspergillus* conidia (29). Pinello *et al.* (82) isolated 73 species of fungi from air, litter, and tissues in a confinement turkey house, and *Aspergillus* was among the 4 major genera found. *Aspergillus* spp. were among the most common fungi found in other studies of air or litter flora of poultry houses (53, 63, 106, 116). Air flora density of the 4 major genera within the poultry house decreased when the windows were opened during the spring (100). Reducing the dust in poultry houses and improving ventilation resulted in a 75% decrease in the incidence of fungal disease (89). Elimination of moldy feed from the diet and environment, along with the proper management of the sawdust litter, prevented reoccurrences of fungal ophthalmitis in poultry houses where there was a history of such problems (11).

Outbreaks occur when the organism is present in sufficient quantities to establish disease or when the bird's resistance is impaired by factors such as environmental stresses, immunosuppressive compounds, inadequate nutrition, or other infectious diseases.

Chute *et al.* (22) observed that *A. fumigatus* is found frequently and is not always pathogenic in young broiler chicks. Sixteen isolates of *A. fumigatus* were compared for pathogenicity by air sac inoculation of turkey poults. Mortalities were not influenced by the number of conidia given or the source of the isolates, although a single environmental isolate produced no mortality (78). Chute and coworkers (22) found the following genera in lungs and air sacs: *Aspergillus, Penicillium, Paecilomyces, Cephalosporium, Trichoderma, Scopulariopsis,* and *Mucor.*

Aspergillosis can be one of the most frequently reported diseases and a source of considerable monetary loss in turkeys (75, 76).

Natural and Experimental Hosts

Aspergillosis occurs in most domesticated and several wild animal species. Mycotic abortion caused by *A. fumigatus* is an economically important disease of dairy and beef cattle worldwide. Infection in horses typically is manifested as guttural pouch mycosis (81). Poultry, exotic, and wild avian species appear to be particularly susceptible to pulmonary aspergillosis. Aspergillosis in humans has increased dramatically in incidence over recent years as a complication of therapeutic immunosuppression (8). Immunocompetent mammals, unlike birds, are naturally resistant to pulmonary aspergillosis unless exposed to an overwhelming dose of conidia. Rodents used as models for the study of invasive pulmonary aspergillosis must be pretreated with cortisone or another immunosuppressive agent for the disease to develop (70). In contrast, experimental aspergillosis in turkeys requires no pretreatment to confer susceptibility (54).

Age of Host Commonly Affected

Pulmonary aspergillosis is the most common form of the disease in avian species and is seen most frequently in young broiler chickens, turkey poults, young and mature breeder turkeys, captive raptors, and penguins (81). The disease is known to occur in a wide variety of avian species, and perhaps all birds, captive and free, domesticated and wild, should be considered as potential hosts susceptible to *Aspergillus* infection.

Pulmonary Aspergillosis

Experimental pulmonary aspergillosis was produced readily by intrathoracic injection of fungal conidia as early as 1884 (119). In 1935, Durant and Tucker (28) produced the disease in a poult by feeding mash contaminated with *A. fumigatus.* Ghori and Edgar (36) found differences in susceptibility to *A. fumigatus* among Japanese quail, turkeys, and chickens, and also strain differences among three strains of chickens (37). Inbred strains were more susceptible than crossbred or outbred strains during an outbreak of aspergillosis in hatchery chicks (14).

Penguins appear to be extremely susceptible to aspergillosis (3), but the disease is significant primarily in captive penguins (52, 72).

Three-to-eight-week-old ostriches in Israel were found to have pulmonary aspergillosis as a dual infection with *A. flavus* and *A. niger* (79). These 2 organisms were isolated from all samples of affected lungs.

Systemic Aspergillosis

Systemic aspergillosis in poults was reported by Witter and Chute (123). Chute *et al*. (21) also reported systemic aspergillosis infection in caponized 5-week-old cockerels. The authors concluded that this resulted from a caponizing infection. An outbreak of *A. flavus*-induced systemic aspergillosis in turkey poults with sternal bone involvement was described by Ghazikhanian (35). Intravenous inoculation of *A. fumigatus* conidia produces acute miliary hepatitis (57).

Dermatitis

Cutaneous lesions as a manifestation of aspergillosis are rare in avian species. Necrotic granulomatous dermatitis was described

in chickens, and *A. fumigatus* was isolated from infected tissue (126). Lahaye (58) discussed cutaneous aspergillosis of pigeons.

Omphalitis

Simultaneous *A. fumigatus* infection of the yolk sac and lungs of young turkey poults has been reported by Cortes *et al*. (24). Increased morbidity and mortality were observed in birds between 3 to 9 days of age. Culture of the organism and demonstration of mycelial invasion of the tissue by histopathology are required to establish a diagnosis.

Osteomycosis

A. fumigatus infection in bone caused deformed vertebrae resulting in partial paralysis of young chickens (13). Presumably, the infections were sequelae to lung disease with hematogenous dissemination of the organism. Note that the outbreak of systemic aspergillosis described previously (35) included involvement of the sternal bone and was caused by *A. flavus.*

Ophthalmitis

Ophthalmic lesions in birds due to *Aspergillus* (Fig. 25.3A) have been reported since 1940 when Reis (90) recognized aspergillosis in the chicken eye. Similar lesions were described by Hudson (44) in young chicks and by Moore (69) in turkey poults. Although these cases of ophthalmitis in avian species were similar in that the infection was unilateral, an important difference occurred in these early reported cases. The first 2 cases had involvement primarily of the conjunctiva and external surfaces of the eye with the development of a cheesy exudate or plaque forming beneath the nictitating membrane. The fungus could be isolated readily from cultured plaque material. The eye infection described by Moore (69) involved turkey poults that had respiratory aspergillosis, and the cornea of the eye was not involved. Most of the pathologic changes occurred in the posterior eye involving the vitreous humor and extending into adjacent tissue. Thus, the pathogenesis of the 2 conditions was apparently quite different; the keratitis and superficial infection probably resulted from exposure of conjunctival surfaces to viable fungal elements from environmental sources. The fungal ophthalmitis involving the posterior eye, however, may have resulted from a hematogenous or lymph dissemination of the organism from a primary respiratory infection. Although not a frequent occurrence, the latter type of eye infection usually is apparent in birds with respiratory involvement. Reis (90) was able to reproduce a superficial eye infection in chickens by introducing conidia of *A. fumigatus* into the eye. The yellow caseous plaque can become adherent to the cornea in the superficial type of infection (47). Because of swelling, this infection may resemble coryza or vitamin A deficiency in chicks (112). After Chute and O'Meara (20) injected conidia of *A. fumigatus* into the abdominal air sacs of chickens, one bird developed a plaque on the surface of one eye. They did not speculate concerning the route of infection.

Recently, Beckman and coworkers (11) described a somewhat different fungal ophthalmitis in a group of chicks from a breeder farm that had recurring problems with similar eye infections. The causative agent was *A. fumigatus*, but in addition to exudate

within the conjunctival sac, there was histopathologic evidence of fungal invasion of the anterior chamber and cornea similar to that described by Moore (69). Although the chicks had respiratory lesions, the authors did not consider the route of infection to be hematogenous from the respiratory lesions, because there was no involvement of intraocular structures.

Occasionally, turkeys experimentally exposed to aerosols of conidia developed a cloudy eye with retinitis, iridocyclitis, and secondary involvement of the remainder of the eye (100). There was a cellular infiltration of heterophils and macrophages, and cellular debris and fungal elements were present in the chambers and retina. The pecten was severely involved with edema, heterophils, mononuclear cells, and fungal elements present. In some turkeys, the pecten contained granulomas.

Following oculonasal vaccination against Newcastle disease, mortalities increased rapidly in chickens that had contracted superficial ocular aspergillosis in the hatchery (66). This type of ocular involvement was described by Moore (69) and occurred in 5 widely separated flocks of young poults and in 3 breeding flocks.

Encephalitis

Numerous reports have described encephalitic or meningoencephalitic aspergillosis in a variety of avian species. In turkeys, necrotic foci in the cerebrum or cerebellum were found in naturally occurring aspergillosis (84). Richard *et al.* (99) found such foci in turkey poults experimentally exposed to aerosols of *A. fumigatus* conidia. Outbreaks of meningoencephalitis have occurred in turkey poults, eider ducklings, and chickens (127). Others have described encephalitic aspergillosis in turkey poults and chickens occurring as caseous necrotic lesions of the cerebrum and cerebellum or as granulomatous encephalitis (1, 38).

Jungherr and Gifford (51) found fungal hyphae in the cerebellum of a poult that had exhibited nervous symptoms. In another outbreak in poults with pneumonomycosis and nervous manifestations, they recovered *A. fumigatus, A. niger,* and *Penicillium varioti* from internal organs. Bullis (15) recovered *A. fumigatus,* and later *Diplococcium* spp., from the cerebra of poults that showed incoordination. In most cases, concurrent infection of the lungs and air sacs occurred, and often the kidney and liver were involved.

Transmission, Carriers, and Vectors

Aspergillosis is not a transmissible disease. Infections are acquired from environmental exposure. Disturbances of soil or movement of hay, compost, or litter can produce aerosols that furnish occasion for respiratory exposure to conidia. Fresh litter contaminated with *A. fumigatus* can precipitate outbreaks of aspergillosis (29).

Aspergillosis can also be acquired *in ovo*. A case of egg-borne aspergillosis was reported by Eggert and Barnhart (30). They suggested that the fungus had penetrated through the eggshell during incubation, and recently hatched chicks were infected. Clark *et al.* (23) reported on other cases of aspergillosis that originated in hatcheries. From 21 ranches where 210,000 chicks were involved, there was mortality of 1–10%. Infection could not be

traced to hatching eggs but was readily found in incubators, hatchers, incubator rooms, and intake ducts. Signs and lesions were noted in some day-old chicks, but generally, classic lesions were observed in chicks 5 days of age.

O'Meara and Chute (73) found that hatching chicks and up to 2-day-old chicks were infected easily with *A. fumigatus* spores by contaminating the forced-draft incubator with wheat seeded with *A. fumigatus.* Chicks older than 3 days were resistant to infection.

Egg embryos are quite susceptible to infection by *A. fumigatus* during incubation. Embryo contamination occurred when a petroleum jelly suspension of *A. fumigatus* conidia was applied to the surface of incubating eggs (124), and infections increased when the incubating eggs were dusted with *A. fumigatus* conidia (125). Within 8 days after the dusting application, the organism had penetrated the eggshell.

Incubation Period

In an outbreak in captive wild poults, mortality totaling 75% began at 5 days, reached a peak at 15 days, and subsided at 3 weeks of age (28). Some affected poults died in convulsions within 24 hours. Onset of signs did not occur before 48 hours in turkey poults experimentally infected with high doses of *A. fumigatus* or *A. flavus* (100). Airsacculitis can be evident within 24 hours of intra-air sac inoculation of *A. fumigatus* (54).

Signs

Signs can be subtle, even in cases in which post-mortem examination reveals severe airsacculitis. Dyspnea, gasping, and accelerated breathing may be present. When these signs are associated with other respiratory diseases, such as infectious bronchitis and infectious laryngotracheitis, they often are accompanied by gurgling and rattling noises, whereas in aspergillosis there usually is no sound. Guberlet (39) ascribed somnolence, inappetence, emaciation, increased thirst, and pyrexia to aspergillosis. Cases under his observation emaciated rapidly and showed diarrhea in the later stages. Dysphagia was noted in cases in which esophageal mucosa was involved. Mortality was as high as 50% in confined birds on some farms, whereas birds running outdoors were more resistant or escaped infection entirely. According to Van Heelsbergen (119), some workers reported serous excretions from nasal and ocular mucosa. Extreme dyspnea was recorded in canaries by De Jong (26). Gauger (34) reported an outbreak of aspergillosis in adult chickens in which about 10% of the flock had signs resembling laryngotracheitis, but there was no increased mortality, although egg production was temporarily lowered.

Because torticollis and/or a lack of equilibrium occurs in both experimental (99) and in naturally occurring infections by *Aspergillus* spp. (84, 120), this should be considered as a sign of avian aspergillosis. However, other infectious agents, including other genera of fungi, can cause similar signs.

Morbidity and Mortality

Aspergillosis is characterized by high morbidity and mortality in chicks and poults and by low morbidity and mortality in mature poultry. Morbidity can be underestimated in finishing flocks until slaughter inspection reveals pulmonary lesions. Condem-

nation of mature young turkey carcasses due to airsacculitis is the second leading cause of post-mortem condemnations in the United States (83).

An outbreak of aspergillosis associated with contaminated litter resulted in the loss of approximately one-third of a flock of turkey poults (29). The litter may have supported fungal growth during the outbreak. Mortality of 96% of a poult flock was recorded in another outbreak; the possible connection of the addition of glucose to drinking water, and the source of infection was not addressed (74). A change of feed and litter may have helped quell an outbreak in chickens which resulted in 26% mortality (67).

Approximately 50% of turkey poults died following a 10-minute aerosol exposure to conidia of *A. fumigatus*, resulting in 5×10^5 colony-forming units/g of lung tissue (98). No deaths occurred in turkey poults similarly exposed to *A. flavus,* perhaps because the size of *A. flavus* conidia (3–6 µm) is considerably greater than that of *A. fumigatus* (2–3 µm) and, thus, they would not reach as deeply into the respiratory tract. Walker (121) reported that 5–7-day-old ostriches succumbed in 2–8 days from pulmonary aspergillosis after conidia were aerosolized into the trachea. Turkey poults aerosol-exposed to 2.2×10^6 viable units of *A. fumigatus*/g of lung tissue all died by day 5; lower doses $(5.2 \times 10^5$ viable units) delayed and reduced mortality. Deaths began by 3–4 days postexposure.

Gross Lesions

The lesions of uncomplicated pulmonary aspergillosis evolve over several days and diminish in a few weeks time. The acute lesions of experimental aspergillosis in turkeys rapidly progressed in severity. At 24 hours, white miliary foci were present on air sac membranes, and lung lesions consisted of straw-colored gelatinous subpleural edema. Air sacs became progressively thicker and opaque and supported granulomata that increased in size and changed shape from raised domes (1 mm) to flat or umbilicated plaques (2–5 mm), which tended to coalesce. Extensive white discoloration of lungs and granulomatous pneumonia were evident by 72 hours after intra-air sac infection with *A. fumigatus* (54).

Lung lesions in experimental aerosol infection of turkey poults consisted of small white caseous nodules (approximately 1 mm in diameter) scattered throughout lung tissue (Fig. 25.3B), usually accompanied by similar sized caseous plaques on thickened air sac membranes (100, 109) (Fig. 25.3C). Occasionally, red-tinged ascites was present.

Durant and Tucker (28) observed yellowish-white nodules up to 5×8 mm in the lungs of wild poults reared in captivity. In an outbreak of aspergillosis in chicks, no evidence of yellowish foci was found, but the lungs were a diffuse grayish yellow (107).

In advanced cases of aspergillosis, the organism can sporulate on the surface of the caseous lesions and on the walls of the thickened air sacs (100, 109) as evidenced by visible greenish-gray mold growth.

Caseous, gelatinous, or less commonly mucopurulent exudate may be present in the syrinx in infected birds (Fig. 25.3D). Localized tracheal aspergillosis caused by *A. flavus,* described by Barton and coworkers (9), was characterized by grossly visible yellow caseous plaques adherent to the mucosal surface that sometimes occluded the lumina. The tracheal walls were reddened as well.

Lesions in brain tissue were described by Richard *et al.* (100) as white to yellow circumscribed areas (Fig. 25.3E) usually visible on the brain surface. They were present either in the cerebellum or cerebrum or less frequently in both.

Julian and Goryo (50) described ascites in chickens as a frequent sequela to pulmonary aspergillosis caused by *A. fumigatus.* Acute cor pulmonale was the suspected initiator of the vascular failure.

Mohler and Buckley (68) described lesions in a flamingo consisting of pseudomembranous bronchitis, in addition to lung nodules. Similarly, airway-centered pseudomembranous lesions were traced from bronchial lumina through parabronchi extending to the pleural surface lesions in an ostrich that succumbed to aspergillosis (4). In another ostrich case, the lungs were covered with miliary foci (49). In canaries observed by De Jong (26), there were small, whitish-yellow, crusty coatings on the tongue, palate, and aditus laryngis, and in the trachea and syrinx. Caseous foci in lungs and caseous coatings on the pleura and peritoneum were also observed. Lahaye (58) stated that *A. glaucus* may be the cause of a skin disease in pigeons, particularly in young birds, and that any part of the body may be affected with yellow scaly spots. Feathers in the affected areas were dry and easily broken.

Histopathology

In a study of acute pulmonary aspergillosis in turkey poults, granulomatous airsacculitis and pleuritis were seen as early as 24 hours after intra-air sac inoculation with *A. fumigatus* (54). Air sac membranes were thickened up to 100-fold by massive infiltrates of heterophils, multinucleate giant cells, and other leukocytes. Germinating conidia were seen in the membrane interstitium, and lymphohistiocytic perivasculitis was discernable in less severely affected areas. Granulomas had centers composed of necrotic cellular debris and heterophils with a peripheral palisade of epithelioid macrophages and aggregates of lymphocytes (Fig. 25.3F). Examination of pyogranulomas stained with Gomori's methenamine silver stain revealed large numbers of germinating conidia centrally and hyphae extending peripherally through the layer of macrophages (Fig. 25.3G). Lung lesions consisted of heterophilic and lymphohistiocytic or granulomatous pleuritis and pneumonia with edema and hemorrhage in the initial 48 hours, but had progressed to extensive effacement of parenchymal architecture by necrosis, hemorrhage, and massive infiltrates of leukocytes by 72 hours. Epithelioid macrophages admixed with multinucleate giant cells were arranged in sheets. Intact and degenerate heterophils predominated in areas of necrosis. Septate hyphae were mostly localized to areas of necrosis and aggregates of multinucleate giant cells.

Nonviable *A. fumigatus* conidia produced a transient airsacculitis and pneumonia characterized by edema and infiltrates of heterophils and macrophages (55). Multinucleate giant cells were not present in these lesions, in contrast to active infections with *Aspergillus* in which both uninuclear epithelioid and multinucleate giant-cell macrophages are a prominent feature.

In a study of subacute and chronic phases of aspergillosis, the examination of lung tissues from turkey poults revealed no differences in histopathologic lesions caused by *A. fumigatus* or *A. flavus* (97). Lesions seen in the first 2 weeks of the study were characterized by focal accumulations of lymphocytes, some macrophages, and a few giant cells. Later, lesions consisted of granulomas with a central area of necrosis containing heterophils surrounded by macrophages, giant cells, lymphocytes, and some fibrous tissue. By 8 weeks postexposure, surviving poults had mature fibrous granulomatous lesions consisting of a necrotic center surrounded by giant cells and a thick layer of fibrocytes and collagen containing a few scattered heterophils. Using Gridley's fungal stain, the organisms could be seen within the necrotic areas of the lesions. In tissue sections of the well-oxygenated bronchi, bronchioles, and air sacs, the organism was sporulating asexually.

Brain lesions consisted of solitary abscesses with necrotic centers infiltrated with heterophils and surrounded by giant cells. Hyphae were seen in the central area of some lesions.

Eye lesions were characterized by edema of the pecten, which was infiltrated heavily with heterophils and mononuclear cells. Granulomas were found in the pecten. Fungal hyphae, heterophils, macrophages, and cellular debris were found in the chambers and retina of the eye. Edema and some heterophils were found in the sclera and surrounding tissues. In cases of ophthalmitis in turkeys described by Moore (69), primary involvement was in the vitreous humor and adjoining tissues. In one turkey, he observed hyphae in the center of the lens.

In tracheal lesions, occlusions consisted of fungal mycelia and pyogranulomatous exudate, although the mucosa was necrotic and infiltrated with macrophages, and fibroplasia was evident in the subadjacent tracheal wall (9).

Pathogenesis

The conidia of *A. fumigatus* are about 3 μm in diameter; once inhaled, they are deposited deep within the respiratory tract. In a study of infected chick lung tissue, Campbell demonstrated that conidia adhered to epithelial surfaces and smooth muscle cells lining the apices of interatrial septae of parabronchi shortly after their inhalation (16). The conidia swelled slightly prior to producing germ tubes, which by 25 hours had developed into septate hyphae. Presumably, this transformation occurred in both intra- and extracellular locations as conidia were found on and in host cells. Hyphae were frequently seen within the cytoplasm of giant cells with little evidence of detriment to either. Examination of infected air sacs revealed that conidia attached to the membrane surface within 1 hour and were translocated from the luminal surface to the interior of the membrane, where conidial germination was evident within 24 hours (54, 55). Necrosis of tissue was concurrent with the fulminant inflammatory response which, by 24 hours, included massive numbers of heterophils admixed with cellular debris. Proteases expressed during the vegetative growth of *A. fumigatus*, in addition to heterophil mediated lysis, may contribute significantly to the destruction of pulmonary parenchyma (46).

Conidia of *A. fumigatus* may be disseminated by the hematogenous route in poultry as has been described in humans (105).

Richard and Thurston (97) isolated *A. fumigatus* from the blood of turkeys immediately after a 15-minute aerosol exposure of conidia. At this time, macrophages harvested by lung lavage contained numerous ingested conidia. This may be the route of dissemination resulting in the eye and brain lesions (100). Some experimentally exposed turkeys had a notable torticollis, and brain lesions were found at necropsy. Torticollis occurs also in naturally occurring infections of *A. fumigatus* in turkeys, geese, and chickens (120). Usually, by 24 hours postexposure the organism was cleared from the bloodstream.

Immunity

Evidence for immunity against aspergillosis in poultry is lacking; however the majority of turkeys experimentally infected with *A. fumigatus* recover from the lesions of pulmonary aspergillosis in 4–5 weeks, if not re-exposed to the agent (55, 57). Likewise, resolution of pulmonary aspergillosis has been described in Japanese quail surviving experimental infection (19). The mechanisms involved in convalescence from aspergillosis in avian species have not been described. It has been proposed that macrophages and neutrophils alone, independent of lymphocyte responses, clear *Aspergillus* from pulmonary tissues in immunocompetent mammals (108); however, immunologic memory is assumed to have a role in protecting mice against lethal challenge subsequent to low-dose challenge (111).

Vaccination of turkeys against aspergillosis has yielded only limited protection in experimental settings by decreasing mortality (99) or lessening early histopathologic lesions (94). However, vaccination did not protect against the development of grossly apparent pulmonary lesions and may have predisposed to chronic *A. fumigatus* infection, in that some vaccinates remained culture-positive and that nonvaccinated controls were culture-negative at 8 weeks post-challenge.

Natural recovery from aspergillosis does not appear to confer protection in turkeys. Convalescent turkeys remained susceptible to pulmonary aspergillosis in a study in which recovery from unilateral *A. fumigatus*-induced airsacculitis did not protect against contralateral air sac challenge (56). Likewise, passive cellular immunization failed to protect turkeys against *A. fumigatus* challenge and splenic lymphocytes did not respond to conidial antigen preparations, regardless of the previous exposure status of the donor turkey (57).

Diagnosis

Isolation and Identification of Causative Agent

Aspergillosis usually is diagnosed at postmortem examination, often based upon the observation of white caseous nodules in the lungs or air sacs of affected birds. Bronchoscopy was used, however, in observing plaques in the bronchi and trachea of an ostrich, and biopsy specimens of infected material were obtained for histologic evaluation and bacterial and fungal examination and culture (65). Although it is sometimes possible to observe fungal growth and sporulation on the caseous nodules or plaques, especially in the air sacs, confirmation should be made by cultural isolation and identification of the causative fungus. Al-

though *A. fumigatus* is the most likely agent of avian aspergillosis, other species of *Aspergillus* can cause the disease. Therefore, isolates should be identified.

Because most agents of the mycoses are ubiquitous saprophytes, diagnostic samples should be collected carefully using aseptic technique. Samples so collected can be examined microscopically by placing a small portion of the nodule in 20% KOH on a microscope slide, teasing the material apart, and covering it with a glass coverslip. Following gentle heating of the slide over a flame, the specimen can be examined for the presence of hyphae within the exudate. If the preparation is too thick, the slide should be incubated 12–24 hours in a moist chamber and re-examined. To aid in elucidating the fungus, the KOH can be mixed with ink dye (Ink blue—pp or asb, Parker Pen Co., Janesville, WI). Hyphae of *Aspergillus* stained with the ink dye appear as blue-stained, septate, dichotomously branched structures 2–8 μm in diameter with hyphal walls generally parallel (Fig. 25.4).

Aseptically obtained specimens can be plated directly onto appropriate mycologic media. Alternatively, specimens can be placed in saline solution, minced briefly in a tissue grinder, and then streaked onto the surfaces of mycologic media. Replicate plates should be incubated at both 27° and 37°C. Collected fluids can be centrifuged, and the sediment can be examined microscopically or cultured as above.

Satisfactory media for the isolation and identification of most isolates from cases of aspergillosis include Sabouraud dextrose agar, Czapek's solution agar, and potato dextrose agar. All cultures should be examined daily, and portions of fungal colonies should be transferred to fresh media.

For light microscopic examination, a small portion of the colony containing reproductive structures can be placed in a drop of suitable mounting medium (e.g., lactophenol blue) on a clear glass slide, teased apart, covered with a coverslip, and examined.

Although an indirect histochemical technique was used to diagnose aspergillosis in a lovebird (17), the major pathogens of aspergillosis can be identified based on specific characteristics of *A. fumigatus* or *A. flavus* (see "Etiology").

Serology

Serologic tests are of limited value due to the nonspecific nature of the antigens. Agar gel precipitin tests were used by Richard *et al.* (98) in comparisons of *A. fumigatus* and *A. flavus* infections in turkey poults. Although most of the *A. fumigatus*-infected poults were positive for precipitating antibodies, poults infected with *A. flavus* were not. Peden and Rhoades found that antibody responses as measured by the enzyme-linked immunosorbent assay (ELISA) and agar gel immunodiffusion test were erratic, although most poults with high antibody scores had marked lesions and low weight (78). Additionally, a direct ELISA technique has been used in turkeys with a correlation occurring between exposure level and ELISA optical density (87). Perhaps the use of serologic methods for identifying poults with aspergillosis for culling procedures would be advantageous, but presently, there is no legal or effective therapy for treating positive birds.

25.4.   Hyphae of *Aspergillus fumigatus* in lesion material prepared as a wet mount in 20% KOH and ink dye. ×450.

Differential Diagnosis

The clinical signs of avian aspergillosis are nonspecific and dependent upon the organ systems involved. Pulmonary aspergillosis usually is differentiated from other avian respiratory diseases by the granulomatous lesions observed at necropsy although Linares and Wigle (62) found *Staphylococcus aureus* pneumonia in newly placed poults can appear similar. Exudative fibrinous or purulent airsacculitis and pneumonia are also frequently seen in cases of mycoplasmosis, colibacillosis, fowl cholera, and chlamydophilosis. Mycobacteriosis and other mycoses should also be considered when granulomas predominate.

Intervention Strategies

Management Procedures

Aspergillus fumigatus infection in young chicks and poults has been somewhat controlled by hatchery sanitation. Sophisticated sampling equipment and media are available to monitor air in hatcheries. Moldy litter or feed and access to musty, moldy strawstacks should be avoided to prevent outbreaks of aspergillosis. Examination of premises or materials used for feed or litter usually will reveal the source of infection.

Areas around feed hoppers and watering places are fertile areas for growth of molds. Unless a permanent yard system is used, frequent moving of feed troughs and watering places is advisable. Placing feed containers and watering fountains on screened, elevated platforms helps to prevent turkeys from picking up molds that develop in such places. Drainage is advisable for areas where water is likely to stand after rains.

Daily cleaning and disinfection of feed and water utensils will aid in eliminating infection. Spraying the ground around containers with chemical solutions may be advisable if it is impossible

to change feeding areas frequently. In outbreaks, a 1:2000 aqueous solution of copper sulfate for all drinking water may be used to aid in preventing the spread, although it should not be relied upon as a method to be used continually. Dyar *et al.* (29) reduced the mold count of contaminated litter and the mortalities of turkeys due to aspergillosis by treating the litter with nystatin and copper sulfate. A thiabendazole solution sprayed on green oak wood shaving litter was efficacious in reducing mold spore counts in the litter, and there were reductions in pulmonary lesions of aspergillosis in turkeys raised on that litter (32). Mortality due to an aspergillosis outbreak in a broiler flock was reduced within 2 days of treatment of litter with an enilconazole solution (88).

Prevention is currently the preferred means of control. This usually involves eliminating the source of the organism, such as moldy feed and litter, and treating the poultry houses and litter with antifungal compounds. In spite of precautions and preventive measures, outbreaks of aspergillosis frequently occur in some houses and at certain times of the year, particularly during the winter in closed rearing houses. Evidently, increased ventilation within poultry rearing houses reduces the airborne mycoflora (100) suggesting that this could be used as a preventive measure in controlling aspergillosis. Natural ventilation appeared to be better than forced-air ventilation. A significant effect of the type of natural ventilation design (curtain or sliding door), however, was not evident in studies evaluating turkey performance using mortality, average daily gain, feed conversion, condemnations at slaughter, or average individual bird weight as measures of production (25).

Generally, an effective means of therapy for avian aspergillosis is not available. Although certain drugs have been used for the treatment of mammalian aspergillosis, they are apparently not cost-effective for poultry. Wawrzkiewicz and Cygan (122) studied 64 strains of *Aspergillus,* 26 of *Rhizopus,* and 2 of *Mucor* from 56 lung tissue samples of poultry with aspergillosis. The most active fungistats against these *in vitro* were nystatin, amphotericin B, crystal violet, and brilliant green. Hamycin in the drinking water was reportedly successful in controlling an outbreak of aspergillosis in young chicks (7). Miconazole was used successfully in the treatment of raptors with clinical aspergillosis (33). Infections in chick embryos have been controlled by the use of amphotericin B (45) and phenylmercuric dinaphthylmethane disulfonate (41). Dimethyldithiocarbamate, injected subcutaneously, was effective against *A. fumigatus* infection in 5- and 10-week-old chickens. The drug significantly reduced the lesion size and the rate of isolation of the organism from tissues in comparisons between treated and untreated infected birds (27). Exposure of chicks to enilconazole fumigation at the time of experimental infection with *A. fumigatus* reduced morbidity and mortality (118). In another experimental aspergillosis study comparing the efficacy of azole compounds, treatment of poults by crop gavage with itraconazole was the most effective in reducing lesion scores and weight loss (80).

Vaccines are not a practical alternative, and none are commercially available. Experimental vaccine preparations have not been efficacious. In exception, Richard *et al.* (100) reported reduced mortalities by 50% in turkey poults vaccinated with a germling (germinated conidia) vaccine prepared from *A. fumigatus* and subsequently challenge-exposed to aerosols of *A. fumigatus* conidia. Viable spores of *A. fumigatus* administered to ducks provided some protection from death following challenge exposure (5).

Candidiasis (Thrush)

Introduction

Candida species have a worldwide distribution and are part of the microflora of the healthy digestive system of humans, animals, and birds. Candidiasis is an opportunistic endogenous mycosis in that perturbance of the microflora or other debilitation of the host, rather than exposure to an external source, is the initiator of pathologic infection. Extremes of age and concurrent disease often are implicated when immunosuppression is suspected as the underlying problem. Prolonged or otherwise inappropriate antimicrobial therapy that upsets microflora ecology is likely the most common initiator of candidiasis. Birds are particularly susceptible to oral and crop candidiasis, which resembles thrush in humans.

Definition and Synonyms

Candidiasis is a mycosis caused by infection with the mycelial yeasts of the *Candida* genus, principally *C. albicans*. The organism is commensal and an opportunistic pathogen. The term thrush is applied to *Candida* infections of the upper digestive tract. Stomatitis oidica, muguet (Fr.), Soor (Ger.), moniliasis, oidiomycosis, and sour crop are other terms applied to mycotic infections of the digestive tract.

Significance

Thrush has been observed in chickens, turkeys, geese, pigeons, guinea fowl, pheasants, ruffed grouse, quail, peacocks, lories, lovebirds, finches, parrots, and parakeets (1, 18, 23). The occurrence of avian candidiasis is sporadic, but outbreaks can be costly. The first major reported outbreak resulted in mortality of up to 20% in young turkeys (5), and another report the following year described the loss of 10,000 chicks to the fungal infection (8). A recent outbreak resulted in 40% mortality in a flock of 6-week-old turkeys (18).

History

The significance of yeast-like fungi in infections of the digestive tract of humans was recognized by Langenbeck in 1859. Historical synonyms for the disease and the etiologic agent can be confusing. Moniliasis denotes infection with the genus *Monilia*, which is outdated. *Candida* has since replaced the once familiar but invalid *Monilia* in accordance with a decision reached at the Third International Microbiological Congress in 1939. *C. albicans* is the most frequently isolated etiologic agent of candidiasis, which is sometimes yet referred to as moniliasis.

Jungherr (10) stated that *Monilia albicans* is of widespread occurrence in gallinaceous birds, pathogenic to birds and also to rabbits on intravenous (IV) injection, and indistinguishable from strains isolated from human sources. He also associated *M. albicans, M. krusei,* and *Oidium pullorum* sp. n. with cases of thrush but considered *M. krusei* to be of no etiologic significance (9, 10). *Mucor* spp. and aspergilli were also found in association with some cases. Hinshaw (7) reported *M. albicans* to be found in most cases of thrush in turkeys and chickens that came to his attention. Both investigators noted that the mycotic infections were apt to be associated with unhygienic conditions.

Studies of Benham (2), Worley and Stovall (28), Martin *et al*. (16), and others indicated the complexity of etiology. Stovall (21) presented a means of improving the identification of isolates by suggesting a specific set of environmental conditions under which the biologic characteristics of the organism were constant and could be demonstrated.

Etiology

Candida albicans is the primary agent of thrush, although other *Candida* species have been isolated from both healthy and diseased birds. In a mycological survey of crops obtained from broilers, *C. albicans* comprised 95% of the isolates, and the remainder were identified as *C. ravautii*, *C. salmonicola*, *C. guilliermondii*, *C. parapsilosis*, *C. catenulata*, or *C. brumptii* (30). Only *C. albicans* and *C. parapsilosis* were associated with the cases of crop mycosis reported in the study. An outbreak of thrush in turkeys yielded isolations of *C. albicans*, *C. rugosa*, *C. famata*, *C. tropicalis*, and *C. guilliermondii* with *C. rugosa* as the sole isolate from several of the diseased crops (18).

Pathogenesis and Epidemiology

Incidence and Distribution

C. albicans is a commensal fungus readily isolated from the intestine and mucocutaneous surfaces of birds, animals, and humans. Its distribution is worldwide. Pathology due to infection is an aberration brought on by a lapse of immunologic homeostasis or shifts in the ecology of microflora colonizing the host. The condition is sometimes seen as a sequela to coccidiostat treatment.

Mycosis of the digestive tract may occur more frequently than the paucity of diagnoses in reports from diagnostic laboratories suggests. Perhaps, in many cases, it may not be of great consequence. Serious outbreaks have been reported, however, in many species of birds. Animals and humans are also affected. Gierke (5) reported an outbreak of a thrushlike disease occurring in turkeys in California. Hart (6) reported the disease in turkeys and other fowl in New South Wales. A review of the disease in turkeys and chickens in California was recorded by Mayeda (17). A mortality rate of 40% was reported in an affected turkey flock in central Italy (18). Hinshaw (7) reported thrush in 12 flocks of turkeys, with lesions similar to those noted in chickens. Blaxland and Fincham (3) studied 5 serious outbreaks in young turkeys. Their observations supported previous conclusions that monilia-

sis is likely to be associated with unhygienic surroundings and other debilitating conditions.

Clinical Signs

Signs are not particularly characteristic. Affected chicks show unsatisfactory growth, stunted appearance, listlessness, and roughness of feathers. When candidiasis occurs as a secondary infection, the signs of the predisposing disease may predominate the clinical picture.

Young birds are more susceptible than older birds to mycosis of the digestive tract. Thus, as infected birds grow older, they tend to overcome the infection. Jungherr (8) observed an outbreak in which losses amounted to 10,000 chicks out of 50,000 that were less than 60 days of age. He also reported that turkeys under 4 weeks of age succumbed rapidly to infection (10), but that outbreaks in birds 3 months of age resulted in a high percentage of recoveries.

Gross Lesions

Lesions occur most frequently in the crop and consist of thickening of the mucosa with whitish, raised circular or rugose formations (Fig. 25.3H [*Note*: Fig. 25.3 can be found in "Aspergillosis" earlier in this chapter]). Often, there are curdy pseudomembranous necrotic patches that are peeled easily from the eroded mucosal surface. The mouth and esophagus may be diphtheritic and eroded.

Underwood (24) described an instrument known as McCarthy's foroblique panendoscope that was used to diagnose experimental crop moniliasis. This instrument was equipped with a viewing lens and an independent light source. Birds were starved for 12 hours to empty the crop to allow a clear view of the mucosa. A normal crop appeared to be light pink, with a glistening smooth surface having numerous shallow convolutions, whereas a fungus-infected crop showed severe corrugations to mild whitish streaks, erosions or diphtheritic formations, and a deep red surrounding mucosa.

When the proventriculus is involved, it is swollen, the serosa has a glossy appearance, and the mucosa is hemorrhagic and may be covered with catarrhal or necrotic exudate. The frequent association of mycosis of the digestive tract with other debilitating conditions, such as gizzard erosions and intestinal coccidiosis, must be considered. Gizzard erosions, as such, probably are not directly related to thrush. Likewise, the thickened intestine with watery contents frequently noted in cases of thrush is probably due to coccidiosis or other protozoan infections.

Wyatt *et al*. (29) induced systemic candidiasis in 14-day-old broiler chickens with an intravenous injection of a suspension of *C. albicans* cells. Growth was severely retarded; neural disturbances were noted; and there was marked hepatic, renal, and pancreatic congestion. Miliary abscesses are produced in kidneys of rabbits injected intravenously (2).

A case of integumentary candidiasis resulted in feather loss and superficial dermatitis in 70% of a flock of 18-month-old laying chickens (14).

Microscopic Lesions

Colonization of the keratinized stratified squamous epithelium of oral, crop, and esophageal mucosa typically is limited to the stra-

tum corneum or with extensions into the stratum spinosum. The mucosal surface may be covered by a crust composed of an admixture of necrotic debris, sloughed epithelial cells, leukocytes, bacterial colonies, and the yeast and pseudohyphal forms of *Candida*. Epidermal edema and parakeratotic hyperkeratosis may be evident. Epidermitis characterized by mixed infiltrates of macrophages, lymphoctes, plasmacytes, and heterophils is commonly seen. Epidermal and superficial dermal microabcesses, submucosal or dermal edema, and interface dermatitis may be present. Submucosal or dermal colonization with attendant inflammation is a less frequent feature.

The morphology of *Candida* in tissues is fairly characteristic in that mycelial and yeast forms are all usually present in lesions. The yeastlike cells are oval and 3–6 μm in diameter. Mycelia consist of both hyphae and pseudohyphae. Pseudohyphae are composed of elongated yeastlike cells arranged in chains that appear similar to hyphae but have prominent constrictions between adjoining cells. The hyphae have parallel sides, are septate, and measure 3–5 μm in width. Periodic acid Schiff and Gomori's methenamine silver stains are helpful in visualizing the fungal morphology in tissue sections.

Periportal focal necrosis in the liver in some cases suggested toxic action upon the system. A soluble endotoxin, toxic for mice, has been isolated from *Candida albicans.* Tripathy (22) considered that vascular damage in infected turkeys may be associated with *Candida* endotoxin. Atheromatous lesions were present on the intimal surface of the abdominal aorta in more than 50% of turkeys exposed to *C. albicans;* whereas there was only a 12.5% incidence of similar lesions in uninfected controls. *Candida* isolated from infected humans have been shown to produce a metabolite similar to the *Aspergillus* gliotoxin, a member of the chemical class epipolythiodioxopiperzine, which possess immunomodulating and antiphagocytic properties (20).

Diagnosis

A clinical picture including poor hygiene or history of long-term antimicrobial therapy is supportive when *Candidiasis* is suspected. Observation of characteristic proliferative white curd-like lesions and heavy growth, predominated by yeastlike colonies, on primary cultures, serves to diagnose thrush. Because of the possibility of cultivation of *C. albicans* from apparently normal tissues, an original heavy growth is considered essential for diagnosis. Direct microscopic examination of fresh tissue samples is useful if pseudohyphae and budding yeast can be demonstrated. *Candida* cells stain Gram-positive.

Aseptically collected scrapings of mucosal lesions can be streaked onto Sabouraud's dextrose agar with 50 μg/ml chloramphenicol and 0.5 mg/ml cycloheximide, to inhibit bacterial and mold growth, respectively. Additional agar plates with chloramphenicol only should be streaked, as some *Candida* isolates are sensitive to cycloheximide. Incubation of duplicate plates at both 27°C and 37°C is recommended. Plates should be examined daily for 5 days and discarded after 1 month. On Sabouraud dextrose agar, it produces a whitish, creamy, high-convex colony after incubation for 24–48 hours at 37°C.

Microscopic morphology of young cultures consists of oval budding yeast cells about 5.5 × 3.5 μm. Older cultures show hyphae and occasionally chlamydospores, which are spherical, swollen cells with a thickened cell wall. Formation of chlamydospores is facilitated by growth on cornmeal-Tween 80 agar or other chlamydospore agar. Clusters of blastoconidia on the sides of pseudohyphae are distinguishing features as is germ-tube production in appropriate media (13).

Candida species can be identified by substrate utilization panels. In Dunham's peptone water containing 1% fermentable substance and 1% Andrade's indicator, the organism produces acid and gas in dextrose, levulose, maltose, and mannose; slight acid in galactose and sucrose; and does not use dextrin (variable according to brand), inulin, lactose, and raffinose. Gelatin stab cultures show short villous to arborescent outgrowths without liquefaction of the medium. Commercially available carbohydrate assimilation panels, such as the API 20C yeast identification system and RapID Yeast Plus System, are used in medical diagnostic laboratories (19, 26).

Treatment and Control

Because mycosis of the digestive tract is apt to be related to unhygienic, unsanitary, overcrowded conditions, they should not be allowed to exist or should be corrected. Jungherr (9) found that denatured alcohol and coal-tar derivatives were ineffective as disinfectants and suggested that iodine preparations be used. As a treatment, he recommended that following an Epsom salt flush, 1 level teaspoon of powdered bluestone ($CuSO_4$) be added to each 2 gallons of drinking water in nonmetal containers every other day for 1 week. Hinshaw (7) recommended that a 1:2000 solution of $CuSO_4$ for turkeys be used as the sole source of drinking water during the course of the outbreak. However, Underwood *et al.* (25) found $CuSO_4$ to be ineffective for treating or preventing the disease in chicks and poults with experimentally produced moniliasis. Affected birds should be segregated for protection against cannibalism. Lesions in the mouth can be treated by local application of a suitable antiseptic. Appearance of the disease in very young chicks suggests that the surface of the egg is a source of infection. Such a possibility could be removed by dipping eggs in an iodine preparation prior to incubation.

Kostin (12) found that *C. albicans* organisms mixed with poultry droppings and applied to wooden boards could be killed by exposure to 2% formaldehyde or 1% sodium hydroxide solution for 1 hour. Treatment with a 5% solution of iodine monochloride in hydrochloric acid for 3 hours was also successful in disinfection.

Nystatin treatment has been studied by Gentry *et al.* (4) and Kahn and Weisblatt (11). One group reported that a 220 mg nystatin/kg diet was effective in eliminating moniliasis in a flock of turkeys. The other group found that in experimental infections with *C. albicans* in both chickens and turkeys, crop lesion severity appeared to be significantly reduced in the group fed the lowest level of nystatin (11 mg/kg). The highest level (110 mg/kg) showed very significant protection against mycotic infection.

Yacowitz *et al.* (31) reported the successful prevention of can-

didiasis in chickens by the addition of nystatin at a minimum level of 142 mg/kg ration for 4 weeks. Kahn and Weisblatt (11) obtained similar results. Wind and Yacowitz (27) successfully treated crop mycosis with nystatin by dispersing it in drinking water at levels of 62.5–250 mg/L with sodium lauryl sulfate (7.8–25 mg/L) for 5 days.

Tripathy (22) found that the addition of chlortetracycline (500 g/ton) to a vitamin A-deficient ration had no effect on incidence or severity of crop candidiasis but increased the cells being shed in feces. Turkeys fed nystatin (100 g/ton) had a higher average weight and milder crop lesions than untreated controls.

Lin reported results of *in vitro* drug susceptibility testing of clinical isolates of *Candida* and recommended nystatin treatment be administered by water because poultry with thrush tend to show decreased feed consumption and increased water consumption (15).

Dermatophytosis (Favus)

Dermatophytosis, dermatomycosis, ringworm, and favus are terms applied to the condition of fungal infections of skin. The term favus usually is used to denote the disease in poultry. Favus has a worldwide distribution but its occurrence is sporadic. The infection is contagious and is transmissible to humans, as is the case with the majority of dermatophytoses. The primary etiologic agent of favus is *Microsporum gallinae*.

The etiologic agent of favus was first described in 1881 as

Epidermophyton gallinae, later known as *Achorion gallinae*, then *Trichophyton gallinae*, and eventually accepted as *Microsporum gallinae*. Favus caused by *M. gallinae* has been reported in the chicken, turkey, duck, quail, and canary (1). Although a rarely encountered disease in large-scale poultry production, *M. gallinae*-induced favus may be more common in backyard, hobby, or game chicken flocks (2, 3, 4).

M. gallinae is a primary pathogen. Other than skin lesions, affected birds are typically healthy. Favus spreads gradually through a flock by direct contact, if left unchecked, and can produce ringworm lesions in their human handlers. In chickens, infection typically produces white scaly or crusty lesions on the comb and on the skin of the head and neck with loss of feathers. Microscopically, colonization is limited to the epidermis. The skin surface may appear thickened by orthokeratotic hyperkeratosis and serocellular crusts with a primary component of heterophils admixed with mycelia. Acanthosis and acantholysis with hydropic degeneration may be present. Lymphohistiocytic and heterophilic epidermitis and dermatitis are also seen. Examination of feather follicles reveals mycelial colonization of the keratinized shaft. In tissues stained with periodic acid-Schiff or Gomori's methenamine silver stains, the fungal morphology is that of branching, septate hyphae with parallel sides, 2–5 μm in diameter.

Skin scrapings placed in a drop of 10% KOH on a glass slide, which is then cover-slipped and gently heated over a flame, can be used to visualize the intact and fragmented intralesional hyphae. Scrapings can be cultured on Sabouraud's dextrose agar with 50 μg/ml chloramphenicol and 0.5 mg/ml cycloheximide and incubated at or around 27°C. Colonies of *M. gallinae* usually will develop in 1–2 weeks at 27°C, or about 4 weeks at 20°C. Initially, colonies are white and velvety and become tinged with pink as the culture ages. The colony reverse is initially yellowish and gradually changes to red. Microscopically cultures are composed of slender (2–5 μm) branching, septate hyphae bearing abundant microconidia and fewer macroconidia. Microconidia are pyriform (pear-shaped) and measure 2 × 4 μm. Macroconidia (6–8 × 15–50 μm) have thin smooth or echinulate walls, contain 4–10 cells, are blunt tipped, and have a curved and tapering base (5).

Introduction of birds with lesions of favus into existing flocks should be avoided. Other reservoirs, such as contaminated soil, may exist, but *M. gallinae* has been isolated only from infections. Birds with favus should be segregated to prevent transmission of the agent. There is no label-approved treatment for poultry, but topical application of miconazole ointment on affected areas is apparently efficacious (3). Care should be exercised when handling birds with favus to prevent zoonotic transmission. Use of examining gloves with proper disposal after use is encouraged.

Dactylariosis

Dactylariosis is a sporadic fungal encephalitis of birds caused by the dematiaceous thermophilic fungus *Dactylaria gallopava* (1), first described in 1964 as *Diplorhinotrichum gallopavum* (3). The disease has been described in young chickens, turkey poults, and quail chicks (3, 4, 5).

Although dactylariosis does not occur frequently, when it does, a moderately large proportion of a flock may be affected with mortality approximating the morbidity rate. Ranck *et al.* (4) described an outbreak in a flock of young chickens resulting in fatal encephalitis in 200 birds from a flock of 65,000. The disease was reproduced experimentally by a spore suspension injected into the left posterior thoracic air sac, left maxillary sinus, and cerebrum. Waldrip (7) reported an outbreak in 60,000 broilers with a mortality rate of 3–5%. Blalock described an outbreak of dactylariosis in turkey poults causing 20% mortality (2). Shane (5) reported a mortality rate of 15–20% in an outbreak involving Japanese quail chicks.

Clinical signs are consistent with central nervous system pathology and include incoordination, loss of equilibrium, tremors, torticollis, paralysis, and death. Gross lesions may be confined to the brain with involvement of both the cerebellum and cerebrum. Lesions have been described as large, hardened, grayish, and circumscribed (2) or as focally extensive areas of prominent red discoloration (5). Pulmonary granulomas are seen in some cases (2).

Histologically, lesions are characterized by multifocal to coalescing areas of infiltrates of massive numbers of heterophils, macrophages, and multinucleated giant cells with central areas of necrosis. The dematiaceous hyphae of *Dactylaria* are readily apparent in hematoxylin and eosin stained tissue sections. The hyphae typically are scattered throughout the lesion in a random arrangement and are yellow to light brown, septate, irregularly branched, and 1.2–2.4 μm in diameter.

Small pieces of brain tissue containing the lesions can be ground and inoculated onto slants of Sabouraud's dextrose agar and incubated at both 24°C and 37°C. *Dactylaria gallopava*

grows well at both room temperature and 37°C; however, maximum growth of this thermophilic fungus is achieved at 45°C. Chloramphenicol (0.05 g/liter) may be used in the media to retard bacterial growth. Growth is inhibited on media containing cycloheximide (4). Within 2–5 days at 24°C or 37°C, the colonies appear on Sabouraud's dextrose agar as velvety, gray-brown colonies with a flat or wrinkled surface, and the reverse side of the colony is a deep purple-red. The red pigment diffuses into the surrounding medium, forming a halo around the colony. Microscopic examination will show light-tan-to-brown septate hyphae and oval two-celled, brownish conidia (3.2 × 9.0 μm) borne on short unbranched conidiophores.

Occurrences of dactylariosis have been associated with contaminated litter and egg incubators. Introduction of contaminated wood chip and sawdust litter was implicated in an outbreak in chickens (7). The organism apparently prefers acidic environments with moderately high temperatures.

Dactylaria gallopava occurs and grows in effluents of acid hot springs, acid thermal soils, and coal waste piles (6). Removal of contaminated litter and decontamination of incubators by fumigation is recommended when outbreaks occur.

Sporadic Fungal Infections

Histoplasmosis

Histoplasmosis is an infectious, but not contagious, mycotic disease of humans and animals. It has been reported commonly in zoo birds, and occasionally, in chicken and turkey populations. It occurs worldwide, especially in areas in the United States bordering the Missouri, Ohio, and Mississippi rivers where the disease appears to be indigenous. *Histoplasma capsulatum* is a dimorphic fungus that occurs as an environmental mold and as a yeast in its warm-blooded hosts. Infection is acquired by inhalation of conidia produced by the mold form.

The *Histoplasma capsulatum* organism grows readily in culture media and soil as a white to brown mold that bears spores of two types: 1) spherical, minutely spiny microconidia 3–4 μm in diameter and 2) spherical, or rarely clavate, macroconidia 8–12 μm in diameter, with evenly spaced finger-like projections. The organism grows in the yeast-like phase, but with difficulty. It requires a temperature of 37°C, a medium rich in protein, preferably blood, and high levels of humidity and carbon dioxide.

The mycelial phase grows on Sabouraud's medium, dextrose agar, potato, gelatin, or bread at any temperature. Colonies appear as white to brownish mold after 2 weeks. The segmented branched hyphae are 2.5 μm wide and give rise to chlamydospores, often in chains with large round cells 20 μm in diameter.

Dodge (1) found the organism in samples from a starling roost in Italy and in soil samples from the adjacent schoolyard; a high proportion of the school children were histoplasmin-positive.

Diagnosis is based on 3 criteria: culture of the organism, histopathology, and histoplasmin sensitivity. The characteristic histopathology is histiocytic to granulomatous inflammation with intracytoplasmic narrow-based budding yeasts measuring 2–4 μm in diameter.

Mold cultures of *H. capsulatum* should be handled with disposable gloves within a biological safety cabinet and care should be exercised to disinfect equipment with phenol-based disinfectants. Plates should not be removed from the safety cabinet until sealed and their surfaces disinfected.

Cryptococcosis

Cryptococcosis is a disease of humans and animals. In humans, it is characterized by a meningitis. Synonyms are torulosis, torula, yeast meningitis, and European blastomycosis.

Although it has not been diagnosed as a pathogen in birds and epizootics have not occurred, its importance to public health and its occurrence in bird's environments warrant discussion. The disease is distributed widely around the world, and although not of economic significance in poultry, there are many sporadic reports from zoo birds.

The fungus belongs to the imperfect yeast group under the

name of *Cryptococcus neoformans.* It reproduces by budding; cells are perfectly spherical and surrounded by a thick mucilaginous capsule. Cell diameter is 4–6 μm, and the capsule is 1–2 μm thick. It grows well within 48 hours at 30°C on glucose agar.

Bisbocci (1) isolated cryptococci from a pheasant with enterohepatitis. Chickens were experimentally infected and developed the disease. Lesions consisted of granulomas and necrotic processes in liver, intestines, lungs, and spleen.

Emmons (3) shocked the public health world by isolating *C. neoformans* from 16 of 19 premises and 63 of 111 specimens of pigeon droppings. The organism was found in the dropping sites but was not isolated from 20 pigeons examined. It appeared to grow as a saprophyte. Bishop *et al*. (2) confirmed those findings by isolating *C. neoformans* from 6 of 13 samples of pigeon nests and droppings.

Staib (5) isolated cryptococci from 28 fecal samples obtained from 201 species of birds at zoological gardens and pet shops in Germany. Twelve isolates were from canaries, one was from a wild pigeon, and the remainder were from psittacine and other birds. Fragner (4) isolated cryptococci from feces of 48 pigeons, 13 fowl, 7 pheasants, 10 house martins, 4 jackdaws and 3 chaffinches.

Infections can be diagnosed by culturing the organism. Histopathology has proved useful in diagnosis of cases in mammals. A significant feature is absence of an inflammatory reaction despite the presence of massive numbers of cryptococci in infected tissues. Mucicarmine stain is used to demonstrate the thick capsule and delineate the budding spores by imparting a deep red color to the capsule.

Prognosis is grave in cases of cryptococcal meningoencephalitis.

Zygomycosis (Phycomycosis)

The zygomycoses primarily are caused by fungi belonging to genera *Mucor*, *Rhizopus*, *Absidia*, *Rhizomucor*, and *Mortierella* of the order Mucorales. Commonly used synonyms are mucormycosis and phycomycosis. The clinical syndromes associated with a zygomycosis are dependent upon the organ or system infected. Zygomycoses are encountered in both birds and mammals, and infection of mammals is associated with immunosuppression. In avian species, zygomycoses are uncommon. Both localized and systemic infections in birds have been reported (1). The zygomycoses are acquired from environmental sources, are not contagious, and occur in birds, animals, and humans.

Bigland (2) reported a case of systemic zygomycosis in a penguin that died following a course of clinical signs progressing from incoordination and unilateral photophobia to paralysis. A pedunculated, "orange-sized," intrathoracic, homogenous, gelatinous mass that involved ribs, vertebral column, spinal cord, and thoracic soft tissues was seen at necropsy. The posterior chamber of the enlarged globe of the right eye also contained a homogenous mass of similar texture. Nodular airsacculitis was also noted. A tentative etiologic diagnosis of *Mucor* was based on histologic and mycologic examinations.

A case of pulmonary zygomycosis in a chicken presented at necropsy with multifocal white nodules in lung parenchyma as the sole lesion. The diagnosis of zygomycosis was based upon histopathology (6). A case of zygomycotic airsacculitis, with involvement of intercostal musculature, in a duck yielded growth of *Mucor* (5).

Zygomycotic ventriculitis and proventriculitis resulting from *Rhizopus* (7) or *Mucor* infection (3) have been described in ostriches.

Zygomycoses can be diagnosed with relative assurance by histopathology. Lesions are characterized by pyogranulomatous or granulomatous inflammation usually with a pronounced component of multinucleate giant cells. Necrosis and angioinvasion are near-constant features. Granulomas typically have a necrotic center. The zygomycetes are more easily visualized with periodic acid-Schiff or Gomori's methenamine silver stain. Hyphae are relatively wide (7–20 μm) with nonparallel sides and irregular distensions, with no or few septae, and infrequent random branching.

Specific etiologic diagnosis is based upon growth and colony characteristics and microscopic morphology. Samples can be streaked on Sabouraud's dextrose agar with chloramphenicol. Cycloheximide inhibits growth. Growth is relatively rapid at 27°C, mature colonies are obtained within 4 days in most cases. Information concerning differentiation of the genera in laboratory culture is most easily obtained by consulting an illustrated laboratory manual (4).

Macrorhabdosis (Megabacteria)

Megabacteria have recently been shown to be novel anamorphic ascomycetous yeasts and not bacteria. The name *Macrorhabdus ornithogaster* has been given to the organism (8) and the disease is referred to as "avian gastric yeast infection." The organism causes a progressively debilitating, gastrointestinal disease typical of malnutrition characterized by emaciation, prostration, anorexia, cachexia, and death (2). Mortality can be as high as 90%. Characteristic large, gram-variable, PAS+ organisms are found in fecal smears and in large numbers in the proventriculi and koilin layer of the ventriculi of affected birds (Fig. 25.5). They are often arranged in parallel bundles in tissue sections and are most numerous in the isthmus between the proventriculus and ventriculus. *Macrorhabdus* needs to be differentiated from *Candida,* which is similar in size and morphology. Combined antibacterial and antifungal treatment has been used to reduce losses. Depopulation, thorough cleaning and disinfection, and leaving the premise vacant for at least 6 weeks are necessary to control the disease. Prevention in ostriches is based on isolation from pet and free-living birds, providing good husbandry and nutrition, and minimizing stress (1).

A variety of avian species are susceptible to infection with the yeast (2) and it is a serious problem among pet and aviary birds. Among domesticated birds, *Macrorhabdus* infection has been identified in chickens, turkeys, guinea fowl, quail, partridge, pigeons, ostriches, and rheas (2, 3, 4, 6, 7). Proventriculi are enlarged because of thickening of the walls and there is moderate to marked lymphoplasmacytic and heterophilic inflammation of the proventriculus and ventriculus microscopically. Numerous megabacteria, especially in areas of heterophilic inflammation, are present in the mucus, proventricular crypts, and occasionally penetrate the epithelium. Most birds with megabacteria have other concurrent diseases (4, 7).

Day-old chicks were readily infected with an isolate from a budgerigar. The organism multiplied in the proventriculus and isthmus. Efficiency of food utilization was impaired but growth was not affected (5). This study indicates the possible threat to the poultry industry posed by *Macrorhabdus.*

25.5. Large, elongated, variably stained gram-positive organisms arranged in parallel bundles in the glandular crypts of the proventriculus are diagnostic features of *Macrorhabdus ornithogaster.* Gram stain, ×400. (Dr. O. Fletcher)

IV Parasitic Diseases

Chapter 26
External Parasites and Poultry Pests

Nancy C. Hinkle and Leslie Hickle

Introduction to Arthropod Pests

External parasites, or "ectoparasites," are arthropods that live on or in the skin or feathers, using the host as both shelter and food source. Ectoparasites can have significant impacts on animal health and productivity. Other pests found in the environment can also have both health and economic effects. Although many avian ectoparasites exist, this chapter focuses specifically on those associated with poultry production.

Flies, beetles, mites, and other arthropod pests present concerns for commercial poultry operations. Modern high-density, confined housing systems create conditions favoring development of manure-breeding flies, beetles associated with accumulated litter, and northern fowl mites.

The three main poultry production facility types (caged-layer, broiler, and breeder houses) have their own pest problems and unique management needs. A poultry house with its stable environment, regulated temperature, high ambient humidity, and abundant food provides a nearly ideal habitat for several arthropod pests, explaining why flies and stored product beetle pests thrive in such situations. Animals maintained in close proximity to one another readily share ectoparasites, as in high-density housing.

Caged-layer houses, especially environmentally-controlled, deep-pit, or high-rise houses, are widely used for commercial egg production. Typically, they consist of two to four cage tiers on each side of an aisle, with multiple birds per cage. The deep pit below presents the greatest fly-breeding potential, because of manure accumulation under the cages.

Broiler houses are constructed as wide-span structures with litter (locally varying from rice hulls to wood shavings) covering the floor upon which the birds roam freely. The dry litter does not support maggot development, but high beetle populations may thrive under these conditions. Breeder or broiler-breeder houses are also wide-span structures with birds running free on a litter central portion surrounded on both sides by elevated slats supporting nesting boxes and hen feeders. The dead air space under the slats creates an area of high humidity, inhibiting manure drying and producing conditions conducive for fly oviposition and maggot development. Because of direct bird-to-bird contact, northern fowl mites can spread rapidly in breeder houses.

Animals have physical, physiological, and behavioral adaptations that affect their susceptibility to ectoparasites, including plumage, immunological responses, and grooming predilections. Commercial genetic (breeding) lines typically are developed and chosen for features other than resistance to ectoparasites, but host animal resistance is a characteristic that can be genetically selected and may offer future control options.

The all-in/all-out practice limits flock-to-flock transmission. Through sanitation, ectoparasite exclusion, and use of ectoparasite-free stock, poultry facilities can maintain flocks free of lice, mites, fleas, and other external parasites. Alternate hosts (such as wild birds and rodents) and contaminated fomites (egg flats, equipment, personnel, etc.) must be kept away from uninfested birds to prevent transmission. Broiler facilities seldom have ectoparasite problems because the interval from chick placement to slaughter is too short for arthropod populations to build to substantial levels.

Ectoparasites vary in their host specificity, with some (such as bird lice) living exclusively on birds. Others with intermediate host ranges (such as sticktight fleas) primarily are found on birds, but can develop successfully on mammals. Generalists (such as mosquitoes and bedbugs) are equally comfortable utilizing birds and mammals, frequently moving between the groups during their lifetimes.

Pest biology, ecology, and behavior determine the effect these arthropods have on their hosts, including infestation duration and severity. Similarly, bionomic attributes affect control strategies and determine their effectiveness.

Etiology

The three most significant arthropod pests in poultry production are flies, beetles, and mites (12).

Flies Associated with Poultry Production

Among the numerous species of muscoid fly pests on or around poultry operations, the most important develop primarily in accumulated manure and include the house fly (*Musca domestica*) and the little house fly (*Fannia canicularis*). Other flies commonly associated with poultry include blow flies (Calliphoridae), flesh flies (Sarcophagidae), dung flies (Sphaeroceridae), and fruit flies (Drosophilidae).

Classification
*House Flies (*Musca domestica*)*
House flies are gray, about 1/4 inch long, and present year-round in poultry houses, due to the suitable conditions continuously

maintained in such facilities (Fig. 26.1A). Not only are they annoying, but they can spread more than 100 disease agents to animals, including humans (20). Because they have sponging mouthparts, house flies cannot bite; however, they may play a significant role in pathogen transmission to humans and other animals. Flies carry tapeworm and nematode eggs externally and in their digestive tracts, subsequently transmitting the worms when the flies are eaten by poultry. House flies do not affect birds directly but can cause public health problems, disturb neighbors, and incite legal action by offended parties. Fly populations may create a public health nuisance around the farm and nearby communities, resulting in poor neighbor relations and threats of litigation. House flies have a potential flight range of up to 20 miles, but they are usually found within 1–2 miles of their breeding site. They reproduce in moist manure, spilled feed, and other decaying organic materials. The house fly life cycle can be completed in as little as a week at optimum conditions. House flies are active during the day, particularly when temperatures are between 25°C and 33°C. They are inactive at temperatures below 7°C.

House flies live an average of two to four weeks, with a female capable of producing up to six batches of 75 to 200 eggs at 3- to 4-day intervals. Females oviposit on moist manure, and the eggs generally hatch within 24 hours. Although development is temperature-dependent, larvae (Fig. 26.1B) can complete three instars, pupate in drier areas, and emerge as adult flies within 7–10 days in typical poultry house conditions. Adult flies tend to remain near larval development sites but may disperse several kilometers, with factors promoting dispersal poorly understood. Preferred resting sites become covered with "fly specks," consisting of regurgitated material and darker fecal spots.

House flies are implicated as carriers of rotaviruses (32), *Shigella* (22), trachoma (9), *Helicobacter pylori* (14), mycobacteria (10), *Escherichia coli* (28), *Corynebacterium pseudotuberculosis* (34), *Giardia lamblia* (8), *Vibrio cholerae* (11), and *Cryptosporidium parvum* (13).

Intervention Strategies

Management. In layer houses, if manure is rapidly dried as it is deposited, manure will form a cone-shaped mound as it accumulates, and only fresh additions at the peak will be suitable for oviposition and maggot development. Houses with scraper boards usually have drier manure rows than those without, but the effect is negated if water leaks exist.

Manure moisture is reduced by ventilation, which also maintains desirable air temperatures, removes gases such as ammonia, and provides fresh air. In environmentally controlled high-rise houses, exhaust fans located in the manure pit walls provide ventilation, drawing fresh air in through ceiling inlets, circulating it through the cage area, and pulling it out over manure in the pit. Exhaust fans located on both sides of the pit can help reduce moisture. Supplemental fans suspended above the manure rows will enhance manure drying, reducing house fly production in the pit.

Another tool that assists in managing insect populations in high-rise layer houses is in-house composting (26). Active composting is produced by incorporating a carbon source and agitat-

ing the manure to add oxygen and enhance microbial activity. Each time the manure is turned, it is heated up as microbial breakdown is stimulated, increasing the temperature and releasing additional ammonia. Core temperatures exceed the fly thermal death point, killing eggs and pupae; mobile larval stages may migrate away from the heated regions. Immobile beetle stages, likewise, are killed by this process. Constant disruption makes the habitat inhospitable for species with long life cycles, favoring colonizers.

Composting eliminates beneficial arthropods, so severe pest rebound situations may develop if composting ceases. Because turning machines cannot handle high piles, the house must be cleaned out once the pile reaches ca. 0.65 m in height. And disturbing the manure produces intense ammonia flushes, necessitating the use of appropriate protective devices.

Conscientious facility sanitation is another factor in fly control. Mortality must be removed daily and properly disposed of according to local ordinances. Spilled feed and broken eggs attract pest beetles and adult flies. Grounds maintenance, including mowing weeds and grass around houses, limits resting areas for adult flies and permits optimum airflow through the fans.

To minimize fly numbers while sustaining beneficial predator and parasitoid populations, manure management must be a year-round priority. Conserving manure and allowing it to accumulate over long intervals promotes beneficial arthropod populations. Manure produced immediately following cleanout dries slowly and has low beneficial constituents, making it ideal for fly breeding (16). Typically, severe fly outbreaks occur 3 to 6 weeks following cleanout, unless manure is removed only during cooler months when fly activity is minimal.

Chemical Treatment. Judicious use of insecticides against house flies is one component of a total house fly suppression program but should only be used as an adjunct to nonchemical strategies such as manure and moisture management. Residual insecticides applied to fly resting surfaces such as walls and overhangs or fly baits targeted at sites where flies congregate will assist in lowering adult fly numbers. Baits are ineffective when flies have access to alternative food.

Little House Fly (Fannia)

The little house fly (*Fannia*) is the predominant fly in California open-style layer houses during the winter. The little house fly resembles the house fly but is only two-thirds the size (ca. 0.4 cm) and has three brown stripes on the thoracic dorsum. At rest, *Fannia* hold their wings over the back, creating a narrower V-shape to the wing outline (Fig 26.2).

Its developmental cycle is similar to but longer than that of the house fly. Eggs are deposited on decaying organic material, especially mammal and avian excrement. Larvae hatch from the eggs in ca. 48 hours and feed in the manure, requiring eight days or longer to complete development to the pupal stage. Lesser house fly larvae are flat, brown, and spiny, a distinctive appearance retained by the pupa. Typically, egg to adult interval is two to three weeks, with the pupal period requiring almost a week. Although house flies are warm weather pests, developing optimally in summer conditions, *Fannia* develop poorly at temperatures above
26.2. *Fannia* spp. Adult and spinose larva. (Coop Extention, University of California).

27–30°C, so populations often rise in early spring, decline in midsummer, then peak again in late fall.

Male *Fannia* exhibit a distinctive lekking behavior, hovering ca. 1.7 m off the ground within poultry houses or outside in wind-protected areas, where they wait for passing females. This places them at head-level with humans, making them particularly noticeable and annoying. Strong air currents tend to disperse these male aggregations.

Little house flies are less likely to enter homes than are house flies; instead they tend to congregate in sunlit outdoor areas such as patios, entryways, and garages. They seldom land on human foods and are not considered a significant carrier of human pathogens. However, the males' habit of hovering at face height makes them annoying, although they readily move out of the way when approached.

Larval *Fannia* are adapted to utilize a wide moisture range in their developmental sites, making them particularly difficult to control through manure management (25). Oviposition and larval development frequently occur in animal wastes, but various moist organic materials can serve as suitable substrates.

Intervention Strategies
Eliminating breeding sites is the preferred method of controlling *Fannia*. Manure accumulations and other decaying organic matter provide ideal developmental sites. *Fannia* are not attracted to the same fly baits or traps that collect house flies. Placing fans in areas where male *Fannia* tend to congregate can disperse their swarms, because the increased air movement makes the site less attractive to them.

Other Pest Flies
Flies in the family Calliphoridae (blow flies, green or blue bottle flies) primarily develop in carrion and can become problems where poultry carcasses or broken eggs accumulate. Larval habitats include bird carcasses, broken eggs, dog feces, and other garbage. Adult blow flies are metallic blue, green, or black and are 1/4 to 1/2 inch long.

Small dung flies of the family Sphaeroceridae are common throughout the world, and species such as *Coproica hirtula* can be especially numerous in the weeks immediately following cleanout. They are very small, blackish or brownish flies that breed in manure and other decaying materials, often occurring in large numbers in poultry manure. Being colonizers, they frequently are among the first insects to arrive in new manure, allowing them to exploit the habitat before competitors move in. Adult sphaerocerids predominate where manure moisture is highest, typically the peak of the manure cone, but forage over a broad range of manure moisture conditions. Generally, they are not a nuisance on the farm or in nearby communities because of their fidelity to the manure ecosystem. Because they can serve as an alternative food source for beneficials such as hister beetles, control efforts are discouraged.

Fruit Fly, Drosophila melanogaster
Fruit flies are common around rotten or fermented food. They are 1/8 inch long, gray or brown, and usually have red eyes. Fruit flies lay their eggs on the surface of rotting organic materials, such as wet feed, manure, or broken eggs. The most common breeding sites are on dropping boards, or in belt houses where belts are run less than once a week. Adults are also common in egg rooms, offices, and other cool, shady areas. Fruit flies are annoying and can transmit bacteria or other disease organisms. Fly populations are highest in the winter months and early spring but decline by summer. Fruit flies are weak fliers and seem to "swarm" when workers walk through poultry facilities. *Drosophila repleta* is a pest in caged layer and breeder houses where wet feed provides suitable larval habitat, accumulating on slats, dropping boards, or other difficult to clean and treat locations (15).

Economic Significance
Although fruit flies are not known to cause direct production losses in poultry, except for their role in avian pathogen transmission, their primary economic impact is through annoyance of people on and near the poultry operation. Flies regurgitate and defecate on resting surfaces, causing unsanitary and unsightly specks on eggs, facilities, etc. Flies irritate workers and disperse to surrounding areas where the presence of flies may constitute a violation of health ordinances and create liability issues. Producers may be compelled to institute costly corrective actions or close the operation in severe cases. Because male *Fannia canicularis* assume aerial patrolling positions hovering at eye level in close proximity to humans, they are particularly visible and objectionable.

Biological Control Organisms

The black dump fly (*Hydrotaea aenescens*) is also common in poultry manure, with larvae frequently being mistaken for those of house flies and other pests. *Hydrotaea* eggs are laid in manure and hatch within 24 hours. The larvae are facultative predators, feeding both on manure and larvae of other flies. They require two weeks or more (14 to 45 days) for development to the adult stage (17). All stages are found throughout the year under suitable conditions in poultry houses. Black dump flies are 1/4 inch long, shiny, and a bronze-black color. Adults stay on the food source at night, unlike house flies and little house flies. Females lay their eggs on dead birds, spoiled feed, or very wet manure. Adult black dump flies prefer the darker areas of poultry houses and will congregate in manure pits. Black dump fly larvae are biological control agents of house fly maggots and can be mass propagated on poultry premises for inundative releases in infested houses. However, they are not entirely beneficial because populations can explode and move to neighboring homes and businesses. Like house flies, they leave vomit/fecal spots on eggs and equipment.

The soldier fly, *Hermetia illucens*, can serve as a biocontrol agent of other, more serious fly pests, but may be considered a pest itself. They are more common in high-rise, deep pit, caged-layer houses. Soldier flies are bluish black and 3/4 inch long, with large eyes and long antennae that project forward from the head. Females choose to lay their eggs in drier manure. Soldier fly larvae are large and churn manure as they develop, making the environment less hospitable to house fly maggots. They also inhibit house fly oviposition. Larvae will also feed on dead birds. Soldier fly adults are weak fliers and spend their time basking in sunny areas on structures or vegetation.

Natural biological control organisms include parasitic wasps (*Muscidifurax* and *Spalangia*), which attack fly pupae, as well as predatory mites (*Macrocheles muscaedomesticae*) and hister beetles (*Carcinops pumilio*), which feed on fly eggs and larvae (4). Manure that ages and dries supports fewer flies, due in part to the complex assemblage of natural enemies that colonize it over time (21). Because flies colonize and reproduce more rapidly than their natural enemies, flies tend to proliferate immediately after a manure cleanout. Although producers may collect extant predators/parasites for release and re-establishment following cleanout, this practice may perpetuate disease agents, as well (19).

Intervention by Management or Insecticides

Direct application of larvicides to manure is discouraged due to their deleterious effects on natural enemies of flies. Predatory and parasitic insects and mites in the manure can kill most fly immatures before they become adults.

Manure management and other forms of cultural control are critical to fly suppression, determining the type and effectiveness of other fly control methods, including chemical and biological components. For instance, frequent clean-out coupled with thin-bed manure drying may work seasonally in some areas, but it also can increase odor and dust problems.

Manure can accumulate for several months in open-sided single-story housing, or for a couple of years in two-story, deep-pit housing where manure falls into a separate pit level below the upper story that houses the hens. In these situations, manure must be effectively dried to make it less suitable for fly oviposition and larval development, while encouraging the activity of natural enemies.

Manure conditions suitable for fly development include fairly moist but not liquefied consistency, with house flies abundant in 65% to 80% moisture manure, but rare if moisture levels drop below 60% (30).

Beetles

Two beetle species associated with poultry litter and manure accumulations can cause structural damage to poultry housing, serve as potential disease reservoirs, and create community problems by migrating to nearby homes at cleanout.

*Darkling Beetles (*Alphitobius diaperinus*)*

The most significant arthropod pest in broiler production worldwide is the darkling beetle, *Alphitobius diaperinus* (Fig. 26.1C), whose larval stage is known as the lesser mealworm (Fig. 26.1D). These beetles are omnivorous, feeding on spilled feed, bird droppings, dead birds, and other components of the litter environment, as well as being cannibalistic.

The poultry house provides an ideal environment for darkling beetles, including a temperate climate, plentiful food, a protected habitat in the litter, and relatively high humidity. There are no known predators or pathogens, but cannibalism helps regulate populations under extreme crowding.

Larvae concentrate in protected areas under feed lines, feeder trays, etc. Newly hatched larvae are less than 1 mm long, but feed and molt 6 to 11 times, reaching ca. 18 mm before pupating. The final instar larva (prepupa) is the migratory, nonfeeding stage that seeks sheltering crevices in which to pupate, hollowing out a crypt in which to conceal itself while transforming from the larval to pupal stage (Fig. 26.3). Within 3 to 13 days, the adult emerges. Adult darkling beetles are ca. 1/4 inch long, dark brown or black, with subtle striations on the wing covers. Typical adult lifespan is 3 months to 1 year. In the laboratory, darkling beetles have been shown to live over 700 days (27), with females averaging over 800 eggs in their lifetime. Generally, large numbers of beetles are not observed in houses until manure has accumulated for 5 or 6 months.

Alphitobius beetles have been shown to harbor several poultry pathogens including *Escherichia coli*, *Salmonella typhimurium* (5), *Campylobacter jejuni* (29, 31), and the viral agents of fowl pox, avian leukosis, Marek's disease, Newcastle disease, and avian influenza. Additionally, they serve as intermediate hosts of several helminths (3).

These beetles cause structural damage when prepupae tunnel into insulation and structural materials to pupate, and large populations may present problems at clean-out because of migration from fields into nearby residential areas. While beetles are capable of flying up to a mile, they typically move by crawling.

Tunneling activity of lesser mealworm larvae may aerate and

dry the accumulated manure, permitting penetration by predaceous beetles and mites.

Darkling beetles cannot survive prolonged exposure to freezing temperatures, so houses in cold climates can utilize between-flock chilling to reduce beetle numbers. Pupae in insulated protected areas where micro-habitat temperatures do not drop below 0°C (clay floors, expanded foam insulation, etc.) will survive to perpetuate the infestation.

Hide Beetle (Dermestes maculatus) and Larder Beetle (D. lardarius)

Hide beetles are scavengers, attacking carcasses and feathers, as well as causing structural damage to facilities as prepupae tunnel in preparation for pupation. Mature larvae stay in poultry litter or bore into structures (wood, paneling, dry wall, or insulation) to pupate. As a result, "honeycombing" and structural weakness may occur. Adults are 1/3 inch long—slightly larger than darkling beetles. Hide beetles are dark brown with white ventral pilosity. Larvae are thickly covered with long hairs and reach a length of almost 18 mm before pupating. They are scavengers and will feed on dead birds, skins, hides, feathers, dead insects, or broken eggs. Because they are capable of digesting keratin, hide beetles assist in the breakdown and recycling of shed feathers. Females lay their eggs on manure and litter in poultry facilities. The hide beetle life cycle is completed in four to nine weeks, with adults living two to three months.

Beetle Suppression

Darkling beetles are more prevalent in broiler houses, while both darkling beetles and hide beetles frequently occur in layer facilities. Beetle control can be particularly challenging in broiler houses, because most pesticides cannot be applied when birds are present, limiting control activities to intervals between flocks. After a poultry house becomes infested with darkling beetles, they migrate throughout the house, making control difficult. Thoroughly cleaning the house and treating with an approved insecticide typically will suppress the population for a short time. Migration may be reduced by using physical barriers to prevent larvae and adults from climbing walls and posts.

Broiler production practices limit beetle control options. When complete clean-out is delayed for prolonged intervals, deep litter becomes a haven for the beetles, providing food, warmth, and a protected environment. If litter or cake is taken from the house and piled nearby, beetles will migrate back into the houses, so cleanout should be followed by immediate removal of litter from the premises.

At cleanout time, large numbers of beetles may disperse into the community. A litter pile can be solarized by covering it with a tarp that is sealed at the base to prevent pest emigration. Heat built up within the pile kills beetles; however, anaerobic conditions produce noxious odors and create condensate.

Applying dusts and sprays to litter and manure can be effective, but such tactics can destroy existing fly biological control agents. Many of the approved insecticides rapidly degrade under the high pH conditions found in poultry litter, so do not maintain their effectiveness very long. Additionally, the larva is able to burrow into the built-up litter, evading insecticides. In-house pesticide applications can help to reduce beetle numbers if applied at vulnerable points. The most effective strategy targets insecticide application following flock removal, immediately after the litter is decaked. Once birds exit the house, beetles migrate, so timing is crucial. In cool weather, leaving the house heated for a few days will stimulate beetle activity, maximizing their exposure to the pesticide residue. Another opportune treatment time is about the third week of the flock cycle, targeting spot treatments to the area directly beneath feeders before beetles and larvae that are concentrated under feeders begin to disperse. The second treatment opportunity is limited to insecticides that can be used while birds are present, so attention to label restrictions is critical.

Mites

The northern fowl mite, *Ornithonyssus sylviarum* (Family: Macronyssidae) (Fig. 26.4) is the most important mite on caged-layers, breeders, range turkeys, and pheasants. Northern fowl mites feed on blood and can cause anemia, itching, irritation, and reduce egg production by 10–15%. Large northern fowl mite populations can cause direct economic losses by affecting bird health and productivity (7). Heavy infestations (> 50,000 mites) can drain up to 6% of a bird's blood daily, lowering weight gains and, in male birds, reducing seminal fluid volume. Mites also annoy egg handlers and other personnel. The infestation originates on the vent and then moves to the tail, back, and legs of fe-

26.5. Two levels of feather blackening and spoiling by northern fowl mite. (Matthysse)

males; the mites are more scattered on male birds. Infested poultry have feathers soiled with mite eggs, cast skins, dried blood, and excrement. The most obvious signs that a bird is infested with northern fowl mites are black feathers and scabs in the vent area (Fig. 26.5). Northern fowl mites flourish in colder weather and become well established in large numbers after poultry reach sexual maturity, being more common on four- to ten-month-old birds. Older birds apparently develop resistance to mites, seldom supporting the high mite numbers experienced by younger birds. The life cycle consists of egg, larva, two nymphal stages, and adult, and can be completed in as little as one week. All life stages occur on the host, but mites can survive for a few weeks off the avian host and readily move along cage wires to infest other birds (24). Rodents and wild birds are reservoirs for the mites and help spread them to poultry.

Northern Fowl Mite Management

Northern fowl mite control in caged layer operations depends on efforts to prevent infestation and to apply an acaricide when infestation occurs. Mite-free birds should be used to stock clean houses, to prevent northern fowl mite infestations. Because mites can be introduced on personnel, equipment, and wild animals (e.g. rodents and birds), flocks should be regularly inspected for mites. Using a bright light the inspector should part the feathers around the vent and look for mites, mite debris (eggs, shed skins, and feces), and scabbing. Caught early, an infestation can be forestalled by treating birds in proximity to the infested birds to limit mites from radiating outward.

Effective chemical control in caged layer operations requires direct acaricide application to the vent region with sufficient sprayer pressure to penetrate the feathers and deliver the pesticide to the skin. To reach the vent, the spray wand (delivering spray at 100 to 125 psi) must deliver the spray upward from beneath the cages. Ready-to-use dust formulations are available for mite control and can be applied to caged layers using a power blower. In broiler-breeder operations and other situations where birds are not confined to cages treatment is more difficult, necessitating individual application.
Typically, mite population buildups are greatest in young flocks, while older birds seldom support numbers necessitating treatment. Mite populations are generally highest in cool months, and decline in summer.

On the farm, personnel should always move from mite-free areas to mite-infested flocks, to avoid transferring mites to uninfested animals. Because mites can survive on equipment, clothing, and other materials, each house should have duplicated equipment, to prevent transporting mites as items are moved among houses.

Other Mites

The chicken mite, *Dermanyssus gallinae* (Fig. 26.6), also known as the red mite or roost mite, is an occasional problem in turkey breeder facilities and grow-out houses. These parasites are visible to the naked eye and complete their life cycle in as little as seven to ten days. Chicken mites have been known to spread fowl cholera. They are transmitted to poultry via wild birds or rodents. Unlike the northern fowl mite, chicken mites spend only part of their time on the poultry host, moving onto the birds at night to feed, and hiding in crevices during the day. They can survive off their host for up to a month and will infest poultry workers or

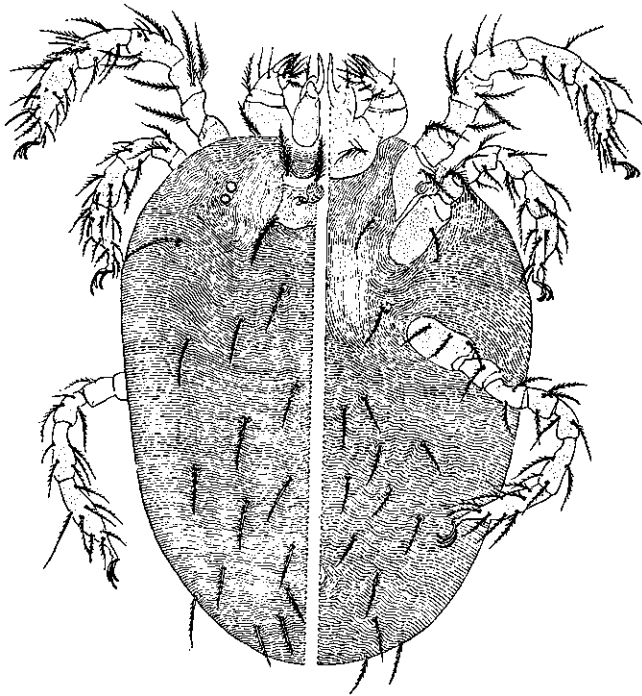
nearby facilities when infestation levels are high. In high numbers, chicken mites cause a reduction in weight gain and egg production.

The chicken mite life cycle consists of egg, larva, protonymph, deutonymph, and adult. Within 12 to 24 hours of her first blood meal, a fertilized female can lay a batch of three to seven eggs in a crevice or under debris in the poultry house. Eggs hatch within two or three days and the larva, which does not feed, molts in one to two days to the protonymph, which feeds on blood. A few days later, it molts to the deutonymph, which does not feed but molts to the adult stage after one or two days. Under optimal conditions, a life cycle (egg to egg-laying adult) requires only 7 to 9 days. However, both feeding nymphs and adults can survive several weeks without blood meals, greatly increasing the life cycle duration.

Scaly leg mites, *Knemidocoptes mutans* (Fig. 26.7), burrow under the leg scales of chickens, turkeys, pheasants, and other birds. Their presence stimulates host epithelial proliferation, resulting in hypertrophy and cornification. The legs become thickened and distorted; affected birds may be crippled if the infestation is severe. Scaly leg mites are found on wild birds, which can introduce infestations into domestic flocks. These mites complete their life cycle within 10 to 14 days.

Depluming mites, *Neocnemidocoptes laevis* var. *gallinae*, are similar to, but smaller than, the scaly leg mite. They are present throughout the United States on chickens, geese, and pheasants. Depluming mites burrow into the skin at the base of feathers on the back, wings, vent, breast, and thighs, causing intense itching and feather pulling. They are more prevalent in spring and summer, with very low numbers in autumn. The life cycle takes between 10 and 14 days to complete. Depluming mites are more common in noncommercial flocks.

Fowl ticks, *Argas persicus* (Fig. 26.8), or blue bugs, are rare pests of commercial poultry. They are light red to dark brown, 6–9 mm long as adults, and have wrinkled skin. Female fowl ticks lay their eggs in cracks and crevices near the flock. Fowl ticks are active at night, moving to the birds and taking a blood meal, causing roosting birds to act flustered. During the day these ticks secrete themselves in protected hiding places nearby. The life cycle can be completed in as little as one month. All life stages of fowl tick feed on blood, but they can live for up to a year without feeding. Ticks can transmit various bacterial and rickettsial diseases.


26.9. *Neoschongastia americana* larva, chigger of chickens. (Baker)

26.10. *Menopon gallinae*, shaft louse. (Kriner)

Chiggers, *Trombicula splendens*, *Neotrombicula alfreddugesi*, and *Neoschongastia americana* (Fig. 26.9), also known as harvest mites and red bugs, are bright red and less than 1 mm long. Birds on range may be exposed to chiggers, but housed animals are not at risk. *Trombicula splendens* feed on all kinds of animals and are most common in damp habitats. Common chiggers are prevalent in transition areas between forests and grasslands, swamp margins, berry patches, and thickets. They occur on a variety of animal hosts, as well. The chigger life cycle takes between 50 and 55 days, but the duration depends on habitat, temperature, humidity, and food quality. Larvae do not burrow or suck blood. Instead, they inject an enzyme into the animal host that causes irritation and a raised wheal. Bird carcass quality is greatly reduced due to raised, red chigger bite welts. Nymphs and adults are predaceous on insect eggs or immature arthropods. Turkeys are affected more often than chickens. Young poultry may refuse to eat and eventually die. *N. americana* is prevalent in the southern states of the United States in dry areas with hard, rocky soils. The population peaks in June, decreases in late summer, may increase in fall, and declines in the winter. *N. americana* infests chickens, turkeys, and wild birds. The chiggers feed in clusters on the thighs, breast, underside of the wings, and around the vent. Scabby lesions result and may take weeks to heal, causing carcass devaluation.

Lice

The chicken body louse, *Menacanthus stramineus* (Figs. 26.1E, F), and the shaft louse, *Menopon gallinae* (Fig. 26.10), are ectopara-

sites of longer-lived chickens in layer and breeder flocks. These are chewing lice, feeding on dry skin and feathers, with the entire life cycle (egg, nymph, and adult) occurring on the host. Female lice glue their eggs (nits) to host feathers. These eggs hatch into nymphs in about four to seven days. Nymphs have the same feeding habits as adults and resemble adults, except that they are smaller in size. Nymphs undergo several molts, reaching adulthood in about three to four weeks (6). The shaft louse is also known as the feather louse. These lice have chewing mouthparts and do not pierce the skin, but may feed on the blood in young quill feathers, biting into the shaft. The feeding habits of poultry lice actually make the avian host inhospitable to northern fowl mites, limiting mite infestation of lousy birds. Poultry lice are yellowish and approximately 1/16 inch long. They cause irritation, which leads to appetite loss and increased disease susceptibility. They are not specific to poultry, but are found on several wild bird species. Symptoms include red, scabby, irritated skin and reduced egg production (33). Pesticide resistance is not known in bird lice and recommended insecticides are typically quite effective in eliminating infestations, though entire flocks must be treated to avoid reinfestation.

Fleas

Fleas are rare in poultry facilities, but when they do occur, they are more common in breeder and grow-out houses. The European chicken flea, *Ceratophyllus gallinae*, is a nest flea that is fairly common in poultry facilities and in wild birds' nests, having been found infesting several dozen avian species (Fig. 26.11). *C. gal-*

26.13. *Cimex lectularius*, common bedbug. (USDA)

linae larvae develop in the nest material and feed on detritus and undigested blood excreted by the parents (23). Adult fleas leave the nest shortly after host fledging, often being carried away on the nestlings themselves (18). Flea larvae remaining in the deserted nests complete their larval development within a few days. The third larval instar spins a cocoon, pupates, and molts to the adult stage. Most of the imagoes remain quiescent in their cocoons until the next spring (18). Optimal temperature and humidity conditions for *C. gallinae* developmental stages are unknown, but larvae are known to tolerate a broad range of humidity (2), and high relative humidity seems beneficial to the survival of overwintering pharate adults in cocoons (18). Emergence from the cocoon is triggered by the spring rise in temperatures and mechanical disturbances (18).

The sticktight flea, *Echidnophaga gallinacea*, is also known as the southern chicken flea (Fig. 26.12). Adult females are permanently affixed to the host via their mouthparts, which are tightly embedded in the skin. Females attach themselves and lay their eggs on the face and wattles of poultry. Sticktight fleas may also attack mammals, especially dogs and cats, in close proximity to the infested flock. The life cycle of the sticktight flea lasts be-

tween two weeks and eight months. Young fowl may die, while older birds exhibit reduced egg production and anemia. Other symptoms include reduced growth, blood loss, and skin irritation. Sticktight fleas are more common in late spring and early summer.

Bed Bug, *Cimex lectularius*

Bed bugs are flat, 1/5 inch long, wingless, and bloodsucking (Fig. 26.13). Bed bugs feed at night, hide during the day, and lay their eggs in cracks of walls and other dark crevices. They can survive one to five months without feeding. The bed bug life cycle is completed in one to four months. Bed bugs leave fecal spots on walls, roosts, and eggs. Bed bugs may move from poultry houses into homes, infesting the human living environment. They are not known to transmit any pathogens, either mammalian or avian.

Control of Arthropod Pests

Historically, poultry pest management relied almost exclusively on pesticides to maintain pest populations below economic injury levels or nuisance thresholds. Because these thresholds were not well defined, control efforts typically were initiated when pests were observed, either on the birds or in the poultry house. Extensive or improper pesticide use results in destruction of biological control agents and pesticide resistance development in pests. It can also create harmful and illegal residues in meat and

eggs, as well as increasing human exposure and contaminating the environment. Pesticide resistance and elimination of biological control organisms result in bigger pest populations, increased pesticide use, and higher control costs.

Integrated pest management (IPM) programs for poultry combine cultural, physical, biological, and chemical control tactics (1). The first step in any IPM program is pest identification, including determining whether a problem exists, and its damage potential. For instance, mites are very common on manure in poultry houses. These are not pest mites, but beneficial mites that prey on flies and other pests. So presence of an arthropod does not constitute a problem. Once a problem has been identified, appropriate management techniques should be considered. Producers incorporate multiple pest management strategies into their production practices. Manure management, moisture control, sanitation, and pesticide applications are integrated with sound flock management practices to keep pest populations below economically damaging or nuisance levels. Successful IPM programs yield better community relations, improved flock performance, reduced structural damage, and lower control costs. Arthropod pest management must be implemented in concert and compatibly with other management considerations such as flock health, nutrition, facilities design, and production economics.

Cultural and Physical Control

While adult flies are considered the pestiferous stage, the larval stage should be the prime target for suppression. Fly control is dependent on manure and moisture management. Dry manure (50% moisture or less) is not suitable for fly oviposition or larval development, but simultaneously provides a desirable habitat for beneficial predators and parasitoids. Moist poultry manure is highly attractive to adult flies, emanating volatiles that lure in gravid females and stimulate oviposition. Fresh poultry manure at ca. 75 to 80% moisture also provides ideal conditions for larval development. Maggots can exploit manure having moisture levels between 50 and 85%. Saturation of manure from leaking waterers, condensation from noninsulated overhead water lines, improper ventilation, and seepage from outdoors can reconstitute previously dried manure, leading to maggot concentrations.

Biological Control

Several beneficial insects and mites are associated with poultry manure, including predaceous mites, hister beetles, and parasitoids. Compatible cultural and physical control practices encourage biological control by fostering retention of beneficial predators and parasitoids that can help suppress house fly populations.

A common predaceous beetle found in poultry manure is *Carcinops pumilio* (Family: Histeridae), a small oval black beetle ca. 3 mm long. Adults and larvae feed on house fly eggs and early-instar larvae, foraging in the surface layers of manure.

The most common predaceous mite in poultry manure is *Macrocheles muscaedomesticae* (Family: Macrochelidae), a reddish-brown mite ca. 1 mm long that feeds on house fly eggs and first-instar larvae. A single mite can consume up to 20 house fly eggs per day. These mites forage externally on the manure pile, particularly at the peak in fresh manure where fly oviposition is concentrated. Large mite populations can substantially reduce house fly numbers, so mite conservation efforts can produce significant benefit.

Another predaceous mite, *Fuscuropoda vegetans* (Family: Uropodidae), forages deeper in the manure, preying on first-instar fly larvae and complementing activity of macrochelid mites at the surface.

Parasitic wasps, or parasitoids, are tiny wasps that lay their eggs in fly pupal cases, killing the developing flies. Wasp species have predilections for specific fly groups, and most filth flies have parasitoids adapted to utilize their puparia. Naturally-occurring parasitoid populations inhabit virtually all poultry facilities, but because they are extremely small (ca. 1–2 mm), parasitic wasps are seldom noticed. A female wasp seeks for a fly puparium, then inserts her ovipositor, and deposits an egg on the pupa within. The wasp egg hatches and the wasp larva consumes the fly pupa, pupates within the puparium, and eventually emerges as an adult parasitoid.

Even though these parasitoids occur naturally wherever flies are found, parasitism rates are low and fly populations are not adequately suppressed. Control programs sometimes implement mass releases of commercially reared parasitoids to augment extant populations. For successful releases, parasitoid species must be matched to the release area, as some species are adapted for xeric conditions while others are best fitted for more humid climates. When parasitoids are used, manure management can enhance their effectiveness, and insecticide use must be minimized to avoid adverse impacts on the parasitoids.

Chemical Control

Insecticides and acaricides can play an important role in poultry IPM programs, if they are used in concert with other components of the management plan. Monitoring of pest populations serves to evaluate control effectiveness, as well as alerting personnel when interventions are required. Keeping accurate records allows better future planning, with seasonal cycles and needed actions noted. Poor timing, indiscriminate pesticide use, poor manure management, inadequate moisture control, and lapsed sanitation will increase pest populations and necessitate additional insecticide applications. Most fly insecticides are toxic to predators and parasitoids, so can result in their destruction if used indiscriminately. Selective application of these chemicals, however, can target pests with minimal impact on beneficials.

Because insecticide registrations change frequently, updated recommendations can be obtained from the cooperative extension service. Always read product labels carefully before purchase, to ensure that the product will achieve your desired result. Mix and apply as directed, do not use more than the label recommends, and follow all precautions (including personal protective gear) exactly. Remember that improper practices can lead to illegal residues, even when legal materials are used, and that it is illegal to use a pesticide in any manner inconsistent with the label.

Insecticides are available in several formulations (sprays, baits, feed additives, etc.) and target different life stages (larvicides, adulticides). Understanding the advantages and limitations of each product is essential for economic and effective use.

Space sprays, typically containing synergized pyrethrins, provide a quick adult fly knockdown in a confined space. These have very little residual activity, affecting only the flies present at the time of application.

Residual sprays are used to treat building surfaces with chemicals that persist for sustained periods, so that flies landing on these treated surfaces acquire lethal doses of the toxicant and are killed. These products should be targeted to locations where adult flies are known to congregate and spend time, such as overnight resting areas and other sites marked by fly specks.

Fly baits combine a stomach poison with an attractive food (such as sugar) to lure in flies and get them to consume the material. They are excellent selective adulticides for suppressing low fly populations, especially once numbers have been reduced using a space spray. Baits should be placed where adult flies have access to them, but with minimal contamination of predator and parasitoid habitat. In high-rise houses, baits should be distributed upstairs. In addition to locating baits so that they are inaccessible to children and other nontargets, they must be used in a way to ensure they will not be eaten by birds or contaminate their feed.

Larvicides include traditional organophosphate and pyrethroid insecticides formulated for use in the manure as well as insect growth regulators (IGRs). One IGR, cyromazine, is available as both a spray and a feed-through. This compound is selective, not affecting predators and parasitoids. However, because the feed-through material ensures that all manure in the house is contaminated, and that all maggots are therefore exposed to treated manure, this formulation has resulted in development of insecticide resistance in many house fly populations. No larvicide can be expected to substitute for proper water and manure management. Larvicide sprays are formulated for direct application to the manure surface to kill maggots. Since they will destroy predators and parasitoids in the manure, larvicides should be used only as spot treatments, targeting trouble spots in the manure where maggot numbers are high. This usage pattern will minimize impact on overall biological control while slowing resistance development.

In general, reliance on chemical control of flies is decreasing due to rising application costs, increased environmental concerns and constraints, regulatory limitations, development of resistance in the target pest, and a paucity of new insecticide products.

Fly Population Monitoring in Control Programs

Control decisions should be made based on population monitoring by a standardized, quantitative method that suits the situation. Objective sampling methods include baited jug traps, sticky ribbons, and spot cards. Several sampling devices should be placed within the house, in areas of high fly activity, and checked weekly. Weekly counts should be recorded, both as a means of signaling need for control interventions and as verification of control effectiveness.

Production practices and facilities significantly determine the types of pests that can persist in animal housing. For instance, rearing laying hens in elevated wire cages removes them from exposure to parasites and pathogens in the manure, effectively breaking the disease cycle. Minimizing harborage reduces incidence of periodic ectoparasites such as bedbugs and *Dermanyssus* mites.

Rodents

Rodents are common pests in and around poultry facilities but are not unique to poultry. Rodents are capable of extensive damage to facilities, feed and poultry unless an effective control program is implemented and maintained. Rodents undermine foundations by burrowing and destroy curtains and insulation. Rodents eat and contaminate feed, increasing feed costs and adversely affecting feed conversion. These pests serve as reservoirs for a variety of diseases and ectoparasites, and may directly attack and cause injury to birds.

Rats

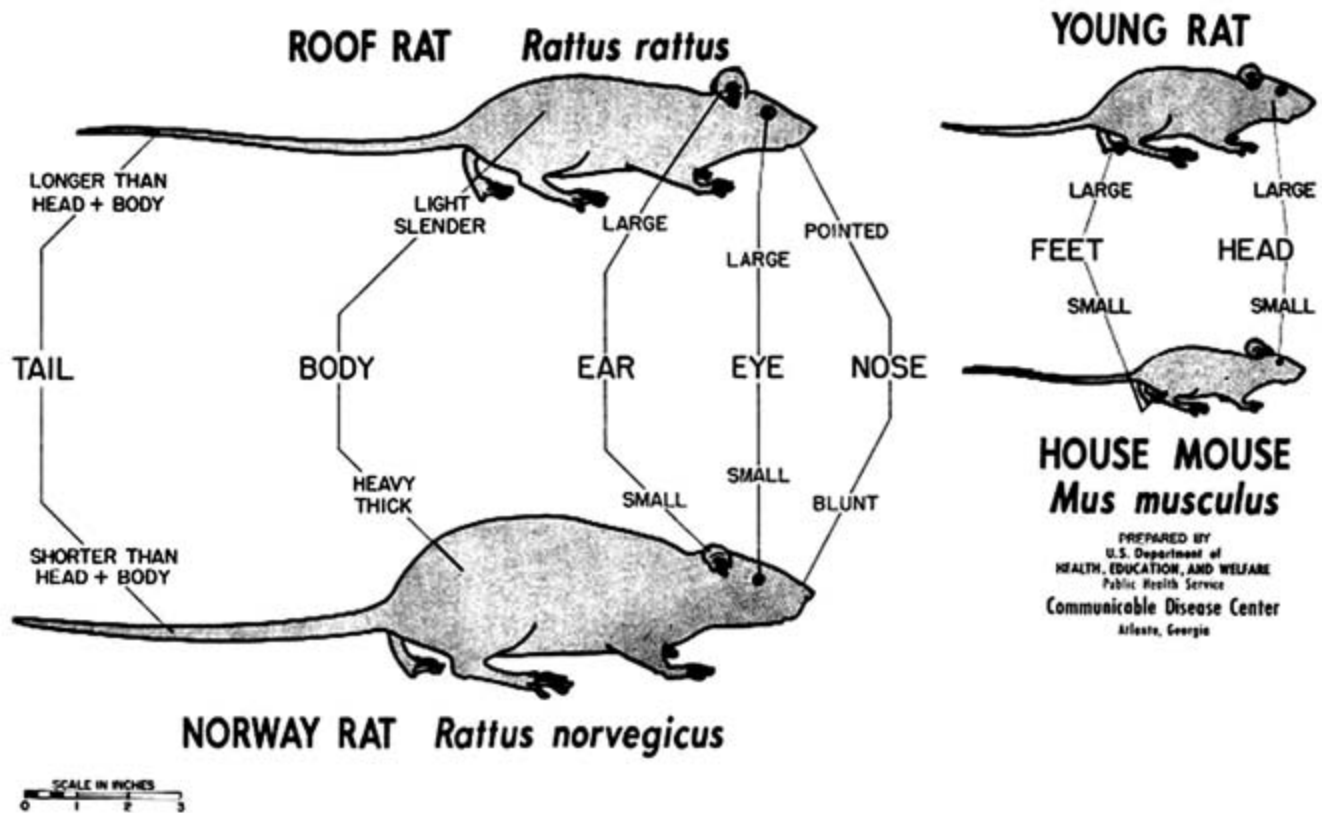
There are two main species of rats commonly found on poultry farms. These are the Norway rat (*Rattus norvegicus*) and the roof rat (*Rattus rattus*). Norway rats are easily distinguished from roof rats by their size and their nesting habits. The Norway rat is large (10–17 oz) and its tail is shorter than its body. They nest in soil outside of buildings and under concrete foundations. The roof rat is smaller (6–12 oz) and its tail is longer than its head and body combined. It nests high in buildings, lofts, ceiling insulation, etc., and in trees. Both of these rats multiply rapidly, with 3–7 litters per year. Rats breed at 3–5 months of age and the gestation period is about 3 weeks. A population of 200 adult rats reportedly consume up to 25 lbs of feed daily. Rats are largely nocturnal in feeding and other activities. Breeding is most frequent during spring and fall. Rats tend to migrate indoors in cooler weather.

Mice

The house mouse (*Mus musculus)* is the most common mouse in and around poultry facilities and wherever food, water, and harborage are available. Mice are often active throughout the day, but peak activity is at dusk or dawn. Mice burrow into the ground, insulation in the walls, rolled-up curtains, and elsewhere. Mice reproduce at an age of 6–8 weeks, and the gestation period is about 3 weeks. They produce 5–6 young per litter, and produce 5–8 litters per year. Mice tend to breed throughout the year, with no seasonal variation.

Rodent Control

Effective rodent control consists of a combination of three methods: 1) rodent-proofing of facilities; 2) sanitation and facility management; 3) trapping; and 4) effective use of rodenticides. Rodent-proofing a poultry facility is difficult, but access to buildings can be limited by patching holes in the walls and foundations, and proper screening. Sanitation simply involves cleaning up around facilities. Rodents are secretive creatures; they do not like to move about in open areas. Therefore, mowing grass and weeds on a regular basis creates a less favorable habitat. Remove piles of old wood, unused equipment, brush, discarded feed, and any other debris to make the area less attractive to ro-

FIELD IDENTIFICATION OF DOMESTIC RODENTS


26.14. Field identification of domestic rodents.

dents. Unroll house curtains twice a week even during summer months to disturb mice nesting there.

After implementing management procedures, consider an appropriate rodenticide program. Rodents can be killed with baits, fumigation, trapping, or even shooting. A properly conducted baiting program is usually the easiest and most effective means for killing rodents. Many products are marketed as rodenticides. These are of several types (Table 26.1). The largest class is the anticoagulants, which includes brodifacoum, difethialone, bromadiolone, chlorophacinone, diphacinone or warfarin. Other types include bromethalin, a metabolic inhibitor; cholecalciferol, which causes a calcium imbalance; and zinc phosphide, a metabolic poison. These products are sold under a variety of trade names. Some are effective as single doses or feedings, while others require multiple doses for effectiveness. Many of these products are available over-the-counter, but others such as zinc phosphide are highly toxic and are restricted to application by licensed pest control personnel.

For any baiting program to be effective, rodents must consume a lethal amount of the bait. Placement of baiting stations is important. Random placement of bait is rarely effective. Rodents will not seek out bait if other food is readily available. Thus, placement of bait in or close to the harborage rather than near their regular food source will be more effective. For a complete discussion of bait stations, consult pest control manuals. When using multiple-dose rodenticides, the bait should be replenished daily until the bait is no longer taken. If single-dose anticoagulants are used, the active burrows should be baited for 2 consecutive days. The burrows should be filled 4–5 days later to prevent easy recolonization. Baits are also sold in block form, which can be nailed or wired to rafters.

Acute rodenticides should be used only in cases of high rodent population when poultry and feed are no longer present. The facilities should be closed so that no animals other than rodents will have access to the bait. Bait placement is not so critical if the rodents' normal food source has been removed. All bait stations must be removed after use. Some rodenticides are available as tracking powders. These are intended to be picked up on the feet, fur, and tails of rodents, then ingested later during grooming.

An important consideration in the use of rodenticides is that resistance to some types of compounds is widespread. Even in sensitive populations, resistance may develop after repeated use of a single type of product. For long-term effectiveness of a program, it is important to rotate between types of compounds.

Table 26.1.   Commonly used rodenticides (USA).

Type	Generic name	Required feeding	LD50 (mg/kg)
Anticoagulant	brodifacoum	single	house mouse, .27–.86 Norway rat, .27 roof rat, .65–.73
	difethialone	single	house mouse, .47 Norway rat, .51 roof rat, .38
	bromadiolone	single	mouse, 1.75 Norway rat, 1.125
	chlorophacinone	multiple	house mouse, 1.06 Norway rat, 2.1–20.5 roof rat, 15.0
	diphacinone	multiple	rat, 1.86–2.88
	warfarin	multiple	rodents, 3.0
Metabolic inhibitor	bromethalin	single	house mouse, 5.0 roof rat, 6.6 Norway rat, 2.0
Calcium metabolism	cholecalciferol	single	rat, 42.0
Metabolic poison	zinc phosphide	single	rat, 45.7

Since there are many commercial products containing identical chemicals, it is important to be aware of the active ingredient and to switch between unrelated products. For instance, switching from one anticoagulant to another will not improve effectiveness against anticoagulant-resistant rodents.

Fumigants used for rodent control include methyl bromide gas and chloropicrin. These are extremely hazardous to humans and nontarget animals, and should be applied only by professionals.

Claims of rodent control by ultrasonic or electromagnetic devices remain unproven in controlled studies.

Overall, the control program must be a continuous effort to be effective. Implementation of a control program after a severe problem develops will require a great deal of effort and expense. Small rodent populations are much easier to control and less expensive. Regular monitoring for rodent activity is essential. Look for rodent signs both inside and outside at least every 2 weeks and use bait as soon as activity is observed.

Chapter 27
Internal Parasites

Introduction
Larry R. McDougald

Trematodes, acanthocephalans, cestodes, and nematodes are important parasites of poultry. In many locales the modern technology of rearing poultry has dramatically changed the importance of many species. Parasites with complicated life cycles, involving intermediate hosts such as insects or snails, were virtually eliminated when commercial poultry were brought inside. Today, only a handful of these parasites are important in commercial poultry, although many are found in small flocks reared in natural environments. A rich fauna of internal parasites can be found by examination of birds from backyard flocks, feral, or free-range birds. Wild birds of nonpoultry species have an abundant fauna of worms of all types. Many are important in the commercial production of game birds. A few nematodes, such as the ascarids, cecal worms, and capillarids, have direct life cycles and are fecund enough to prosper in the poultry house environment, particularly where management does not require frequent cleanouts. Some cestodes are important, even though they use an

intermediate host, because the host also prospers in the poultry house environment.

Control of these parasites is difficult but important. Even though there have been no new products registered specifically for control of worms in chickens in recent years, excellent products approved for use in other animals can be used off-label by veterinary prescription. Even though mild infections of the worms cause little damage, some bring in other diseases, such as the well-known relationship of *Heterakis gallinarum* with *Histomonas meleagridis*. Recent widespread clinical outbreaks of blackhead disease (histomoniasis) underscore the need for advances in this area. Cestode infestations tend to build up when beetle control is lax, signaling a need for better overall management. Among anthelminthics, few have been approved for use in poultry. Recent changes in the FDA's regulation of off-label use of products by veterinarians provide some relief by allowing poultry producers to take advantage of modern products.

Nematodes and Acanthocephalans
Thomas A. Yazwinski and Christopher A. Tucker

Introduction

Nematodes constitute the most important group of helminth parasites of poultry in the number of species, the number of animals infected, and the amount of damage done. The trematodes, cestodes, and acanthocephalans are of relatively minor importance in commercial poultry, but are important in other birds.

This chapter is designed to aid the diagnostician in identifying predominant nematodes of poultry throughout the world. Those reported in chickens raised in the United States are listed in Table 27.1; those from other domestic poultry and/or commercially raised game birds from the United States are listed in Table 27.2. (Nematodes from areas other than North America are mentioned in the text but are not listed in the tables.) Avian nematodes often

have a broad host range. Accordingly, nematodes found in wild birds may constitute a hazard for commercially raised birds (see Table 27.3). For a more detailed description of individual species, see the references listed in the previous editions of this book (62, 80) or other reviews (1, 12, 14, 16, 47). A checklist and descriptions are available for parasites reported from the bobwhite quail and waterfowl (43, 48). Additionally, the internal and external parasites of ratites are thoroughly discussed by Craig and Diamond in *Ratite Management, Medicine and Surgery* (73).

The genus and species names used in this chapter are those of Yamaguti (83), except where usage by recognized authorities supersedes his classification. Yamaguti described 25 families of nematodes from 9 orders in avian species; 13 of these families (Strongyloididae, Trichuridae, Syngamidae, Trichostrongylidae, Subuluridae, Heterakidae, Ascarididae, Spiruridae, Thelaziidae, Gnathostomatidae, Physalopteridea, Acuariidae, and Dipetalonematidae) contain species that infect poultry. Levine (46) used a

Table 27.1. Nematodes reported from chickens in the United States.

Nematode	Location	Intermediate Host	Other Definitive Host
Baylisascaris procyonis	Brain		Raccoons (accidental parasite in chicken, turkey, partridge, quail)
Oxyspirura mansoni	Eye	Cockroach	Turkey, duck, grouse, guinea fowl, peafowl, pigeon, quail
Syngamus trachea	Trachea	None	Turkey, goose, guinea fowl, pheasant, peafowl, quail
Capillaria contorta	Mouth, esophagus, crop	None or earthworm	Turkey, duck, guinea fowl, partridge, pheasant, quail
C. annulata	Esophagus, crop	Earthworm	Turkey, goose, grouse, guinea fowl, partridge, pheasant, quail
Gongylonema ingluvicola	Crop, esophagus, proventriculus	Beetle, cockroach	Turkey, partridge, pheasant, quail
Dispharynx nasuta	Proventriculus	Sowbug	Turkey, grouse, guinea fowl, partridge, pheasant, pigeon, quail
Tetrameres americana	Proventriculus	Grasshopper, cockroach	Turkey, duck, grouse, pigeon, quail
T. fissispina	Proventriculus	Amphipod, grasshopper, cockroach, earthworm	Turkey, duck, goose, guinea fowl, pigeon, quail
Cheilospirua hamulosa	Gizzard	Grasshopper, beetle	Turkey, grouse, guinea fowl, pheasant, quail
Ascaridia galli	Small intestine	None	Turkey, duck, goose, quail
Capillaria anatis	Small intestine, cecum, cloaca	None	Turkey, duck, goose, partridge, pheasant
C. bursata	Small intestine	Earthworm	Turkey, goose, pheasant
C. caudinflata	Small intestine	Earthworm	Turkey, duck, goose, grouse, guinea fowl, partridge, pheasant, pigeon, quail
Capillaria obsignata	Small intestine	None	Turkey, goose, guinea fowl, cecum pigeon, quail
Heterakis gallinarum	Cecum	None	Turkey, duck, goose, grouse, guinea fowl, partridge, pheasant, quail
Subulura brumpti	Cecum	Earwig, grasshopper, beetle, cockroach	Turkey, dove, duck, grouse, guinea fowl, partridge, pheasant, quail
S. strongylina	Cecum	Beetle, cockroach, grasshopper	Guinea fowl, quail
Strongyloides avium	Cecum	None	Turkey, goose, grouse, quail
Trichostrongylus tenuis	Cecum	None	Turkey, duck, goose, guinea fowl, pigeon, quail

Table 27.2. Nematodes reported from poultry or commercially raised game birds other than chickens.

Nematode	Location	Intermediate Host	Other Definitive Host
Cyathostoma bronchialis	Trachea	None or earthworm	Turkey, duck, goose, (chicken)
Cymea colini	Proventriculus	Cockroach	Turkey, grouse, prairie chicken, quail, (chicken)[a]
Tetrameres crami	Proventriculus	Amphipod	Duck
Microtetrameres helix	Proventriculus	Grasshopper	Pigeon
Amidostomum anseris	Gizzard	None	Duck, goose, pigeon
A. skrjabini	Gizzard	None	Duck, pigeon, (chicken)
Ascaridia columbae	Small intestine	None	Pigeon, dove
A. dissimilis	Small intestine	None	Turkey
A. numidae	Small intestine	None	Guinea fowl
Omithostrongylus quadriradiatus	Small intestine	None	Pigeon, dove
Heterakis dispar	Cecum	None	Duck, goose
H. isolonche	Cecum	None	Duck, grouse, pheasant, prairie chicken, quail
Capillaria columbae	Large intestine	None	Pigeon, dove

[a] Experimental

Table 27.3.   Nematodes reported from wild birds in the United States that pose a potential problem for poultry or commercially raised game birds.

Nematode	Location	Intermediate Host	Definitive Host
Oxyspirura petrowi	Eye	Unknown	Grouse, quail, pheasant, prairie chicken
Splendidofilaria californiensis	Heart	Unknown	Quail
Singhfilaria hayesi	Subcutaneous	Unknown	Turkey, quail
Splendidofilaria pectoralis	Subcutaneous	Unknown	Grouse
Chandlerella chitwoodae	Connective tissues	Unknown	Grouse
Aproctella stoddardi	Body cavity	Unknown	Turkey, dove, quail
Cardiofilaria nilesi	Body cavity	Mosquito	Chicken
Echinura uncinata	Esophagus, gizzard, proventriculus, small intestine	Water flea	Duck, goose
E. parva	Proventriculus, gizzard	Unknown	Duck, goose
Tetrameres pattersoni	Proventriculus	Grasshopper, cockroach	Quail
T. ryjikovi	Proventriculus	Unknown	Duck
Cymea neeli	Proventriculus, gizzard	Unknown	Turkey
C. pileata	Proventriculus	Unknown	Quail
Physaloptera acuticauda	Proventriculus	Unknown	Chicken, pheasant
Amidostomum acutum	Gizzard	None	Duck
A. raillieti	Gizzard	None	Duck, dove
Cheilospirura spinosa	Gizzard	Grasshopper	Grouse, partridge, pheasant, quail, turkey
Cymea eurycerea	Gizzard	Unknown	Pheasant, quail, turkey
Epomidiostomum uncinatum	Gizzard	None	Chicken, duck, goose, pigeon
Streptocara crassicauda	Gizzard	Amphipod	Chicken, duck
Ascaridia bonasae	Small intestine	None	Grouse
A. compar	Small intestine	None	Grouse, partridge, pheasant, quail
Porrocaecum ensicaudatum	Small intestine	Earthworm	Chicken, duck
Capillaria phasianina	Small intestine, cecum	Unknown	Partridge, pheasant, guinea fowl
C. tridens	Small intestine	Unknown	Turkey
Aulonocephalus lindquisti	Cecum, large intestine	Unknown	Quail
A. pennula	Cecum	Unknown	Turkey
A. quaricensis	Cecum	Unknown	Quail

Note: Some of these have been reported from domestic poultry outside of the United States.

similar classification but substituted Onchocercidae for Dipetalonematidae. The classification used for families in this chapter is that given in the CIH keys in a series on the nematode parasite of vertebrates edited by Anderson and Bain (3).

General Morphology of the Nematodes Used in Identification

Nematodes, or roundworms, are usually spindle shaped with the anterior and posterior ends attenuated. The body covering, or cuticle, is often marked by transverse grooves. Longitudinal folds, or alae, may be present at the anterior (cervical alae) or posterior (caudal alae, Fig. 27.14) part of the body. The latter are found on the tail of the male worm, and in the case of certain groups, are modified to form a bursa (see Fig. 27.18B). Cuticular ornamentations occasionally found on the anterior extremities take the form of spines, cordons, or shields (see Fig. 27.6A).

The mouth opening, located at the anterior end of the body, is usually surrounded by lips bearing sensory organs (Fig. 27.5A). In some nematodes, the mouth leads directly into a cavity imme-

diately anterior to the esophagus (Fig. 27.24A). The mouth cavity may be reduced or absent in some groups of nematodes. The esophagus may be simple (consisting of 1 undivided part) or more complex (consisting of a short anterior muscular part and a long posterior glandular part). A bulb may or may not be present at the posterior end (Fig. 27.20). The intestine follows the esophagus and leads to a short rectum connecting to the anal or cloacal opening in the posterior.

Nematodes are usually sexually distinct. Sexual dimorphism is remarkably demonstrated by some species of nematodes, such as *Tetrameres americana* (Fig. 27.7), in which the elongate male worm is much smaller than the globule-shaped female. The nematode male usually can be distinguished from the female by the presence of 2 (rarely 1) chitinous structures known as spicules, located in the posterior end of the body. The spicules (Fig. 27.20) have been considered as organs for use during copulation, keeping the vulva and vagina open and, to some extent, guiding the amoeboid sperm into the female reproductive tract. Eggs or larvae are discharged through the vulva, the position of which varies considerably between genera of nematodes.

Nematode Development

Species of nematodes in poultry have either a direct or an indirect life cycle; about one-half of the species require no invertebrate intermediate hosts, whereas the others depend on such intermediate hosts as insects, snails, and slugs. Several use paratenic hosts which facilitate parasite survival and dispersal between hosts.

Nematodes normally pass through four developmental stages and four sucessive molting events (shedding of the cuticle) before adulthood.

Eggs laid by the female nematode reach the outside in the droppings, regardless of the location of the adult worms. Some eggs are embryonated before leaving the host, but most require suitable environmental conditions outside the host for embryonation and the development of infective larvae. Most eggs hatch only when consumed by a new host, but a few hatch in the environment and release free-living larvae. Eggs become embryonated within a few days to several weeks. For nematodes with direct life cycles, the definitive host becomes infected by eating free, infective larvae or embryonated eggs containing the second-stage larvae. For those with indirect life cycles, the intermediate host ingests the embryonated eggs or free larvae. The definitive host becomes infected either by eating the infected intermediate host or by injection of infective larvae by a blood-feeding arthropod. Direct life cycles predominate among nematodes affecting commercial poultry in the United States.

Nematodes

Nematodes of the Upper Digestive Tract

Capillaria annulata *Molin 1858, Capillariidae*
Hosts
C. annulata has been reported in chicken, turkey, goose, grouse, guinea fowl, partridge, pheasant, and quail. It is found in the mucosa of the esophagus and the crop.

Morphology
C. annulata are long, slender worms, similar in appearance to *C. contorta* but easily differentiated by a cuticular swelling at the back of the head (Fig. 27.1A). The male is usually 10–26 mm long and 52–74 µm wide; the tail ends in 2 inconspicuous round lateral flaps, united dorsally by a cuticular flap; the spicule sheath is beset with fine spines (Fig. 27.1B); and the spicule is 1.12–11.63 mm long. The female is usually 25–60 mm long and 77–120 µm wide; the posterior portion of the body (posterior to vulva) is about 7 times as long as the anterior portion; the circular vulva is located opposite the termination of the esophagus; and the eggs are operculated (Fig. 27.1C) and are 55–66 × 26–28 µm.

Life Cycle
Eggs pass out in the droppings of infected birds and require 24 days or more to develop. Two species of earthworms, *Eisenia foetidus* and *Allolobophora caliginosus*, serve as intermediate hosts of the crop worm (78).

Pathogenicity
The crop mucosa is thickened with enlargement of the glands, and there is inflammation of the crop and esophageal walls. In heavy infections, the inner surface of the crop becomes roughened and badly macerated. Masses of worms concentrate in the sloughing tissue.

This worm has been associated with the death of turkeys, pheasants, quail, and other gallinaceous game birds. Other signs include malnutrition, emaciation, and severe anemia.
27.1. *Capillaria annulata.* A. Head end. B. Male tail. (After Ciurea) C. Egg.

Capillaria contorta *Creplin 1839, Capillariidae*
Hosts
C. contorta has been reported in chicken, turkey, duck, guinea fowl, partridge, pheasant, pigeons and quail. It is found in the mucosa of the esophagus, the crop, and sometimes the mouth.
27.2. *Capillaria contorta*. A. Region of vulva. (After Eberth) B. Male tail. (After Travassos)

27.3. *Echinura uncinata*. A. Head. B. Male tail. (After Romanova)

Morphology

C. contorta has a threadlike body, attenuated anteriorly and posteriorly; its head is without a cuticular swelling. The male is 8–17 mm long and 60–70 μm wide; there are 2 terminal laterodorsal prominences on the tail end; the spicule is very slender and transparent, about 800 μm long; and the spicule sheath is covered with fine hairlike processes (Fig. 27.2B). The female is 15–60 mm long and 120–150 μm wide; and the vulva is prominent, circular, and situated near the beginning of the intestine (Fig. 27.2A).

Life Cycle

Eggs are deposited in tunnels in the crop mucosa and escape into the lumen of the crop and esophagus with the sloughed mucosa. They are abundant in droppings from infected birds. Approximately 1 month is required for embryonation. The life cycle is direct, and infection is initiated with the ingestion of embryonated eggs. Worms mature 1–2 months after infection.

Pathogenicity

In light infections the wall of the crop and esophagus becomes slightly thickened and inflamed. In heavy infections, a flocculent exudate covers a mucosa that is inflamed, thickened, and sloughing. The crop may become nonfunctional. In heavy infections, the worms may invade the mouth and upper esophagus.

   Infected birds become droopy, weak, and emaciated. Deaths have been observed among infected wild turkeys, Hungarian partridges, and quail in the United States.

Echinura uncinata *(Rudolphi 1819) Soloviev 1912, Acuariidae*

Hosts

E. uncinata has been reported in wild and domestic ducks and geese and in wild and domestic birds in Canada.

Location

E. uncinata may be found in the mucosa of the esophagus, proventriculus, gizzard, and small intestine. There is a report of this parasite in air sacs.

Morphology

E. uncinata is similar to *Cheilospirura* and *Dispharynx*; however, the cordons are not recurrent and anastomose posteriorly (Fig. 27.3A). The male is 8–10 mm long and 300–500 μm wide; the left spicule is 700–900 μm long; and the right spicule is 350 μm long (Fig. 27.3B). The female is 12–18.5 mm long and 515 μm wide; the tail is 250 μm long; the vulva is 1.0–1.4 mm from the end of the tail; the eggs are 28–37 × 17–23 μm and embryonated when laid.

Life Cycle

E. uncinata utilizes water fleas of the genus *Daphnia* as an intermediate host. Eggs are ingested by water fleas and release the larvae, which become infective after 12–14 days. Adults mature 51 days after ingestion of water fleas by chickens or other hosts.

Pathogenicity

Onset of mortality may be rapid, without any previous signs. Nodules may form in the proventriculus; however, in chronic infections, these may contain only inspissated pus. Birds may be emaciated and listless.
27.4. *Gongylonema ingluvicola.* A. Head. B. Male tail. (After Ransom)

27.5. *Cyrnea colini.* A. Head. B. Male tail. (After Cram) C. Egg.

Gongylonema ingluvicola *Ransom 1904, Gongylonematidae*

Hosts
G. ingluvicola has been reported in chicken, turkey, partridge, pheasant, and quail. Adults of *G. ingluvicola* may be found in the mucosa of the crop and sometimes in the esophagus and proventriculus.

Morphology
G. ingluvicola has an anterior zone of shield-like markings, with a few scattered near the head, numerous and arranged in longitudinal rows farther back (Fig. 27.4A). The male is 17–20 mm long and 224–250 μm wide; the cervical papillae are about 100 μm from the head end; the tail has 2 narrow bursal asymmetrical membranes; the genital papillae are variable in number and asymmetrical; the preanal papillae number up to 7 on the left side and up to 5 on the right side (Fig. 27.4B); the left spicule is as long or nearly as long (17–19 mm) as the body, and 7–9 μm wide with a barbed point; the right spicule is 10–12 mm long and 15–20 μm wide. The female is 32–55 mm long and 320–490 μm wide; and the vulva is 2.5–3.5 mm from the tip of the tail.

Life Cycle
The beetle *Copris minutus* and cockroaches reportedly serve as intermediate hosts for *Gongylonema ingluvicola* (15,16).

Pathogenicity
The only damage associated with these worms is local lesions in the form of burrows in the crop mucosa. The worms and their burrows appear as white convoluted tracks in the crop wall and can be confused with *Capillaria* spp. unless examined microscopically.

Cyrnea colini *Cram 1927, Habronematidae*

Hosts
C. colini has been reported in turkey, grouse, prairie chicken, and quail (and in chickens, experimentally). It is common in bobwhite quail. *C. colini* has also been reported from the turkey in Georgia and from the prairie chicken in Wisconsin and Montana. *C. colini* is found in the wall of the proventriculus, particularly at its junction with the gizzard.

Morphology
C. colini are slender yellowish white worms, similar in appearance to *Cheilospirura hamulosa* but smaller and lacking the so-called cordons or cuticular ornamentations on the anterior part of the body; the tail of the male has winglike expansions or alae (Fig. 27.5B); the head structures are complicated with four lips; dorsal and ventral lips are prominent and bear four conspicuous projecting papillae and a prominent thumblike projection (Fig. 27.5A); the lateral lips are very large, each bearing 2 digitiform processes on the inner surface and 2 winglike expansions on the lateral surface. The male is 6 mm long and 250 μm wide; the buccal cavity is 58 μm deep; the esophagus is 2 mm long; the caudal alae is nearly circular, with 10 pairs of pedunculated papillae, the anterior ones are larger than the posterior; and the spicules are very unequal; the left is 2 mm long and the right is 365–400 μm. The female is 14–18 mm long and 315 μm wide; the buccal cavity is 75 μm deep; the esophagus is about 2.8 mm long; the vulva is 915 μm anterior to the anus; and the eggs are 40.5 × 22.5 μm.

Life Cycle

The cockroach *Blattella germanica* serves as intermediate host for *C. colini* (14). Larvae develop into third stage larvae without encysting, and are fully developed by 18 days. Larvae fed to quail develop into mature worms within 41 days.

Pathogenicity

Little or no pathologic change has been observed.

Dispharynx nasuta *(Rudolphi 1819), Stiles and Hassell 1920, Acuariidae*

Hosts

D. nasuta has been reported in chicken, turkey, grouse, guinea fowl, partridge, pheasant, pigeon, quail, and a number of passerine birds in the United States.

Location

D. nasuta may be found in the wall of the proventriculus, sometimes the esophagus, and rarely the small intestine.

Morphology

D. nasuta has four wavy cuticular cordons on the anterior end, originating at the base of lips, recurrent, with the distal extremity of the cordons turning forward and extending anteriorly a short distance (Fig. 27.6A); postcervical papillae are small and bicuspid, situated between the recurrent branches of the cordons; the body is usually rolled in a spiral (Fig. 27.6B). The male is 7–8.3 mm long and 230–315 μm wide, with 5 pairs of postanal and four pairs of preanal papillae (Fig. 27.6C); the long spicule is 400 μm long, slender and curved; the short spicule is 150 μm long and navicular. The female is 9–10.2 mm long and 360–565 μm wide; the vulva is in the posterior portion of body; and the eggs are embryonated when laid.

Life Cycle

The pillbug (*Armadillidium vulgare*) and the sowbug (*Porcellio scaber*) serve as intermediate hosts in experimental infections (14). Within 4 days after ingestion of embryonated eggs, larvae escape from the eggs and are found among the tissues of the body cavity. The larva completes its development to the third or infective stage in the isopod within approximately 26 days. Female worms become sexually mature and deposit eggs 27 days after ingestion by a susceptible vertebrate host.

Pathogenicity

Ulcers are often observed in the proventriculus where the worms bury their heads deep in the mucosa. In heavy infections, the wall of the proventriculus becomes tremendously thickened and macerated, tissue layers are indistinguishable, and the parasites become almost completely concealed beneath the proliferating tissue.

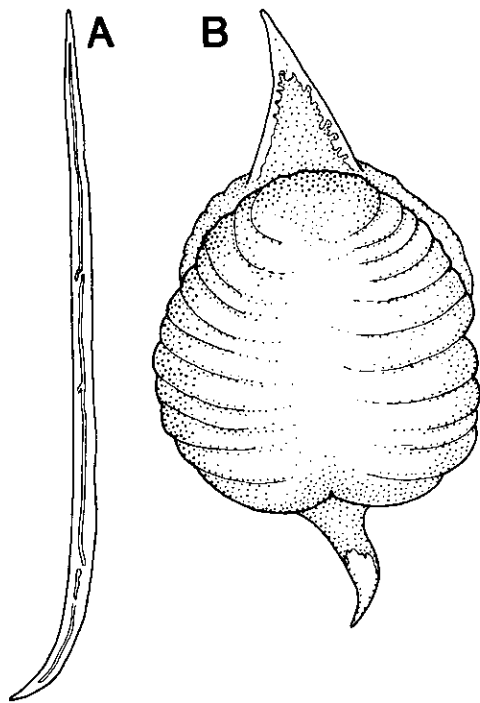
   D. nasuta is considered the chief cause of "grouse disease" in the northeastern United States. Heavy infections have resulted in the death of carrier pigeons. Wild pigeons trapped at the Balboa Zoological Park in San Diego, California, were heavily infected with this parasite.
27.6.   *Dispharynx nasuta*. A. Head. (After Seurat) B. Female (After Piana) C. Male tail. (After Cram)

Tetrameres americana *Cram 1926, Tetrameridae*

Hosts

T. americana parasitizes the proventriculus of chickens, turkeys, ducks, grouse, pigeons, and quail. At necropsy, these bright red worms are often observed through the wall of the unopened proventriculus.

Morphology

There is marked sexual dimorphism (Fig. 27.7). The female is globular (Fig. 27.7B), blood red in color, with four longitudinal furrows; the uteri and ovaries are very long, their numerous coils filling the body cavity; and eggs are 42–50 × 24 μm and embryonated when laid. The female is 3.5–4.5 mm long and 3 mm wide. The mouth is surrounded with three small lips, and a buccal cavity is present (Fig. 27.8A). The male is 5–5.5 mm long and 116–133 μm wide; 2 double rows of posteriorly directed spines extend throughout the whole body length in the submedian lines; cervical papillae are present; the tail is long and slender; and there are 2 unequal spicules, 100 μm and 290–312 μm long.


27.7. *Tetrameres americana*. A. Male. B. Female. (After Cram)

27.8. A. *Tetrameres americana*, head. (Courtesy Graybill) B. *Tetrameres fissispina*, head. (Travassos)

Life Cycle

T. americana requires an intermediate host for its complete development (14). Embryonated eggs consumed by grasshoppers (*Melanoplus femurrubrum* and *M. differentialis*) or cockroaches (*Blatella germanica*) produce infective (third stage) larvae in the body cavities about 42 days later. After ingestion of the insect by birds, the larvae escape and spend at least 14 days in the gastric mucosa, molting to the fourth stage. Females contain embryonated eggs by day 45.

Pathogenicity

Infected chickens become emaciated and anemic in heavy infections. *T. americana* did not produce any damage in quail (16). In chickens, the wall of the proventriculus may be thickened, almost blocking the lumen.

T. americana has been reported both from wild (26) and laboratory-raised pigeons (31). Mild infections produced little evidence of clinical disease; heavy infections result in diarrhea, emaciation, and death.

Tetrameres crami *Swales 1933, Tetrameridae*
Host

T. crami is found in the proventriculus of wild and domestic ducks.

Morphology

T. crami is smaller than *T. americana*. The male is 2.9–4.1 mm long and 70–92 μm wide. It has a narrow curved right spicule, 136–185 μm long, and a twisted left spicule 272–350 μm long.

The female is 1.5–3.3 mm long and 1.2–2.2 mm wide; its tail is 113–156 μm long; the vulva is 319–350 μm from the posterior end; and the eggs are 41–57 × 26–34 μm and embryonated when laid.

Life Cycle

The intermediate hosts of *T. crami* are the amphipods, *Gammarus fasciatus* and *Hyalella knickerbocki* (69). The larvae become infective in 29 days. Adults mature 33 days after infection.

Tetrameres fissispina *(Diesing 1861) Travassos 1915, Tetrameridae*
Hosts

T. fissispina has been reported in the proventriculus of chickens, turkeys, ducks, guinea fowl, geese, pigeons, and quail. It is more common in wild or domestic ducks, geese and wild birds and is rare in other poultry.

Morphology

T. fissispina is similar in appearance to *T. americana*. The male is 3–6 mm long and 90–200 μm wide; it has four longitudinal rows of spines along the median and lateral lines (Fig. 27.8B); and spicules are 280–490 μm and 82–150 μm long. The female is 1.7–6.0 mm long and 1.3–5.0 mm wide; its tail is 71 μm long; the vulva is 310 μm from the posterior end; and its eggs are 48–56 × 26–30 μm and embryonated when laid.

Life Cycle

Intermediate hosts include amphipods, grasshoppers, earthworms, and cockroaches. Larvae are infective by day 10. Worms mature about 18 days after ingestion. Fish may serve as a transport host.

Pathogenicity
Considerable tissue reaction occurs together with degeneration of the glandular tissue, edema, and extensive leukocyte infiltration (72).

Tetrameres pattersoni *Cram 1933, Tetrameridae*

Host
T. pattersoni is found in the proventriculus of quail.

Morphology
Bright red female *T. pattersoni* worms are found embedded in the glands of the proventriculus; males are on the surface of mucosa. The male is 4.2–4.6 mm long and 140–170 μm wide; it has a body with 2 rows of spines ending just anterior to the cloacal aperture; three pairs of lateral and four pairs of subventral spines are posterior to the cloacal aperture; and only 1 spicule exists, 1.2–1.5 mm long with conspicuous cross-striations. The female is 5 mm long and 2–2.3 mm wide; the vulva is about 235 μm from the tail end; the anus is 156 μm from tail end; there is a bulbous enlargement between the vulva and the anus; and the eggs are 42–46 × 25–30 μm.

Life Cycle
Intermediate hosts include grasshoppers (*Melanoplus femur-rubrum* or *Chortophaga viridifasciata*) or cockroaches (*Blattella germanica*) in which it develops into infective third stage larvae within 24 days (15). Larvae encyst in the muscles and the mesenteries of the body cavity, each cyst containing 1–3 larvae. The tail end of the larva has a small protuberance, differing from *T. fissispina* and *T. americana.*

Pathogenicity
Worms can be so numerous that little uninfected stomach wall remains. Severe infections may cause death.

Libyostrongylus douglassii

Hosts
L douglassii is commonly found in the ostrich. It is found in the duct system of glands lining the wall of the proventriculus.

Morphology
These nematodes, as adults, are 4–6 mm in length; spicules are 140 to 160 μm long; and the strongylorin type eggs are 72 × 41 μm when laid. An additional, commonly occurring, related species is *L. dentatus*, which is slightly larger than *L. douglassii* (7–13 mm long), but which lays a similar egg.

Life Cycle
It is direct, with infection commencing upon ingestion of infective, third-stage larvae. Prepatency is approximately 30 days. Infective larvae are resistant to harsh environmental conditions on pasture for as long as 30 months.

Pathogenicity
L. douglassii is highly pathogenic in young ostriches, with reports of up to 50% mortality. The hematophagic nematodes block the ducts of proventicular glands, induce excessive mucus secretions to the point of impaction, and eventually cause an acute diphtheritic condition of the proventriculus ("vrotmaag"; South African for "rotten stomach").

Vaznema zschokkei

Host
It is found in the submucosa of the proventriculus of the rhea.

Morphology
These spirurid nematodes are 16 to 25 mm in length, with spicules approximately 10 mm in length.

Amidostomum anseris *Zeder 1800, Amidostomatidae*

Hosts
A. anseris has been reported in ducks, geese, and pigeons. In the United States, parasites have been reported from domestic geese in New York, Delaware, Pennsylvania, and Washington.

Location
A. anseris is found under the horny lining of the gizzard and less frequently in the proventriculus.

Morphology
A. anseris is slender and reddish; its short wide buccal capsule has three pointed teeth at its base (Fig. 27.9A). The male is 10–17 mm long and 250–350 μm wide; it has a bursa with 2 large lateral lobes and a small median lobe (Fig. 27.9B); its dorsal ray is short, bifurcating posteriorly with the bifurcations forked and terminating in 2 tips; the spicules are 200 μm long, slender, and cleft near their middles; the gubernaculum is slender and 95 μm long. The female is 12–24 mm long and 200–400 μm wide at the vulva, thinning toward both extremities; the vulva is in the posterior part of the body; and eggs are thin shelled, 85–110 × 50–82 μm.

Life Cycle
Direct. Eggs are passed in a partly developed stage; active embryos develop within a few hours and hatch within a few days. Susceptible birds become infected by swallowing food or water contaminated with infective larvae, and adults worms are found within 40 days. This parasite is quite host specific; attempts to infect a variety of other hosts were unsuccessful (20).

Third-stage larvae may also infect through the skin of birds. Larvae migrate via the lungs in percutaneous infections but not in oral infections (19).

Pathogenicity
Heavy losses among geese have been attributed to this nematode. Young birds show loss of appetite, dullness, and emaciation. The lining of the gizzard of a heavily parasitized bird appears necrotic, loosened, and often detached in places. Infection may result in blood loss.
27.9. *Amidostomum anseris*. A. Anterior. (After Boulenger) B. Male bursa. (After Railliet)
27.10. A. Head, *Amidostomum raillieti*. B. Male bursa, *Amidostomum skrjabini*. (After Boulenger)

Amidostomum skrjabini *Boulenger 1926, Amidostomatidae*

Hosts

A. skrjabini is found under the horny lining of the gizzard in ducks and pigeons (and chicken, experimentally).

Morphology

A. skrjabini is smaller than *A. anseris* and can be distinguished from *A. raillieti*. The male is 7.5–8.8 mm long and 100–130 μm wide, with the bursa resembling that of *A. raillieti*; each branch of the dorsal ray is further divided into 2 equal branches (Fig. 27.10B); and spicules are 115–125 μm long. The female is 9–11 mm long and 101–120 μm wide; the vulva is 1.7–2.1 mm from the posterior end; and the eggs are 70–80 × 40–50 μm, and at the morula stage when laid (Fig. 27.10).

Life Cycle

The life cycle of *A. skrjabini* is similar to that of *A. anseris*.

Pathogenicity

A. skrjabini has been involved in clinical disease outbreaks in young ducks.

Cheilospirura hamulosa *(Diesing 1851) Diesing 1861, Acuariidae*

Hosts

C. hamulosa has been reported in chickens, turkeys, grouse, guinea fowl, pheasants, and quail. It is found under the horny lining of the gizzard, usually in the cardiac and/or pyloric regions, where the lining is soft and pliable.

Morphology

C. hamulosa has 2 large triangular lateral lips. The 4 cuticular cordons are irregularly wavy (Fig. 27.11A), and extend at least two-thirds the length of the body and sometimes almost to the posterior extremity; they do not anastomose or recur anteriorly and are characteristic of this species. The male is 9–19 mm long; spicules are unequal and dissimilar, with the left being long and slender, 1.6–1.8 mm, and the right short and curved, 180–200 μm. The tail is tightly coiled; 2 very wide caudal alae are present; and 10 pairs of caudal papillae exist (Fig. 27.11B). The female is 16–25 mm long; the vulva is slightly posterior to the middle of body; the tail is pointed; and eggs are 40 × 27 μm and embryonated when laid.

27.12.   *Cheilospirura spinosa*. A. Head. B. Male tail. (After Cram)

27.11.   *Cheilospirura hamulosa*. A. Head. (After Drasche) B. Male tail. (After Cram)

Pathogenicity

Presence of small numbers of these worms causes little damage, although the lining of the gizzard may show small local lesions that also involve the muscular tissue. Soft nodules enclosing parasites may be found in the muscular portion of the gizzard. In heavy infections, the wall of the gizzard may be seriously damaged.

Cheilospirura spinosa *Cram 1927, Acuariidae*

Hosts

C. spinosa has been reported in grouse, partridge, pheasant, quail, and wild turkey. It is found in the gizzard underneath the corneous lining.

Morphology

C. spinosa has four spiny cordons originating in pairs between the lips (Fig. 27.12A), not extending beyond the anterior third of the esophagus. The male is 14–20 mm long and 183–232 μm wide; spicules are unequal and very dissimilar; one being 660–720 μm long, and the other being 192 μm long. The caudal alae are broad and similar in appearance to *C. hamulosa* (Fig. 27.12B). The female is 34–40 mm long and 315–348 μm wide; the vulva is anterior to the middle of body; the anus is 250–300 μm from the posterior end; and eggs are 39–42 × 25–27 μm.

Life Cycle

Grasshoppers serve as the intermediate host, where development is similar to that of *C. hamulosa.* The tail structures on the third-stage larvae are similar in *C. spinosa*, rather than dissimilar as is the case with *C. hamulosa.* In the bobwhite quail, fourth stage larvae are found underneath the gizzard lining 14 days after infection (14). Worms with fully developed sexual characteristics are seen by 32 days.

Pathogenicity

Mild infections produce few problems in quail, although tortuous paths are found between the lining and muscle tissues of the giz-

Life Cycle

Grasshoppers, beetles, weevils, and sandhoppers serve as intermediate hosts (14). The infective third-stage larvae develop in the arthropod's muscles. Larvae are recognized by the 2 prominent liplike structures at the anterior end of the body, the dorsal curvature of the posterior portion of the body, and the 4 digitiform processes at the tip of the tail.

Larvae are infective for chickens as early as 22 days after entering the intermediate host, and reach maturity in the bird in about 76 days.

27.13. *Epomidiostomum uncinatum*. A. Head. B. Male tail. C. Female tail. (After Skrjabin)

zard. In heavy infections, the gizzard lining may become hemorrhagic and necrotic, with marked proliferative changes in the gizzard wall.

Epomidiostomum uncinatum *(Lundahl 1841) Seurat 1918, Amidostomatidae*
Hosts
E. uncinatum has been reported in ducks, geese, and pigeons (and chickens, experimentally). It is found under the horny lining of gizzard.

Morphology
E. uncinatum differs from *Amidostomum* in that the buccal capsule contains no teeth, and the head has a pair of nodules (Fig. 27.13A). The male is 6.5–7.3 mm long and 150 μm wide; spicules are 120–130 μm long (Fig. 27.13B), dividing to form three terminations. The female is 10–11.5 mm long and 230–240 μm wide; the tail is 140–170 μm long (Fig. 27.13C); the vulva is 2.2–3.2 mm from the posterior end; and eggs are 74–90 × 45–50 μm.

Life Cycle
There is no intermediate host. Third-stage larvae are infective 4 days after hatching (44).

Sicarius uncinipenis *and* S. waltoni
Host
Rhea, gizzard.

Morphology
These spiruid nematodes resemble *Habronema* spp. as seen in the horse. *S. uncinipenis* is 18–30 mm in length. Males have unequal spicules; approximately 3 and 0.7 mm in length. *S. waltoni* is slightly smaller, < 25 mm in length and with unequal spicules 2.5 or 0.35 mm in length.

Nematodes Found Primarily in the Small Intestine

Ascaridia bonasae *Wehr 1940, Ascaridiidae*
Host
Grouse, primarily the small intestine.

Morphology
Several authors have apparently confused *A. bonasae* with *A. galli,* although *A. bonasae* is small and does not infect the chicken. The male is 10–35 mm long, and spicules are 1.8–2.7 mm long and equal. The female is 30–50 mm long.

Life Cycle
The direct life cycle of *A. bonasae* is similar to that of *A. galli.*

Ascaridia columbae *(Gmelin 1790) Travassos 1913, Ascaridiidae*
Hosts
Pigeons and doves. Usually found in the lumen of the small intestine, but sometimes in the esophagus, proventriculus, gizzard, liver, or body cavity.

Morphology
The *A. columbae* male is 50–70 mm long; spicules are 1.2–1.9 mm long and equal. *A. columbae* has a fourth pair of ventral papillae located adjacent to the anus (Fig. 27.14A). The female is 20–95 mm long.

Life Cycle
Direct, similar to that of *A. galli*. Second-stage larvae frequently penetrate the intestinal mucosa and reach the liver and lungs but do not develop further (81). Worms mature in about 37 days in the intestine.

Pathogenicity
Granulomatous lesions with leucocyte infiltration may result from invasion of the liver by larvae. Otherwise, pathogenicity is low.

Ascaridia compar *Schrank 1790, Ascaridiidae*
Hosts
Grouse, partridges, pheasants, and quail.

Morphology
The male is 36–48 mm long; spicules are 1.8 mm long; and there are four pairs of preanal papillae, two near the preanal sucker, two just anterior to the anus (Fig. 27.14B). The female is 84–96 mm long.
27.14. Male tails. A. *Ascaridia columbae*. (After Wehr and Hwang). B. *Ascaridia compar*. (After Linstow) C. *Ascaridia dissimilis*. D. *Ascaridia galli*. (After Wehr)

Life Cycle
The life cycle of *A. compar* is similar to that of *A. galli*.

Ascaridia dissimilis *Perez Vigueras 1931, Ascaridiidae*

Host
A. dissimilis is commonly reported in turkeys and is the only nematode parasite of confinement-raised, commercial turkeys in the USA that exists in patent infections.

Location
The lumen and wall of the small intestine.

Morphology
This worm resembles *A. galli*. Only males can be identified accurately based on caudal papillae and spicule tips. The male is 35–65 mm long; spicules are 1.3–2.2 mm long, and the distal ends of the spicules are rounded; the first pair of preanal papillae are opposite the preanal sucker; the ventral pair of postanal papillae are only slightly separated and just behind the anus (Fig. 27.14C). The female is 50–105 mm long.

Life Cycle
The direct life cycle of *A. dissimilis* is similar to that of *A. galli*. Eggs embryonate in 14–30 days given adequate moisture and temperature. After ingestion, the second stage larvae hatch and are free in the mucous layer of the small intestine for a few days before molting into the third stage. The larvae then either remain in the mucus or invade the mucosa and submucosa for an invariable period of time. Very high levels of third-stage larvae are common in commercial turkeys, as this stage is capable of developmental arrest—providing a reservoir population of this nematode in the small intestine. Eventually, the developing third-stage larvae will accumulate in the mucous layer where they molt to the fourth larval stage. An extensive loss of nematode numbers occurs naturally between the third and fourth stages. Final molt to the adult stage occurs 21 days or more after infection. Natural infections of turkeys are characterized by large numbers of third-stage larvae (upward of 2000 per bird) and low numbers of all other stages.

Pathogenicity
Mortality and lowered productivity are associated with *A. dissimilis* in turkeys (34, 53). Surveys of commercial flocks in the south-central United States indicated that a high percentage of turkey flocks are heavily parasitized with *A. dissimilis* (54). Aberrant migration of *A. dissimilis* larvae may cause hepatic foci and granulomas as the worms migrate through the portal circulatory system into the liver (55). Anorexia; intestinal inflammation; and loss of metabolites, fluids, and proteins lead to lowered feed efficiency and poor performance. In addition, given the extent of mucosal invasion and tissue inflammation, infection of turkeys with *A. dissimilis* also coincides with depression of immune competence and facilitates access of opportunist pathogens into the gut tissue and beyond.

Ascaridia galli *Schrank 1788, Ascaridiidae*
Synonyms
A. lineata Schneider 1866; *H. granulosa* Linstow 1906.

Hosts
A. galli has been reported in chickens, turkeys, doves, ducks, and geese and is normally found in the small intestine.

With aberrant migration, it is occasionally found in the bird's esophagus, crop, gizzard, body cavity, oviduct, and egg.

Morphology
A. galli are large, thick, yellowish white worms; their head has three large lips. The male is 50–76 mm long and 1.21 mm wide; the preanal sucker is oval or circular, with a strong chitinous wall with a papilliform interruption on its posterior rim; the tail has narrow caudal alae or membranes and 10 pairs of papillae; the first pair of ventral caudal papillae is anterior to the preanal sucker; the fourth pair is widely separated (Fig. 27.14D, compare with *A. dissimilis*); and spicules are nearly equal and narrow, with blunt ends and slight indentations. The larger female is 60–116 mm long and 1.8 mm wide; the vulva is in the anterior part of body; and the eggs are elliptical, thick shelled, and not embryonated at time of deposition (Fig. 27.15).
27.15. *Ascaridia galli* eggs freshly voided from a chicken. ×400 (Benbrook)

Life Cycle

A. galli has a simple and direct life cycle. Infective eggs hatch in the proventriculus or the duodenum of the susceptible host. The second stage larvae, after hatching, are free in the mucous layer of the duodenum for the first several days after infection. Then, a portion of their numbers penetrates the mucosa and molt to the third-larval stage. Third-stage larvae return to the lumen by approximately day 17, where they molt to the fourth stage and mature by 28–30 days of age. The life cycle of *A. galli, A dissimilis*, and other worms of this genus are very similar. In commercial birds, however, infection dynamics are quite dissimilar. Populations of the ascarids in turkeys are much greater than those seen in chickens. Additionally, infections in turkeys are predominately third larval stages and maintained at high levels for the life of the turkey. In chickens, adult stages appear to predominate with no reservoir population of developmentally arrested third stages, and a definite age resistance is manifest in the chicken with bird age inversely proportionate to infection size.

A. galli eggs may be ingested by grasshoppers or earthworms (potential, paratenic hosts) and remain infective to chickens, with no development of the larvae occurring in the invertebrate.

Under optimum conditions of temperature and moisture, eggs in the droppings become infective in 7–28 days. Eggs are resistant to low (nonfreezing) temperatures. Embryonated eggs of this worm have survived outdoors at Beltsville, MD, for up to 66 weeks (27). However, eggs are killed by a 12-hour exposure to 43°C.

Pathogenicity

A. galli infection causes weight depression in the host, proportionate to increasing worm burden (59). The nutritional state of the host is also important, because weight depression is greater with high dietary levels of protein (15%) than with low levels (12.5%) (39). In severe infections, intestinal blockage can occur. Chickens infected with a large number of ascarids suffer from loss of blood, reduced blood sugar content, increased urates, shrunken thymus glands, retarded growth, and increased mortality. However, no effects of infection on blood protein level, packed cell volume, or hemoglobin levels were found (38). *A. galli* can also synergize the effects of other disease conditions,

such as coccidiosis and infectious bronchitis. *A. galli* reportedly contain and transmit avian reoviruses.

Chickens 3 months of age or older manifest considerable resistance to infection with *A. galli,* regardless of previous infection status. In older fowl, larvae may undergo little or no development after emerging from the egg (71). Larval development is arrested in the third stage at high dose rates as a result of age resistance (47). Heavier breeds, such as Rhode Island reds and white and barred Plymouth rocks, are more resistant to ascarid infections than are the lighter white leghorns and white minorcas.

The nutritional state of the bird also influences the development of immunity. Diets high in vitamins A and B (complex) increase the fowl's resistance to *A. galli.* Increasing levels of dietary calcium and lysine decreased the length and number of worms recovered (17).

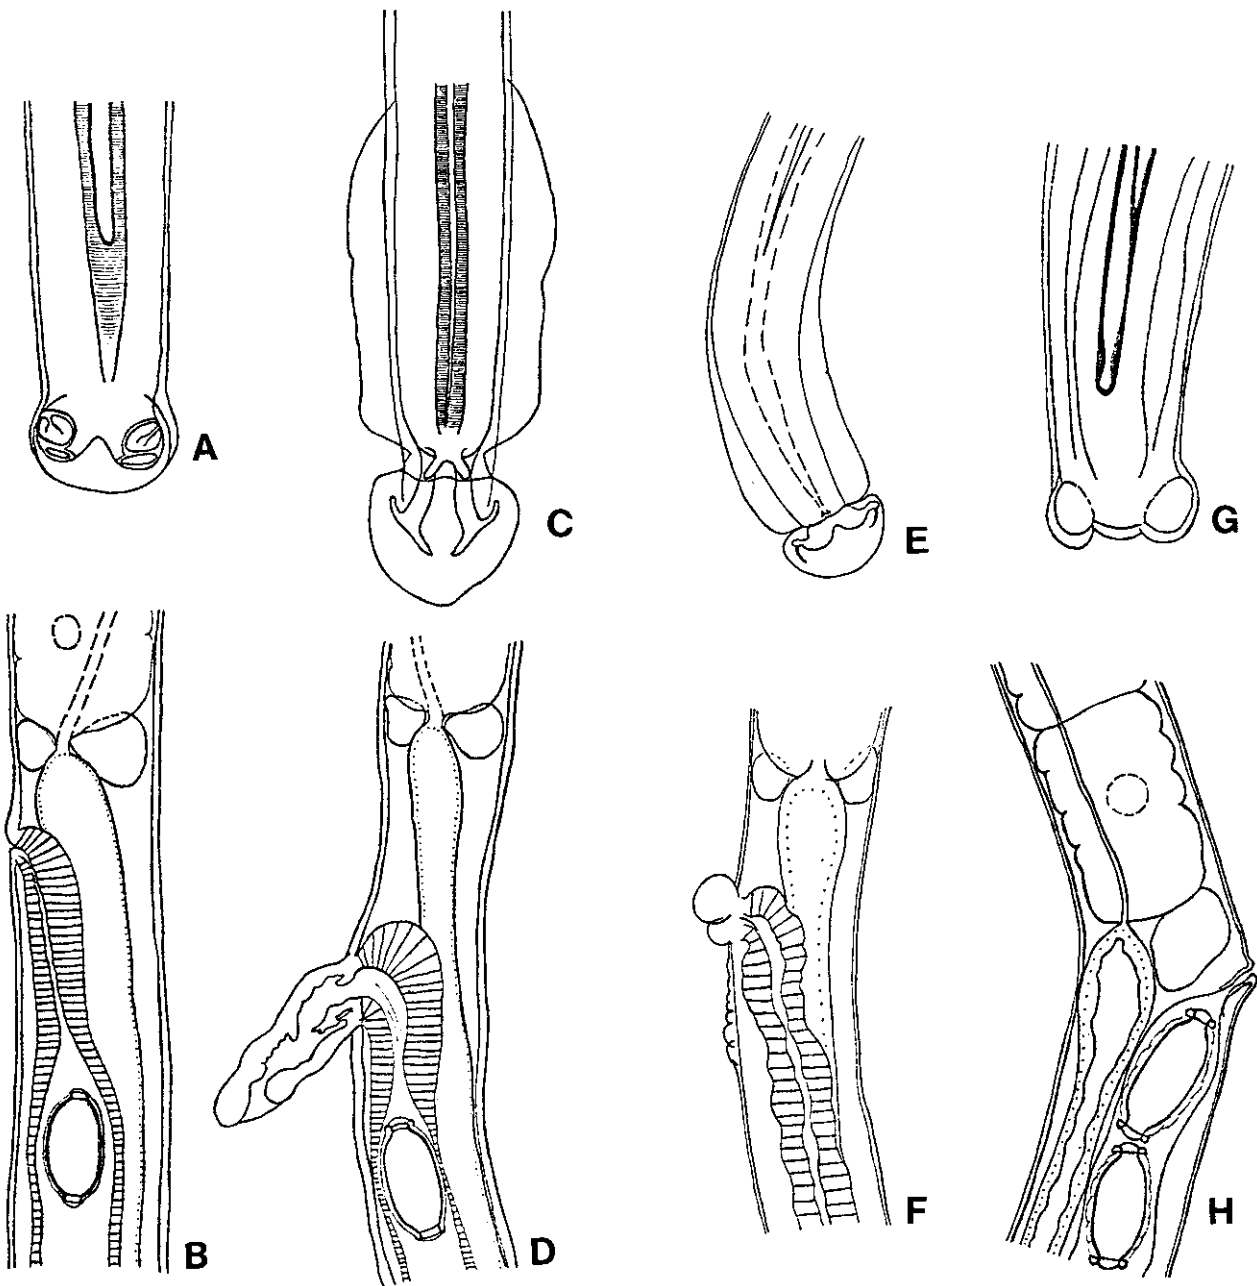
One of the most striking results of infection by this nematode is the occasional finding of this parasite in the hen's egg. Numerous reports of this phenomenon have been made in the literature (60). These aberrant worms have evidently migrated from the intestine, across the cloaca, and up the oviduct, with subsequent inclusion in the egg. It is thought that this phenomomen is a result of the incomplete action of narcotizing wormers such as piperazine. Infected eggs can be detected by candling.

Ascaridia numidae *Leiper 1908, Ascaridiidae*
Host
A. numidae is a parasite of guinea fowl. It is found in the lumen of the small intestine, or sometimes the cecum.

Morphology
A. numidae are much smaller than *A. galli*. The male is 19–35 mm long; it has 10 pairs of caudal papillae, 2 of them preanal and 2 adanal; and spicules are equal, 3 mm long. The female is 30–50 mm long.

Life Cycle
Direct, similar to other ascarids. The larvae remain in the lumen for 4–14 days before penetrating the intestinal mucosa.

Intestinal Capillaria
Species of *Capillaria* from birds have been described under a variety of names, leading to confusion in the literature. In this chapter, names accepted by Levine (46) are used with the exception of *C. dujardini,* which is considered a synonym for *C. obsignata.* The species *C. columbae* (Rudolphi,1819) is retained for the *Capillaria* in the large intestine of pigeons that possesses a vulva with a projecting appendage (Table 27.4 and Fig. 27.16).

Capillaria obsignata *Madsen 1945, Capillariidae*
Hosts
Chickens, turkeys, geese, guinea fowl, pigeons, and quail. *C. obsignata* is common in older, layer or breeder chickens. Infection levels as high as 2000 worms per bird are common with replacement pullets, levels of infection that persist through production (litter confinement). *C. obsignata* is found in the small intestine.


27.16. Male bursa (A, C, E, G) and female vulva (B, D, F, H) of *Capillaria obsignata* (A, B), *Capillaria caudinflata* (C, D), *Capillaria bursata* (E, F), and *Capillaria anatis* (G, H). (After Wakelin)

Table 27.4. Characteristics of *Capillaria* from chickens in the United States.

Characteristic	*C. anatis*	*C. bursata*	*C. caudinflata*	*C. obsignata*

Spicule sheath	Spines	No spines	Minute spines	No spine
Female				
Vulvar appendage	None	Semicircular	Pronounced	None
27.17. *Capillaria obsignata*. (After Gagarin)

Morphology

C. obsignata is hairlike and usually spiraled in appearance (Fig. 27.17). The male is 7–13 mm long with the cloacal aperture almost terminal, and a small bursal lobe on either side, the 2 lobes connected dorsally by a delicate bursal membrane (Fig. 27.16A). The spicule is 1.1–1.5 mm long and the sheath has transverse folds without spines. The female is 10–18 mm long; the vulva is slightly prominent and slightly posterior to the union of esophagus and intestine (Fig. 27.16B). The operculate eggs are 44–46 × 22–29 μm with a reticulate pattern on the shells.

Life Cycle

C. obsignata has direct development (76). Embryonation of ova is complete in 13 days at 20°C or 3 days at 35°C. Exposure of eggs to 23.5°C or 50°C caused reduced infectivity. Hosts are infected by ingestion of embryonated ova. Worms reach maturity in 18 days after oral inoculation of chickens, but the prepatent period is 20–21 days. Pigeons experimentally infected with *C. obsignata* remained infected for about 9 months.

Pathogenicity

Birds heavily infected with *C. obsignata* tend to huddle, and may suffer emaciation, diarrhea, hemorrhagic enteritis, anorexia, lowered feed efficiency, fluid and metabolite losses, and sometimes death. A catarrhal exudate in the upper intestine and some thickening of the wall are seen in heavy infections (76). Experi-

mentally, some weight depression was seen with as few as 14 worms (46); in other cases, infections of 100–1000 worms cause no weight changes. Poor feed conversion may result. Given the "wireworm" appearance of this nematode, it is very probable that it is thigmokinetic in the mucosa and may induce considerable villar detachment.

Experimentally infected chickens had no significant differences in total white blood cells or packed cell volume (76), although globulins and total protein may be increased (7). Conversely, in heavily infected pigeons, there was a marked decrease in total protein and albumen, as well as decreased plasma carotenoids and liver vitamin A (9).

Capillaria caudinflata *(Molin 1858) Wawilowa 1926, Capillariidae*

Hosts

C. caudinflata has been reported from chickens, turkeys, ducks, geese, guinea fowl, grouse, partridges, pheasants, pigeons, and quail. It is found in the mucosa of the small intestine.

Morphology

Male *C. caudinflata* are 9–18 mm long; the spicule is 0.7–1.2 mm long, tapering to a fine point distally; the spicule sheath has fine thornlike spines on the proximal portion; and there is a bursa present, supported dorsally by 2 T-shaped processes (Fig. 27.16C). Females are 12–25 mm long; the vulva has a characteristic appendage (Fig. 27.16D); and eggs are 47–58 × 20–24 μm, with a thick and finely sculptured shell.

Life Cycle

Earthworms of the species *Allolobophora caliginosa* or *Eisenia foetida* are intermediate hosts (2).

Capillaria bursata *Freitas and Almeida 1934, Capillariidae*

Hosts

C. bursata has been reported in chicken, turkey, goose, and pheasant.

Location

C. bursata may be found in the mucosa of the small intestine.

Morphology

The male is 11–20 mm long; spicules are 1.1–1.6 mm long; the sheath is without spines; and the bursa is round and supported by 2 dorsal and 2 ventral projections (Fig. 27.16E). The female is 16–35 mm long; the vulva has 2 semicircular valves (Fig. 27.16F); eggs are 51–62 × 22–24 μm, with a shell that has fine longitudinal ridges.

Life Cycle

Eggs are passed in the feces, and larval development is complete in 8–15 days. Eggs hatch after ingestion by earthworms, releasing larvae, which become infective to the final host after 22–25 days. Worms mature in the final host 20–26 days after ingestion.

Capillaria anatis *(Schrank 1790) Travassos 1915, Capillariidae*

Hosts

C. anatis has been reported in chicken, turkey, duck, goose, partridge, and pheasant.

Location

C. anatis usually is found in the cecum, sometimes in the small intestine.

Morphology

C. anatis are threadlike worms. The male is 8–15 mm long; the spicule is 0.7–1.9 mm long with a spiny sheath; and the tail has 2 lobes but no lateral caudal alae (Fig. 27.16G). The female is 11–28 mm long; the vulva is without appendage (Fig. 27.16H); and eggs are 46–67 × 22–29 μm with a thick rough outer shell.

Life Cycle

The life cycle of *C. anatis* is unknown.

Ornithostrongylus quadriradiatus *(Stevenson 1904) Travassos 1914, Heligmosomidae*

Hosts

O. quadriradiatus is found in the lumen of the small intestine of pigeons and doves.

Morphology

O. quadriradiatus worms are delicate, slender, and red when freshly collected, apparently from ingested blood in the intestine, and they have a cuticle about their head inflated to form vesicular enlargement (Fig. 27.18A). The male is 9 to 12 mm long; the bursa is bilobed, with no distinct dorsal lobe; the dorsal ray is much shorter than other rays, not extending halfway to the bursal margin, bifurcating near its tip to form 2 short tips; there is a stumpy process present on each side near the base of the ray; spicules are equal, 150–160 μm long, somewhat curved, each terminating in three pointed processes (Fig. 27.18B); and the telamon is 57–70 μm long, with 2 longitudinal processes extending backward and forward along the dorsal wall of cloaca and 2 lateral processes forming a partial ring through which the spicules protrude. The female is 18–24 mm long; the vulva is near the end of tail; the vagina is short, followed by 2 powerful muscular ovajectors; the tail tapers to a narrow blunt end, bearing a short spine; and eggs contain developing embryos when deposited.

Life Cycle

Mature worms are found in the small intestine. The oval, thin-shelled eggs are voided in the droppings and hatch in approximately 19–25 hours, depending on moisture and temperature. After hatching, the larva molts twice within the next 3 or 4 days to reach the infective stage. The infective larvae are swallowed by a pigeon or other susceptible host and mature in the small intestine. The female worm matures in 5–6 days after infection.

Pathogenicity

Pigeons may suffer catarrhal enteritis and blood loss. Heavily infected birds are moribund and anorexic. There is a pronounced
27.18. *Ornithostrongylus quadriradiatus*. A. Head. B. Bursa of male. (After Stevenson)

greenish diarrhea, and the bird gradually wastes away. Signs of difficult and rapid breathing usually precede death. Intestines of fatally infected birds are markedly hemorrhagic and have a greenish mucoid content with masses of sloughed epithelium.

Deletrocephalus dimidiatus

Host

Rhea, small and large intestines.

Morphology

Worms are 11 to 24 mm in length. Spicules are approximately 1 mm long and eggs are 70 × 120 μm. Buccal capsule is prominent and armed with gutter teeth.

Life Cycle

Probably direct.

Pathogenesis

Hematophagic activity of this nematode leads to anemia.

Nematodes Found Primarily in the Cecum

Heterakis dispar *(Schrank 1790) Dujardin 1845, Heterakidae*

Hosts

H. dispar infects the cecal lumen of ducks and geese.

Morphology

H. dispar is somewhat larger than *H. gallinarum* but similar in appearance except for spicules. The male is 7–18 mm long and has a preanal sucker 109–256 μm in diameter; its spicules are short and essentially equal, 390–730 μm long (Fig. 27.19A). The female is 16–23 mm long, and eggs are 59–62 × 39–41 μm.

Life Cycle

Direct, similar to *H. gallinarum.*
27.19.   Male tails. A. *Heterakis dispar*. (After Madsen) B. *Heterakis gallinarum*. (After Lane) C. *Heterakis isolonche*. (After Cram *et al.*)

27.20.   A. *Heterakis gallinarum*, head. B. *Subulura suctoria*, head. (After Skrjabin and Shikhobalova) C. *Subulura strongylina*, male tail. (After Barreto)

Pathogenicity

H. dispar is relatively nonpathogenic.

Heterakis gallinarum *(Schrank 1788) Madsen 1950, Heterakidae*

Hosts

H. gallinarum is found in the ceca of chickens, turkeys, ducks, geese, grouse, guinea fowl, partridges, pheasants, and quail. Along with *C. obsignata* and *A. galli*, this nematode is an extremely common and abundant parasite of replacement and productive commercial chickens that are maintained on ground or litter.

Morphology

Adult worms are small and white; the mouth is surrounded by three small, equal-sized lips; 2 narrow lateral membranes extend almost the entire length of the body; and the esophagus ends in a well-developed bulb containing a valvular apparatus (Fig. 27.20A). The male is 7–13 mm long; the tail is straight, ending in a subulate point; there are 2 large lateral bursal wings; the pre-anal sucker is well developed, with strongly chitinized walls and a small semicircular incision in the posterior margin of the sucker wall; there are 12 pairs of caudal papillae, the 2 most posterior pairs being stout and superimposed; and spicules are dissimilar, the right one being 0.85–2.8 mm long, and the left one being 0.3–1.1 mm long with a curved tip (Fig. 27.19B). The female is 10–15 mm long; the tail is long, narrow, and pointed; the vulva

is not prominent and is slightly posterior to the middle of the body; and eggs are thick shelled, ellipsoidal, unsegmented when deposited, undistinguishable from those of *A. galli,* and 63–75 × 36–50 μm.

Life Cycle

The life cycle is direct. Adults in the ceca produce eggs which pass unembryonated in the feces. In approximately 2 weeks, eggs reach the infective stage. When swallowed by a susceptible host, the larvae hatch in the upper intestine and reach the ceca within 24 hrs. Larvae are closely associated with the cecal mucosal tissue until 12 days postinfection, when they become essentially free in the lumen. At necropsy, most of the adult worms are found in the blind ends of the ceca. Although not a normal part of the life cycle, eggs may be ingested by earthworms, where they hatch and live for months. Earthworms may later be ingested by birds, resulting in infections with cecal worms and also *Histomonas meleagridis,* which is carried by the cecal worm. The greatest susceptibility is with the ring-necked pheasant, followed by the guinea fowl and chicken (47). Commercial turkeys rarely develop patent infections, but larval parasitism is   sufficient to allow the initiation of histomoniais (see under "Pathogenicity").

Pathogenicity

The ceca show marked inflammation and thickening of the walls. In heavy infections, nodules form in the mucosa and submucosa, as the response of already sensitized ceca to subsequent infection (41). Hepatic granulomas containing the worms have also been reported in chickens (61).

The chief importance of the cecal worm lies in its role as a carrier of the blackhead organism *Histomonas meleagridis.* Blackhead may be produced in susceptible birds by feeding embry-

onated eggs of *H. gallinarum* taken from blackhead-infected birds. Most isolates of heterakid ova are positive for *H. meleagridis.* Histomonads were found incorporated in the worm egg (74), and their presence was identified in the gut wall, in the reproductive systems of the male and female, and in the developing eggs of this cecal worm (31). Direct transmission of *Histomonas meleagridis* was accomplished using larvae (63) and male worms (67).

Turkeys are highly susceptible to blackhead disease. Commercial turkeys do not support patent infections of *H. gallinarum,* hence, they do not pass eggs of this nematode; eggs that were previously thought required by *Histomonas meleagridis* for survival in the environment and eventual passage of the protozoan to other turkeys. In a series of studies conducted by McDougald and associates, a most probable means of progression of histomoniais through turkey flocks has been elucidated (36, 49). After the initial, accidental infection of a few turkeys in a flock (larvated *Heterakis* eggs brought into a flock on contaminated boots, equipment, etc), histomonad proliferation in the ceca of the turkeys immediately ensues, and histomonad stages are expelled in the very watery droppings of these infected birds and immediately inoculated into flock mates by their "cloacal drinking". The above, experimentally-proven epidemiological events provide a scenario for the rapid transmission of Blackhead disease in turkey flocks, even with the lack of patent or sustained larval *Heterakis* infections in commercial turkeys. At present, given the lack of effective histomonacides on the market, the most effective means of controlling Blackhead in turkeys is to prevent the initial, accidental infection. In addition, McDougald advises the use of in-house barriers to turkey movement, especially around entry points; this, to minimize the spread of blackhead in a turkey barn once an infection has been started.

Not all isolates of *H. gallinarum* eggs are capable of inducing Blackhead disease in turkeys. In one set of studies, 10 different isolates of eggs were gathered from cecal worms obtained from spent breeder hens, larvated, and given to groups of 3-week-old turkeys. Mortality rates of the recipient turkeys varied from 0 to 50% (84).

Heterakis isolonche *Linstow 1906, Heterakidae*

Hosts
H. isolonche has been reported in duck, grouse, pheasant, prairie chicken, and quail. It is found in the lumen of the cecum or mucosa; larvae are found in the mucosa.

Morphology
H. isolonche is similar to *H. gallinarum* but easily differentiated based on the spicules. The male is 5.9–15 mm long; it has a preanal sucker, 70–150 μm in diameter; and spicules are long and essentially equal, 0.72–2.33 mm (generally 1.4–1.9 mm) long (Fig. 27.19C). The female is 9–12 mm long, and eggs are 65–75 × 37–46 μm.

Life Cycle
The life cycle is direct, similar to that of *H. gallinarum* but with a more extensive tissue phase. The second-stage larvae mature in the cecal mucosa, where adults may also be found.

Pathogenicity
H. isolonche reportedly caused mortality in pen-reared pheasants exceeding 50%. Diarrhea and weight depression are common. The invasion of the mucosa causes lymphocyte infiltration and granulation that leads to the formation of nodules in the cecal wall. These nodules may coalesce to form a thickened wall. In quail and grouse, there is little pathology, even when worms are present in large numbers.

Subulura brumpti *(Lopez-Neyra 1922) Cram 1926, Subuluridae*

Hosts
S. brumpti has been reported in chicken, turkey, dove, duck, grouse, guinea fowl, partridge, pheasant, and quail.

Location
Adult *S. brumpti* are found in the lumen of the cecum.

Morphology
S. brumpti are small nematodes with the anterior end curved dorsally; the mouth is hexagonal, surrounded by six weakly developed lips, each with median papillae; there are 2 pairs of larger papillae located dorsally and ventrally, well-developed amphids laterally, and anterior portions of the esophageal wall that are cuticularized, forming three teeth-like structures; the esophagus is dilated posteriorly, followed by a bulb (Fig. 27.20B); and there are cephalic alae extending to the anterior portion of intestine. The male is 6.9–10 mm long and 340–420 μm wide; the esophagus is 0.98–1.1 mm long; the tail is curved ventrally and ends in prolongation; there are caudal papillae (10 pairs) consisting of 3 pairs preanal, 2 pairs adanal, and 5 pairs postanal; caudal alae are narrow and not well developed; the preanal sucker is 170–220 μm long; spicules are similar and equal, 1.22–1.5 mm long; and the gubernaculum is 150–210 μm long. The female is 9–13.7 mm long and 460–560 μm wide; the esophagus is 1–1.3 mm long; the tail is straight and conical, ending in a sharp point; the vulva is anterior to the middle of the body; eggs are almost spherical, thin-shelled, 82–86 × 66–76 μm, and fully embryonated when laid.

Life Cycle
Embryonated ova pass from definitive hosts in cecal droppings. Larvae hatch in 4–5 hours and are consumed by beetles or cockroaches (4, 18). Larvae develop in the body cavity of the insect to the third, or infective stage. When the definitive host swallows an infected insect, the larvae migrate to the ceca and develop to the fourth stage within about 2 weeks. The final molt takes place on about the 18th day after infection. Patency is reach within about 6 weeks after infection.

Pathogenicity
No noticeable lesions were produced by this worm in the ceca of the quail (16). The cecum showed no evidence of inflammatory reactions, even though infection could persist as long as 8 months (18).

Subulura strongylina *(Rudolphi 1819) Railliet and Henry 1912, Subuluridae*

Hosts
S. strongylina has been reported in chicken, guinea fowl, and quail.

Location
S. strongylina is found in the lumen of the cecum.

Morphology
The lateral cephalic alae are well developed and extend from head to the median part of the esophageal bulb. The male is 4.4–12 mm long; the tail is curved into a V or an O shape; the preanal sucker is long and slender, 169 μm long; there are 11 pairs of caudal papillae; and spicules are equal, 890 μm to 1.2 mm long (Fig. 27.20C). The female is 5.6–18 mm long; the vulva is slightly anterior to the middle of the body; and eggs are 84 × 67 μm and embryonated when deposited.

Life Cycle
The exact life cycle of S. strongylina is unknown.

Pathogenicity
No noticeable lesions are produced in the ceca of quail.

Subulura suctoria *(Molin 1860) Railliet and Henry 1912, Subuluridae*

Hosts
Chickens, turkeys, guinea fowl, partridges, pheasants, and quail are hosts. It is found in the lumen or mucosa of the ceca or small intestine.

Morphology
This worm is larger than S. brumpti. The lateral cephalic alae are small and extend to the middle of the esophagus. The male is 11.8–13.8 mm long; spicules are equal and curved, 1–1.5 mm long. The female is 20–33 mm long, and eggs are 51–70 × 45–64 μm.

Life Cycle
The life cycle of S. suctoria is similar to that of S. brumpti. Beetles serve as intermediate hosts.

Pathogenicity
Barus and Blazek (6) reported little pathology.

Strongyloides avium *Cram 1929, Strongyloididae*

Hosts
S. avium infects chickens, turkeys, geese, grouse, and quail. This extremely small roundworm has been reported from chickens in Puerto Rico (13), the junco (*Junco hyemalis*) in Virginia, and the coot (*Fulica americana*) in North Carolina. It is found in the cecum, sometimes in the small intestine.

Morphology
S. avium is characterized by a parasitic generation consisting of only parthenogenetic females in the intestine of the avian host,
27.21. *Strongyloides avium*. A. Free-living male. (After Cram) B. Head, parasitic female. C. Parasitic (parthenogenetic) female. (B and C after Sakamoto and Sarashina)

and a free-living generation of both males and females in the environment (Fig. 27.21A). The parasitic adult female is 2.2 mm long and only 40–45 μm wide; the vulva has projecting lips and is located 1.4 mm from the head end (Fig. 27.21B and C); the uteri are divergent from the vulva; ovaries are recurrent with simple "hairpin bends", the esophagus is noticeably elongate, and eggs have very thin shells, segmenting when deposited, and are 52–56 × 36–40 μm.

Life Cycle
Unlike most species of nematodes, the parasitic cycle of S. avium consists of females only. Eggs hatch soon after being passed in the droppings, sometimes in as soon as 18 hours. Larvae develop in the soil to free-living adult males and females (heterogonic life cycle), or infective larvae (homogonic life cycle). Progeny of the free-living generation are infective, "filariform" larvae that develop into parthenogenetic females after being swallowed by a susceptible host. Infection of the host through the skin is also possible. Infective larvae of this genus can invade the skin of humans and cause cutaneous eruptions (larva currens), which is of some medical concern.

Pathogenicity
The walls of the ceca are greatly thickened; typical pasty cecal contents almost disappear, and cecal discharges are thin and
27.22.   *Trichostrongylus tenuis*. Bursa of male. (After Railliet)

bloody. If the fowl survives the acute stage, the ceca gradually regain function and the thickening of the walls decreases. Young birds suffer most from infections. Light infections cause little clinical effect.

Trichostrongylus tenuis *Mehlis 1846, Trichostrongylidae*

Hosts
T. tenuis infects chickens, turkeys, ducks, geese, guinea fowl, pigeons, emu, and quail. It is found in the ceca and sometimes in the small intestine.

Morphology
T. tenuis worms are small and slender; the body gradually attenuates in front of the genital opening; the mouth is surrounded by three small, inconspicuous lips; the cuticle at the anterior end of the body is lacking in conspicuous striations for a distance of about 200–250 μm from the extremity. The male is 5.5–9 mm long and 48 μm wide near the center of the body; the cuticle is inflated on the ventral surface just anterior to the bursa; the bursa has 1 dorsal and 2 lateral lobes, the dorsal one not distinctly marked off from the lateral; each lateral lobe is supported by 6 rays (Fig. 27.22); the dorsal ray bifurcates at its distal third, and each of these divisions again bifurcates and is very finely pointed; spicules are dark brown and slightly unequal in length, the longer being 120–164 μm, and the shorter being 104–150 μm; both are twisted, especially at distal ends, and have an ear-like structure on the proximal end. The female is 6.5–11 mm long and

77–100 μm wide at the level of the vulva; the vulva is in the posterior end of the body, with crenulated edges; uteri are divergent; and eggs are thin shelled.

Life Cycle
This worm has a direct life cycle. *T. tenuis* from pheasants has been transmitted successfully to domestic turkey and guinea fowl. Chickens have been experimentally infected (77). Eggs hatch within 36–48 hours in the droppings, and the larvae molt twice to become infective in approximately 2 weeks. When picked up by a susceptible host, the larvae molt twice more in the ceca of the bird before becoming adults.

Pathogenicity
T. tenuis was associated with decimation of the red grouse population in Scotland. A fatal dose can be as low as 500 infective larvae. Ceca become extended, and blood vessels show congestion. The mucosa of the ceca is inflamed, and the ridges are greatly thickened. Severe infection causes weight loss and anemia. *T. tenuis* can also be fatal to young goslings. Heavy mortality occurs usually in the fall, mainly in the young birds in that year's hatching, and again in the spring. These 2 seasons are not isolated epidemics, but rather are the peaks of a disease that continues in a chronic form the entire year. With emus, a bloody, mucoid diarrhea is extensive. There is no protective immunity due to prior infection.

Aulonocephalus lindquisti *Chandler 1934, Subuluridae*

Host
A. lindquisti have been reported in bobwhite quail and blue or scaled quail, mainly in western Texas.

Location
A. lindquisti is most commonly found in the cecum, although sometimes in the large intestine.

Morphology
A. lindquisti are bright pink worms; the cuticle is finely striated; cervical alae are present, 45–65 μm in breadth in the female but only 20–25 μm in breadth in the male; the head has 6 trough-like grooves about 65–70 μm long radiating from the mouth (Fig. 27.23A); the esophagus is club shaped, 1.3–1.8 mm long, with the bulb slightly longer than it is broad. The male is 8–10.6 mm long and 420–490 μm wide; the gubernaculum is 170–190 μm long; spicules are approximately equal, 1.16–1.3 mm long (Fig. 27.23B). The female is 10–14.8 mm long and 530–590 μm wide; the vulva is inconspicuous, ranging from slightly anterior to slightly posterior to the middle of the body; the tail terminates in a thin spike; and eggs are broadly oval, 58 × 42–45 μm.

Life Cycle
The life cycle of *A. lindquisti* is unknown.

Pathogenicity
The pathologic effects of this species are unknown, but as many as 300 worms have been recovered from a single host.
27.23. *Aulonocephalus lindquisti*. A. Head. B. Male tail. (After Chandler)

Codiostomum struthionis

Host
Ostrich.

Location
Cecum and colon.

Morphology
Large buccal capsule with both external and internal leaf crowns.

Life Cycle
Unknown, but most likely direct.

Pathogenesis
Not determined.

Other Nematodes of the Digestive Tract

Numerous species of nematodes have been found in domestic poultry in other parts of the world. Occasionally, some are reported from North America from imported birds. The following are some of these species.

Esophagus and Crop

These include *Gongylonema crami* from chickens in Java, *G. congolense* from chickens and ducks in Africa and *G. sumani* from chickens in India. *Capillaria cairinae* is found in the esophagus of ducks in Brazil, and *C. combologioides* is found in the crop of turkeys in Europe. Larvae of *Spirocerca lupi* have been found encysted in the crop of chickens in the southern United States.

Proventriculus

Parhadjelia neglecta (Habronematide) has been reported in domestic ducks in Brazil. *Echinuria jugadornata* was reported from the former Soviet Union. *Physaloptera acuticauda* was reported from chickens and pheasants in Brazil and from falconiform birds in the United States. *Tetrameres* species were reported from various birds, including *T. confusa* from chickens, turkeys, and pigeons in South America and Asia; *T. gigas* from domestic ducks in South America; *T. mohtedae* from chickens in India; and *T. spinosa* from chickens and domestic ducks in India.

Gizzard

Several nematodes not described above are found under the gizzard lining of domestic poultry. *Histiocephalus laticaudatus* has been recovered from chickens and ducks and *Streptocara pectinifera* from chickens and guinea fowl in Europe. *Epomidiostomum orispinum* is found in domestic ducks and geese in Europe and Africa, and *E. skrjabini* is found in domestic geese in Asia.

Small Intestine

Abbreviata gemina, a *Physaloptera*-like worm, occurs in chickens in Egypt. The anisakid *Contracaecum microcephalum* infects domestic ducks in Europe, Asia, and Africa, and *Porrocaecum crassum* is in domestic ducks and guinea fowl in Europe. *Capillaria anseris* occurs in domestic geese in Europe. *Hartertia gallinarum*, which uses a termite as an intermediate host, causes diarrhea and decreased growth and egg production in chickens in Africa.

Cecum

Numerous species of *Heterakis* not mentioned above are found in chickens throughout the world. These include *H. beramporia*, Asia; *H. bervispiculum*, South America and Africa; *H. caudabrevis*, former Soviet Union; *H. indica*, India; and *H. linganensis*, China. Turkeys in China are infected with *H. meleagris*. *Subulura differens* is widespread in chickens, guinea fowl, and quail in South America, Europe, Africa, and Asia and sometimes is found in the small intestine. Several *Capillaria* have been described including *C. monteividensis* and *C. uruguayensis* from chickens in Uruguay and *C. spinulosa* from ducks in Europe.

Nematodes of the Respiratory Tract

Cyathostoma bronchialis *(Muehlig 1884) Chapin 1925, Syngamiidae*

Hosts
C. bronchialis has been reported in ducks, geese, and turkeys (and chickens, experimentally). *C. variegatum* has been reported from the emu in the United States and is extremely similar in all aspects to *C. bronchialis*.

Location
C. bronchialis is found in the larynx, trachea, bronchi, and sometimes in the abdominal air sacs.

Morphology
C. bronchialis is very similar to *Syngamus* but is larger and less firmly united *in copula*; the buccal capsule is somewhat wider than
27.24.   *Cyathostoma bronchialis*. A. Head. B. Male tail.

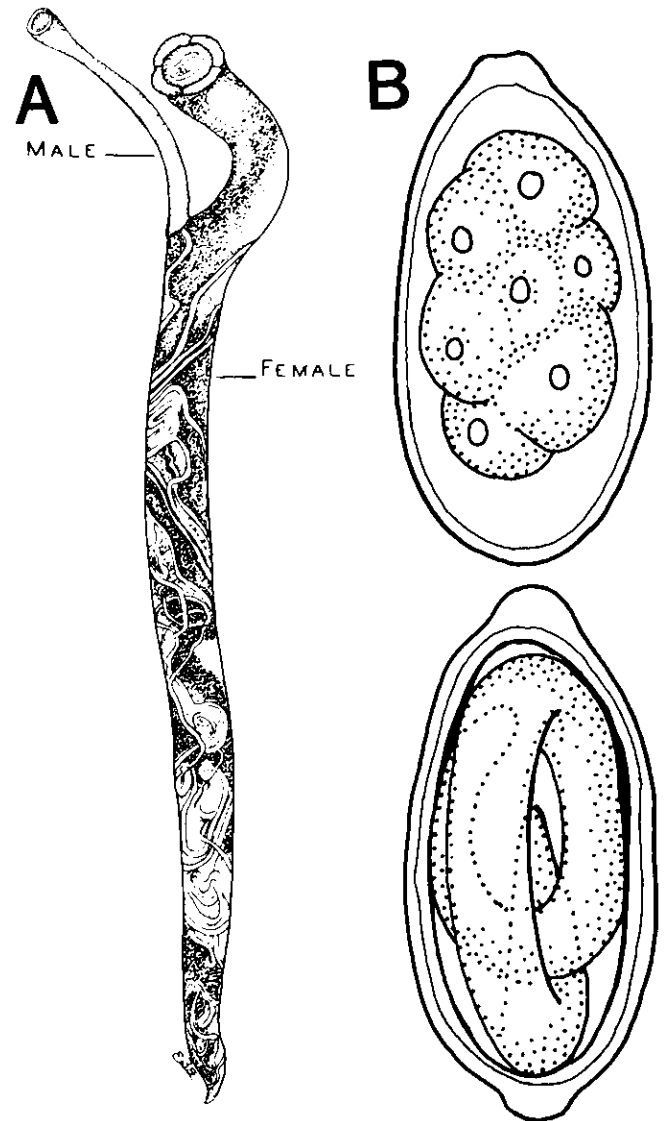
deep, with usually 6 but occasionally 7 triangular buccal teeth (Fig. 27.24A). The male is 8–12 mm long and 200–600 μm wide; spicules are long and slender, 540–870 μm, with tips slightly curved inward (Fig. 27.24B). The female is 16–30 mm long, 750 μm–1.5 mm wide; the vulva has fairly prominent lips, situated in the terminal portion of the anterior third of the body; the tail is acute; and eggs are 68–90 × 43–60 μm, with slight opercula.

Life Cycle

The life cycle of this species of gapeworm may be direct or indirect. Infections may begin directly with ingestion of third-stage larvae, or indirectly by the ingestion of a paratenic host (earthworms). The infecting third-stage larvae migrate to the lungs through the peritoneal cavity and air sacs, rather than through the bloodstream as does *S. trachea* (29). The larvae molt twice in the lung at 1 and 4 days post-infection. They migrate into the trachea at 6 days, copulate at 7 days, and reach full maturity by 13 days post-infection. Eggs are first found in the tracheal mucus 13 days post-infection.

Pathogenicity

Morbidity of 80% with a mortality of 20% was reported in a flock of domestic geese near Duluth, Minnesota (33). The course of the disease lasted 5 months, during which time the birds showed signs of respiratory distress (gaping). Severely affected birds died soon after the appearance of respiratory disturbances and signs may be similar to those of laryngotracheitis. Recovered birds showed growth retardation.

Experimentally infected domestic geese developed bronchitis of the primary, secondary, and tertiary bronchi (30). During prepatency, hyperplasia of the epithelium of the primary bronchi was the predominant lesion. During patency, generalized pneumonitis was prominent in response to aspirated nematode eggs. Mandarin ducks, infected via earthworms, suffered dyspnea and


27.25.   *Syngamus trachea*. A. Male and female worms. (After Wehr) B. Egg.

mortality (87). Other earthworms from the same source were found to harbor 4–5 nematode larvae each.

Syngamus trachea *(Montagu 1811) Chapin 1925, Syngamidae*

Host

S. trachea has been reported in chicken, turkey, goose, guinea fowl, pheasant, peafowl, emu, and quail. It is found in the trachea, bronchi, and bronchioles.

Morphology

S. trachea are called "redworms" because of their prominent color, "forked worms" because the male and female are always locked in copulation to form a "Y" (Fig. 27.25A), and "gapeworms", because birds tend to gasp or "gape" with heavy infection. *S. trachea* has an orbicular mouth, with a hemispheric

chitinous capsule, usually with 8 sharp teeth at the base; the mouth is surrounded by a chitinous plate, the outer margin of which is incised to form 6 festoons opposite each other. The male is 2–6 mm long; the bursa is obliquely truncated and is provided with rays, sometimes with strikingly asymmetrical dorsal rays; spicules are equal, slender, short, and 57–64 μm long. The female is 5–20 mm long (longer in the turkey); the tail end is conical, bearing a pointed process; the vulva is prominent, about one-fourth of the body length from anterior end, but the position varies with age; and eggs are 90 × 49 μm, ellipsoidal, and operculated (Fig. 27.25B).

Life Cycle
Transmission from bird to bird may be either direct (by the ingestion of embryonated eggs or infective larvae) or indirect (by ingestion of earthworms or other invertebrates containing free or encysted gapeworm larvae). The female gapeworm deposits eggs through the vulvar opening underneath the bursa of the attached male into the lumen of the trachea. The eggs reach the bird's mouth cavity, are swallowed, and pass to the outside in the droppings. Eggs embryonate and hatch in about 8–14 days, and larvae live free in the soil for a time. The earthworms *Eisenia foetidus* and *Allolobophora caliginosus* become infected with gapeworm larvae, where the larvae enter the body cavity and invade the body musculature and encyst. Gapeworm larvae in the earthworm remain infective to young chickens for as long as 4 years. Slugs and snails may also serve as transfer or auxiliary hosts of larvae. While the paratenic host is not necessary for transfer of gapeworms to other birds experimental infection has been more successful by feeding infected earthworms.

Infective larvae either penetrate the wall of the crop and esophagus and migrate to the lungs or penetrate the duodenum and are carried to the lungs by the portal bloodstream (5, 28). Molting and development to the adult stage occur in 4–5 days and worms produce eggs in about 2 weeks. The importance of wild birds in the spread of gapeworm disease to poultry is still unclear.

Pathogenicity
In the United States, *S. trachea* is the causative agent of "gapes" (labored breathing due to parasites) in chickens, turkeys, peacocks, emus, and pheasants (Fig. 27.26).

Gapeworms represent a serious menace to pheasant production in the United States. Confinement rearing of young chickens has reduced outbreaks, but this parasite continues to present problems for turkeys raised on range.

Young birds are the most seriously affected by gapeworms. The rapidly growing worms soon obstruct the lumen of the trachea and cause the birds to suffocate. Turkey poults, baby chicks, and pheasant chicks are most susceptible to infection. Turkey poults usually develop gapeworm signs earlier and begin to die sooner after gapeworm infection than do young chickens. Experimentally infected guinea fowls, pigeons, and ducks do not exhibit characteristic signs of gapeworm infections. Adult birds rarely develop heavy infections.

The trachea of infected birds becomes irritated with inflamed mucous membranes, resulting in coughing. Lesions are usually

27.26. *Syngamus trachea*. Trachea showing attached gapeworms. (After Wehr)

found in the trachea of turkeys and pheasants but seldom in the trachea of young chickens and guinea fowl. These lesions or nodules result from an inflammatory reaction at the site of permanent attachment of the male worms. The female worms apparently detach and reattach. The net blood loss with *S. trachea* is minimal. Turkey poults may have marked heterophilia, monocytosis, eosinophilia, lymphocytopenia, and a decreased packed cell volume (37).

Nematodes of the Eye and Associated Structures

Of 70 known species of *Oxyspirura*, only 3 (*O. mansoni, O. petrowi,* and *O. pusillae)* have been reported from North America north of Mexico. *O. petrowi* is a species of wide geographic range. It shows little host specificity and has been found in 14 species of wild birds in Louisiana and 5 species in Michigan. Although this species has not been reported in domestic chickens, it is found in grouse and prairie chickens.

Oxyspirura mansoni *Cobbold 1879, Thelaziidae*

Hosts
O. mansoni has been reported in chickens, turkeys, ducks, grouse, guinea fowl, peafowl, pigeons, and quail. It is located beneath the nictitating membrane, and in the conjunctival sacs and nasolacrimal ducts.

Morphology
The body of *O. mansoni* is attenuated at both ends, with the anterior rounded and the posterior pointed; the cuticle is smooth; no membranous appendages exist; the mouth is circular, surrounded
27.27. *Oxyspirura mansoni*. A. Head. B. Male tail. C. Female tail. D. Eggs. (B–D after Ransom)

by a 6-lobed chitinous ring with 2 lateral and 4 submedian papillae in relation to the clefts of this ring; 2 pairs of subdorsal and 1 pair of subventral teeth are in the mouth cavity; the buccal cavity has a short, wide anterior portion and a long, narrow posterior portion (Fig. 27.27A). The male is 8.2–16 mm long and 350 μm wide; the tail is curved ventrally, without alae; there are 4 pairs of preanal and 2 pairs of postanal papillae; spicules are unequal (Fig. 27.27B), one 3–4.55 mm long, and the other, 180–240 μm. The female is 12–20 mm long and 270–430 μm wide; the vulva is 0.78–1.55 mm wide; the anus is 400–530 μm from the tip of the tail (Fig. 27.27C); and eggs are embryonated when deposited, 50–65 × 45 μm (Fig. 27.27D).

Life Cycle
Eggs of the mature worm are deposited in the eyes of the bird host, washed down the tear ducts, swallowed, and passed in the droppings. The cockroach *Pycnoscelus* (*Leucophaea*) *surinamensis* ingests the nematode eggs in the feces. Within approximately 50 days, the body cavity of the cockroach contains larvae infective to bird hosts. These larvae are often contained within cysts deep in the adipose tissue or along the course of the alimentary tract of the insect; sometimes larvae are free in the body cavity and legs of the cockroach. Upon ingestion by a susceptible host, the infective larva is freed in the crop, migrates up the esophagus to the mouth and through the nasolacrimal duct to the eye.

Various wild birds may serve as reservoirs of infection for poultry. The blackbird (*Agelaius phoeniceus*), bobolink (*Dolichonyx*

oryzivorus), wild pigeon (*Columbia livia*), loggerhead shrike (*Lanius ludovicianus*), and blue jay (*Aphelocoma cyanea*) have been experimentally infected. The eyeworm occurs naturally in the English sparrow, mynah, Chinese dove, Japanese quail, and pheasant (*Phasianus torquatus torquatus* and *P. versicolor versicolor*) in Hawaii. In Hawaii, the local wild birds appear to be of little importance in the dissemination of this poultry parasite (65).

Pathogenicity
Infected birds show a peculiar ophthalmia and may scratch at the eyes. The nictitating membrane becomes swollen, projects slightly beyond the eyelids at the corners of the eyes, and usually is kept in continual motion, as if trying to remove some foreign object from the eye. The eyelids sometimes become stuck together, and a white cheesy material collects beneath them. If left untreated, severe ophthalmia may develop; as a result, the eyeball may be destroyed. The worms are rarely found in the eyes when severe signs are manifested.

Oxyspirura petrowi *Skryjabin 1929, Thelaziidae*
Hosts
O. petrowi has been reported in grouse, pheasants, and prairie chickens.

Location
O. petrowi may be found beneath the nictitating membrane of the eye.

Morphology
The body of *O. petrowi* is slender, yellow to cream colored, bluntly rounded anteriorly, and attenuated posteriorly; cervical alae are present, with the cuticle transversely striated; the mouth has 4 submedian pairs and 3 circumoral pairs of cephalic papillae; an undivided cuticularized bursal capsule exists. The male is 6.3–8.6 mm long and 185–330 μm wide; the right spicule is 121–320 μm long and slender with a sharp tip. The female is 7.7–12.3 mm long and 200–455 μm wide; the vulva is 500–700 μm from the tip of the tail; the anus is 242–400 μm from the posterior extremity; and eggs are embryonated and 35–44 μm × 15–31 μm.

Life Cycle
The life cycle is similar to that of *O. mansoni*.

Pathogenesis
Infection with *O. petrowi* produces a condition similar to that seen with *O. mansoni*.

Tissue-Dwelling Nematodes Outside the Intestinal Tract
Aproctella stoddardi *Cram 1931, Dipetalonematidae*
Hosts
A. stoddardi is found in the body cavity of turkeys, doves, and quail. This species has been recovered from the bobwhite quail in the southern United States and from grouse in New England.
27.28. *Aproctella stoddardi.* A. Head. B. Male tail. (After Anderson)

27.29. *Singhfilaria hayesi.* A. Head. B. Mail tail. (After Anderson and Prestwood)

Morphology

The body of *A. stoddardi* is slender; the cuticle is divided into 4 fields, 2 medians longitudinally striated and 2 smooth laterals; the mouth is simple without definite lips (Fig. 27.28A). The male is 6–7.6 mm long and 60–140 μm wide; the spicules are stout and curved, with the right one 50–60 μm, and the left 73–90 μm (Fig. 27.28B). Caudal papillae are absent. The female is 13–16.5 mm long and 71–260 μm wide; the vulva is 1.3–1.6 mm from the anterior end, with no protuberance; the anus is 140–180 μm from the caudal extremity; there are no eggs; and unsheathed larvae are present in the uteri.

Life Cycle

The life cycle is unknown, but a biting arthropod is thought to be the intermediate host.

Pathogenicity

Small numbers of *A. stoddardi* are not pathogenic; however, heavy infection may result in mortality in doves. A granulomatous pericarditis has also been reported.

Singhfilaria hayesi *Anderson and Prestwood 1969, Onchocercidae*

Host

S. hayesi is found in subcutaneous tissues in the region of the esophagus, crop, and trachea of turkeys and quail in the southern United States.

Morphology

S. hayesi have no structures on the head (Fig. 27.29A); the cuticle has innumerable tiny, transverse thickenings. The male is 13.6

mm long and 250 μm wide; spicules are markedly dissimilar, with the right one tooth shaped, 81 um long, and the left 125 μm long, divided into a broad shaft and short filament (Fig. 27.29B). The anus is subterminal, 28 μm from the caudal extremity; the caudal papillae consist of 1 large pair of postanal papillae and 1 large medial papilla anterior to the anus. The female is 35–40 mm long and 420–500 μm wide; the vulva is 390–400 μm from the cephalic extremity; and there are microfilariae in uteri.

Life Cycle

The life cycle of *S. hayesi* is unknown.

Pathogenicity

Few pathologic lesions have been found.

Dicheilonema rhea

Dicheilonema rhea is a filariid of rheas. The nematode is 65 cm in length, approximately 3 mm wide, and is found in the abdominal and appendage fascia. Little pathology has been associated with this worm. The life cycle is unknown.

Other Tissue-Dwelling Nematodes

The guinea worm *Avioserpens taiwana* causes fibrous tumors in the subcutaneous tissue under the mandible and on the thigh of domestic ducks in Asia.

Fifteen genera of filarial nematodes that infect birds have been recognized (3). Many species are not host specific. *Cardiofilaria pavlovsky* and *Aproctella stoddardi* have been reported from at least 7 families of birds. In general, filarial nematodes cause little problem in domestic poultry. The species shown in Table 27.1

are from game birds in North America. Other species that infect chickens but have not been reported in North America include the following from India: *Aprocta babamii* from the heart, *Cardiofilaria mhowensis* from the body cavity, and experimentally-induced *Chandlerella quiscali.*

Chandlerella quiscali is of major importance in emus, particularly those that are less than 1 year in age. This nematode is commonly found in the brain ventricles of grackles, cowbirds, blue birds etc., but do not appear to cause any pathologic condition. In the emu, torticollis, incoordination, emaciation and eventual death are associated with cerebral infections. The primary intermediate host is *Culicoides crepuscularis,* but other hematophagic arthropods could also serve as intermediate hosts. Emus do not develop patent infections and hence, no microfilariemia.

Baylisascaris procynois and *Baylisascaris columnaris* from raccoons and skunks, respectively, are reported to cause avian cerebral and neural/spinal infections in a variety of birds including chickens, bush turkeys, partridges, emu, and quail. Affected birds often show high morbidity and mortality after consuming raccoon feces. The damage is caused by migrating larvae, which never reach adulthood in birds. This disease has been produced experimentally in chickens (42).

Prevention and Control

Modern poultry practices, such as the confinement rearing of broilers and pullets and caging of laying hens, have significantly decreased the quantity and variety of nematode infections in poultry. Many that cause extensive problems in backyard or farmyard flocks are seldom seen in commercial operations. Others, such as *Ascaridia, Capillaria*, and *Heterakis,* are still found in large numbers and of high incidence in all types of commercial bird production. In addition, increased pen-rearing of game birds has led to increased nematode problems in these species. At present, an increasing trend has been emerged for "organic" and / or "humane" bird maintenance and production wherein birds are placed in more natural settings without the prophylactic use of drugs (parasiticides, antibiotics, etc). This trend may lead to greater parasite incidence at a time when chemical intervention is decreased. This trend has already been recognized in the EU (25).

For nematode parasites, control measures should include sanitation, interruption of the life cycle(s), and strategic use of efficacious parasiticides. Confinement rearing on litter largely prevents infections with nematodes using intermediate hosts such as earthworms or grasshoppers. Conversely, nematodes with direct life cycles or those that use indoor intermediate hosts such as beetles may prosper. Treatment of the soil or litter to kill intermediate hosts may be beneficial (50). Extreme care should be taken to ensure that feed and water are not contaminated. Removal or effective management of litter can reduce infections. After the old litter has been removed from commercial houses or banked for heating, spraying the exposed soil with a saturated salt solution or acceptable (environmentally compatible) insecticide before replacement of new or piled litter may help control populations of potential intermediate hosts, as well as reduce the

numbers of viable nematode eggs. However, there is little documentation of the value of such treatments.

Raising different species or different ages of birds together or in close proximity creates more opportunity for some parasites to prosper. For instance, turkeys should not be raised with any birds likely to harbor patent *Heterakis* infections, due to the turkey's high susceptibility to blackhead disease.

Chemotherapy

Because of the high cost of securing data necessary for FDA approval of new compounds, investigation into the efficacy of anthelmintics has been limited to parasites of incidence and magnitude that would suggest a large potential drug market. Current information on drug efficacy for poultry is therefore limited to treatment of ascarids, capillaria, and heterakids, the most important nematode parasites in commercially grown poultry.

Only a few compounds have been approved by the FDA for use in poultry. Producers should be aware that the use of unapproved drugs is not legal in birds that are intended to produce eggs or meat for market. Recent regulatory changes concerning the extra-label use of drugs have been made in the United States which make it easier for products approved for other animals to be administered under the direction of veterinarians. However, it is necessary to document the status of the parasitism and the lack of available, efficacious, and label-indicated product for control. Extreme care should be taken to obtain current information from authoritative sources before any medication is used. Label directions, dosages, and withdrawal periods must be followed.

Ascaridia galli *and* A. dissimilis

Approved Compounds

Piperazine compounds have been widely used for the treatment of turkey and chicken ascaridiasis for a number of years. In a series of studies conducted at the University of Arkansas, the efficacies of various piperazine salts at dose levels that ranged from 50 to 400 mg/kg bw were tested, and very little efficacy was observed in either chickens or turkeys (35).

Fenbendazole has recently been approved for the treatment of growing turkeys infected with *Ascaridia dissimilis.* The product is given in the feed at 16 ppm, thereby providing an approximate dose rate of 5 to 10 mg/kg bw over 6 days of treatment.

In naturally-infected commercial turkeys, fenbendazole was found to be >98% effective in the removal of adult and larval turkey ascarids (86).

Experimental Data

Fenbendazole administered in the feed at the level of 30 ppm for 4 days or 60 ppm for 3 days was 100% effective against *A. galli* in chickens (58, 85). Drenching chickens with 10% fenbendazole suspension for a dosage of 5 mg/kg bw is effective in the elimination of all parasitic stages of *A. galli*. In a recent study, albendazole drench given to chickens at the rate of 5 mg/kg bw was 100% adulticidal and 88% larvacidal for *A. galli* (Yazwinski, Tucker and Cummins, unpublished data). With prescription, commercial turkeys and chickens are commonly treated with oxfendazole at dose rates of 3.5 mg/kg bw or slightly higher for ascarid control.

Ascaridia galli infections were effectively removed with dl-tetramisole at the dose rate of 40 mg/kg of body weight (8,57). L-tetramisole (levamisole), the more efficacious isomer of tetramisole, was effective against *A. dissimilis* in turkeys when given at the rate of 30 mg/kg of body weight (40). Levels of 0.06% or 0.03% levamisole in the drinking water removed 99% of adult *A. dissimilis,* and 94–98% of larval *A. dissimilis*(57). Twenty-five milligrams of levamisole per kilogram of body-weight was found to be an effective dose rate for the treatment of *A. galli* infections in chickens (10). Levamisole hydrochloride is commonly given under prescription to chickens and turkeys for the treatment of ascarid infections, but at dose rates rarely in excess of 12 mg / kg bw. Controlled study evaluations of levamisole at this dose level have not been reported.

Pyrantel pamoate was not efficacious in the treatment *A. galli* in chickens (75). Conversely, pyrantel tartrate at a single dose of 15–25 mg/kg body weight gave 99.6–100% removal of adult *A. galli* from chicks but was relatively ineffective against the larval stages (56).

Capillaria obsignata *(Threadworms)*
Approved Products
No approved products are currently available for the efficacious removal of *C. obsignata* infections from chickens. Off-label use of other products on a prescription basis is therefore indicated.

Experimental Data
Fenbendazole was reportly more than 97% effective in removing experimental infections of *C. obsignata* when administered to turkeys at 45 ppm for 6 days (52). The compound was greater than 99% efficacious in chickens (58). Other research indicated slightly lower efficacy when lighter breed chickens were fed fenbendazole at 80 ppm for 3 days or 48 ppm for 5 days (85).

Treatment of naturally-infected breeder hens with albendazole in a drench formulation at the rates of 5, 10 or 20 mg/kg bw reduced burdens of *C. obsignata* 90, 91 or 95%, respectively (Unpublished data).

Methyridine injected subcutaneously beneath the wing as a 5% aqueous solution was effective for the removal of *C. obsignata* from pigeons (82). Injections of 25–45 mg methyridine per bird were 99–100% effective against *C. obsignata* in naturally-infected birds, but doses of 23 mg per bird was only 62% effective. The anthelmintic action of methyridine was relatively rapid, as indicated by elimination of the majority of the worms within 24 hours of treatment. Piperazine citrate, phenothiazine, thiabendazole, and bephenium were inactive against *C. obsignata.*

C. obsignata was effectively removed with dl-tetramisole at a dose rate of 40 mg/kg of body weight (8,57). L-tetramisole (levamisole) given to turkeys at the rate of 30 mg/kg of body weight was effective against naturally-acquired infections of *C. obsignata* (40). Levamisole in the drinking water at the levels of 0.06% or 0.03% removed 99–100% of the *C. obsignata* burdens of chickens (57). Twenty-five milligrams of levamisole per kilogram of body weight was found to be effective for the treatment of *C. obsignata* infections in chickens (10).

Heterakis gallinarum *(Cecal worms)*
Approved Products
No approved products are currently available for the efficacious removal of *Heterakis gallinarum* infections from chickens. Off-label use of other products on a prescription basis is therefore indicated.

Experimental Data
Fenbendazole had 100% efficacy in turkeys experimentally infected with *H. gallinarum* and given in the ration at 120 ppm for 3 days or 45 ppm for 6 days (52). The compound had the same efficacy at 30 ppm for 6 days or 60 ppm for 3 days in experimentally infected chickens (58). A separate study indicated 100% efficacy could be achieved when experimentally infected birds were given feed with 30 ppm fenbendazole for 5 days (85).

In a recent study, albendazole, delivered as a drench at the rates of 5–20 mg/kg bw, removed *Heterakis gallinarun* from naturally-infected breeder hens by greater than 90% (Unpublished data).

Heterakis gallinarum was effectively removed with dl-tetramisole at the rate of 40 mg/kg of body weight (8,57). L-tetramisole (levamisole) given to turkeys naturally infected with *H. gallinarum* at the rate of 30 mg/kg of body weight was also effective (40). Levels of 0.06% or 0.03% levamisole in the drinking water removed 99–100% of the *H. gallinarum* (57).

Syngamus trachea *(Gapeworms)*
Mash containing 0.5% thiabendazole fed to 4-week-old turkey poults for 9–20 days removed 98% of the gapeworms from 117 birds (79). The drug appeared effective, whether treatment was initiated on post-infection day 30 or started on the day of infection. Continuous medication of pen-reared birds at dietary levels of 0.1–4% has been recommended but is not economically practical.

Several other compounds have been shown effective against *Syngamus.* Mebendazole was 100% efficacious when fed prophylactically at 0.0064% and curatively at 0.0125% to turkey poults (70). A dietary level of 0.044% for 14 days has also been shown effective.

Cambendazole was found to be more efficacious than thiabendazole or disophenol (21). The level of control with three treatments of cambendazole on days 3–4, 6–7, and 16–17 post-infection was 94.9% in chickens (2 × 50 mg/kg) and 99.1% in turkeys (2 × 20 mg/kg).

Levamisole at a dietary level of 0.04% for 2 days or in the drinking water with a concentration of 2 g/gal for 1 day each month has proven effective in game birds. Fenbendazole at 20 mg/kg for 3 to 4 days is also effective (68).

Other Nematodes
Cambendazole (60 mg/kg) was effective against both adult and larval *Amidostomum anseris* (22). Pyrantel (100 mg/kg) was effective against adults. Some success was also obtained with citarin (40 mg/kg). Mebendazole at 10 mg/kg given for 3 consecutive days completely eliminated *A. anseris* (24). Other benzimidazoles may also be effective against these worms.

Haloxon was 46–100% effective against *C. contorta* in quail

when administered at levels of 0.05–0.5% in the feed for 5–7 days (11). Results were best at the 0.075–0.5% levels. However, the highest concentration was toxic, and one-fourth of the birds died. Single oral doses of the drug were not uniformly effective and produced undesirable side effects, primarily ataxia.

Tetramisole is not effective against *Dispharynx nasuta*, although mebendazole has some efficacy.

Subulura brumpti can be partially controlled with several different tin compounds or tetramisole.

Tetramisole also has some effect against *Strongyloides avium.*

Piperazine has been used against *Tetrameres fissispina.*

Trichostrongylus tenuis can be controlled by cambendazole (30 mg/kg), pyrantel tartrate (50 mg/kg), thiabendazole (75 mg/kg), and citarin (40 mg/kg) (23). Mebendazole was completely effective at 10 mg/kg given for 3 consecutive days (24).

C. Acanthocephalans

The Acanthocephala (thorny-headed worms) live as adults in the intestinal tract of vertebrates. Superficially, they resemble nematodes and cestodes, but many differences are apparent. At the anterior end, they have a retractible proboscis, which bears a considerable number of recurved hooks arranged in rows. The number, form, and arrangement of the hooks are valuable diagnostic characteristics. The body is usually unarmed but may bear small spines on some portion of the external surface. Like tapeworms, this group of worms has no digestive tract. Nutrition is obtained by absorption through the body wall. The sexes are separate. The male is smaller and more slender than the female and often distinguished externally by a bell-shaped bursa that surrounds the genital pore.

All known species of Acanthocephala require one or more intermediate hosts before becoming infective for the final host. Various arthropods, snakes, lizards, and amphibians serve as hosts of the larval stages (66).

Only four species of thorny-headed worms have been reported as parasites of domestic poultry in North America. Three of these were immature forms and may have been the result of accidental (dead end) infections.

Oncicola canis *Kaupp 1909*

O. canis was found in young turkeys around San Angelo, Texas (Fig. 27.30). The worms were encysted under the epithelial lining of the esophagus in numbers varying from a few to 100 or more. They were reported as the possible cause of death.

Adults normally occur in the dog and coyote. The presence of larval forms in young turkeys suggests an accidental occurrence, with young worms encysting when taken into an unsuitable host.

Larvae of *O. oncicola,* a parasite of South American jungle cats, have been recovered from chickens in Costa Rica.

Prosthorhynchus formosus *(Van Cleave 1918) Travassos 1926*

An immature male and 2 female specimens of *P. formosus* were reported from the small intestine of a chicken necropsied at Vineland, New Jersey. Other bird hosts from which this species
27.30. *Oncicola canis*. A. Male showing reproductive organs. B. Proboscis. C. Hooks from proboscis (numerals indicate row). D. Egg. (Price)

has been reported are the flicker (Bowie, Maryland), crow (Washington, D.C.), and robin (New Jersey) (Fig. 27.31). Several authors have suggested that this species is a potential hazard to domestic poultry; however, the level of experimental infections in chickens and turkeys is low (64).

Polymorphus boschadis *(Schrank 1788)*

This worm (Fig. 27.32) has been reported from the duck in Canada. It causes serious illness and death in domesticated waterfowl, especially in young birds. It causes an inflammation of the intestine with subsequent anemia and cachexia. Affected birds become visibly sick, with staggering gait and drooping head and wings.

Other Acanthocephalans from Poultry

Other acanthocephalans infecting fowl, but not found in North America, include *Leiperacanthus gallinarum, Mediorhynchus gallinarum*, and *Neoschongastia gallinarum* in Asia; *Macracanthorhynchus hirudinaceus* in chickens in Brazil; *Prosthorhynchus rhea* in South America and *Prosthorhynchus transversus* in passerine birds, partridge, and pheasant in Europe. The latter is experimentally infective for chickens.

Public Health Significance

None of the helminths discussed in this section pose a threat to public health. Persons may become accidentally infected with
27.31. *Prosthorhynchus formosus*. A. Young female (l, lemniscus; o, ovary; pr, proboscis receptacle). (Jones) B. Male. C. Hooks from proboscis. D. Egg. (VanCleave)

some of the helminths, especially those that also accidentally infect poultry (e.g. *Baylisascaris* spp.), but fowl will not be the source of the infection as they also represent dead end hosts. Larvae of *Strongyloides avium* may cause a creeping, cutaneous eruption in accidental infections (larva currens), but the lesions soon regress with no lasting pathology. Cutaneous hypersensitivity has been noted with some lab personnel who have been working with this genus (*Strongyloides ransomi*) for long periods of time (51).
