Chickens and turkeys inoculated orally with rotaviruses showed serum antibody responses as early as 4–6 days postinfection measured by indirect IF. In general, older birds developed higher antibody titers and responded more quickly than younger birds (119, 120, 121). Little is known about development or duration of immunity to rotaviruses following infection of birds. Using immunoglobulin class-specific enzyme-linked immunosorbent assays (ELISAs) (78) to follow antibody responses in chickens experimentally infected with a group A rotavirus, rotavirus-specific IgM, IgG, and IgA were detected in serum; whereas the intestinal antibody response consisted almost entirely of IgA. Embryonic bursectomized chicks recovered from infection and developed resistance to a subsequent homotypic challenge more slowly than intact chicks (76), indicating that the intestinal IgA response is not the sole mediator of recovery from infection and development of resistance to reinfection, but that it plays a part. Natural killer cell-like activity has been demonstrated in chick intraepithelial leukocytes against rotavirus-infected target cells, and this may be an important *in vivo* immune response (77).

Passive
Maternally derived antibodies to rotavirus are passively transferred to the avian embryo through the egg yolk. They progressively decline in titer in the serum and are undetectable at 3–4 weeks of age (56, 120). Presence of maternal antibody in the serum had no apparent effect on susceptibility of chickens and turkeys to experimental group A rotavirus infection (67, 120). Progeny of hyperimmunized turkey hens, however, were more resistant to experimental infection with rotavirus at 2 or 5 days of age, but not at 12 days of age, compared with poults without circulating maternal IgG antibodies to rotavirus. It was suggested that circulating maternally derived IgG protects the intestinal mucosa against rotavirus infection during the first week of life and that this effect depends on the titer of antibodies (67, 98, 120). It was subsequently shown that, during the first week of life, maternally derived anti-rotavirus IgG (rIgG) titers in intestinal washings of poults derived from hyperimmunized (vaccinated) hens were 200–500-fold less than rIgG titers in serum and that intestinal titers at 10 and 13 days of age were negligible. Evidence suggested that the rIgG had been transferred from the blood to the intestine. However, maternally derived rIgG could not be detected in intestinal washings of progeny derived from naturally infected hens (97).

Similarly, an increase in serum neutralizing antibodies was observed in pheasant hens vaccinated with an inactivated group A pheasant rotavirus vaccine, compared with mock-vaccinated controls. When challenged with a group A rotavirus at 1–2 days of age, mortality in the progeny of the vaccinated hens was 19.4% and mortality in the progeny of the controls was 48.3% (25). These results and those cited previously for the progeny of vaccinated turkeys suggest (i) that maternally derived antibodies in the progeny of unvaccinated turkeys and pheasants are unlikely to provide significant protection against a field challenge with rotavirus; and (ii) that much higher titers of antibody would need

to be produced by vaccination to completely protect young birds even for the first week of life.

Diagnosis

Isolation and Identification of Causative Agent

The classic way to diagnose avian rotavirus infections in the laboratory is to identify the virus in feces or intestinal contents by direct electron microscopy. This technique is relatively sensitive and detects rotaviruses of all serogroups. Material can be prepared in a variety of ways (63). The standard method is to extract an approximately 15% suspension of feces made in phosphate-buffered saline with an equal volume of fluorocarbon. Following centrifugation at $3000 \times g$ for 15–30 minutes to separate aqueous and fluorocarbon phases, the aqueous phase is removed and centrifuged at approximately $12,000 \times g$ for 15 minutes using an Eppendorf 5414 bench centrifuge. This pelleting procedure gives similar results to those obtained by ultracentrifugation, but is quicker and simpler. The pellet is resuspended in a few drops of water and examined. Some workers use immune electron microscopy. Although this technique requires availability of specific antisera, it allows rotaviruses of different serogroups to be distinguished (93, 105). The morphology of rotavirus is sufficiently distinct that experienced electron microscopists should have little difficulty identifying the virus with certainty. Rotaviruses can be confused with reoviruses, however, which are also frequently found in avian feces. The main distinguishing feature is the more clearly defined outer capsid shell of rotavirus (see Fig. 12.5).

Detection of rotavirus RNA in intestinal contents or feces provides an alternate means of diagnosis. Following extraction of RNA, electrophoresis on polyacrylamide gels, and silver staining, rotavirus RNA can be identified by the pattern of migration of the 11 genome segments. This technique is almost as sensitive as electron microscopic techniques (54, 64, 103, 105), provides provisional information on the serogroup(s) present, and is a convenient means of distinguishing between different isolates. At present, this technique is used mostly by those interested in rotavirus epidemiology and classification.

Using feces samples collected from turkeys experimentally infected with a group A rotavirus, it was found that negative contrast electron microscopy was more sensitive than a staphylococcal protein-A coagglutination test and a commercial ELISA developed for mammalian group A rotavirus detection; the latter two tests had approximately the same sensitivity (87% and 90%, respectively) and were slightly more sensitive than virus isolation in MA104 cells (44). Commercially available ELISAs are commonly used to detect group A rotaviruses in mammalian and avian feces. However no available ELISAs detect rotaviruses of groups D, F, and G. Given the frequent occurrence of infection with these serogroups in poultry, use of commercial ELISAs for diagnosis in poultry will result in many infections being missed.

Diagnosis of rotavirus infection by virus isolation in cell cultures is useful only for group A avian rotaviruses. It has proven extremely difficult to isolate other rotavirus serogroups in cell cultures (16, 46, 64, 107). As infections with other serogroups constitute the majority of rotavirus infections in chickens (64,

109) and turkeys (86, 108), virus isolation in cell cultures cannot be recommended as a diagnostic technique. Even with group A avian rotaviruses, in most cases, serial passage can be achieved only by activation of virus infectivity with proteolytic enzymes such as trypsin. Furthermore, not all group A avian rotaviruses detected by electron microscopy grow in cell cultures. Those that do are often noncytopathic on primary isolation, requiring immunofluorescence to detect virus growth. For isolation of group A avian rotaviruses, the MA104 cell line or primary cultures of chick embryo liver or chick kidney cells, trypsin treatment, and centrifugation of inoculum onto the cell monolayer are recommended (46, 60, 66, 69, 75, 100, 107, 118).

It is anticipated that polymerase chain reaction methods developed to detect rotavirus nucleic acid in the feces of mammalian species (29, 116, 117) will be used for diagnosis in avian species.

Serology

Serologic diagnosis of rotavirus infections is difficult and not recommended. The high prevalence of antibody (58, 69) makes results difficult to interpret. Few laboratories offer serologic tests for avian rotaviruses on a routine basis. Furthermore, the inability to adapt some avian serogroups to cell culture has resulted in gaps in the available battery of antigens. Serologic screening using indirect immunofluorescence (58) or ELISA (78) is useful for establishing and monitoring the status of specific-pathogen-free flocks.

Differential Diagnosis

Rotavirus infection must be differentiated from other conditions causing diarrhea. Because the clinical signs and pathology of rotavirus infection are not pathognomonic, laboratory diagnosis is necessary. It is important to remember, however, that rotavirus infection does not necessarily result in disease, as discussed previously. Furthermore, it is not unusual to find other potential viral enteropathogens, in addition to rotavirus, in flocks with enteric disease (3, 23, 35, 80, 86, 93, 123). Thus, diagnosis of outbreaks of enteric disease can be problematical.

Intervention Strategies

Management Procedures

The ubiquity of rotavirus infections in turkeys and chickens indicates that it is not practical to keep commercial flocks free from infection. At present, no specific treatment or means of control exists. The effect of diarrhea on the litter can be minimized by increasing ventilation rate and temperature and by adding fresh litter. Where litter is reused several times, infection will build up, and problems are likely to be more severe than in situations in which houses are cleaned and fumigated and fresh litter is used for each batch of birds. If severe problems arise, remove litter and thoroughly clean the house and equipment and fumigate with formaldehyde before restocking with a new flock.

Vaccination

Commercially available vaccines have not yet been developed. Given the extent of antigenic diversity that exists in avian ro-

taviruses and the difficulty in growing nongroup A rotaviruses in cell culture, obvious problems exist in vaccine development. Preliminary work on experimental group A rotavirus vaccines in turkeys (97) and pheasants (25) indicates that inactivated vaccines administered to the breeders are unlikely to protect the progeny against challenge for more than the first week of life, unless much higher titers of anti-rotavirus antibody can be produced.

Astrovirus Infections

D. L. Reynolds and S. L. Schultz-Cherry

Introduction

Astroviruses cause, or have been associated with, acute gastroenteritis in humans, cattle, swine, sheep, cats, dogs, deer, mice, turkeys, guinea fowl as well as fatal hepatitis in ducks (1, 4–6, 9, 15, 22, 23, 28, 29, 34, 35, 41, 59, 52–54). Chickens can be infected with astroviruses that are genetically more similar to turkey astrovirus strains (2) or with avian nephritis virus (ANV) (10). However, ANV will not be covered in this chapter (see Chapter 14). More recently, astroviruses have been detected in birds with poult enteritis and mortality syndrome (PEMS); although the exact role of astroviruses in PEMS remains unclear (10, 20, 21, 55, 56). The economic impact of astrovirus infections on the poultry industry has yet to be determined. Whether or not avian astroviruses can infect other animal species, including humans, constituting a public health concern, is also unknown. Intriguingly, recent studies demonstrated that antibodies to chicken astrovirus (CAstV) were found retrospectively in some turkey flocks tested in 1982 suggesting that cross-species infection may occur (2).

Astroviruses were first identified in 1980 by McNulty *et al.* (28) from the intestinal contents of 11-day-old turkey poults with diarrhea and increased mortality. Subsequently, astroviruses in flocks of young turkeys have been reported in the United States since at least 1985 (7, 8, 19–21, 31, 34, 35, 38, 40, 55, 56).

12.10.   A star-shaped astrovirus particle (arrow) among an aggregate of astroviruses from intestinal samples of experimentally infected diarrheic poults, detected by immune electron microscopy. Average particle size is 29.6 nm. (*Avian Diseases*)

Incidence and Distribution

Astrovirus infections are geographically widespread and are usually the most prevalent virus infection, other than rotavirus infection, in poults 1–5 weeks old with enteric disease (34–36). In one study, astrovirus infections occurred in nearly 80% of affected flocks and was the most prevalent virus detected (36). Astroviruses have also been detected in normal healthy flocks but far less frequently (30%). Astroviruses are seldom the only virus detected in flocks with enteric disease. Generally, they occur with other enteric viruses, especially group D rotavirus (36).

Astrovirus infections typically occur within the first 4 weeks of life (35). When flocks were continuously monitored for enteric viral infections from 1 day of age until market, the first samples positive for viruses always contained astroviruses, either alone or with other viruses (35).

Etiology

Astroviruses are small, round viruses typically 25–35 nm in diameter typically spread via the fecal-oral route. They get their name from the 5 or 6 pointed star-like surface projections observed using electron microscopy (EM); see Figure 12.10. However, only 10% of astroviruses in a population may exhibit this morphology, and visualization is dependent on sample preparation (19, 21, 23, 25–27, 29, 52).

Astroviruses are nonenveloped, positive sense RNA viruses. Their viral genome is 6.5–7.5 kilobases (kb) long and contains 3 open reading frames (ORF). These reading frames code for nonstructural proteins (ORF1a), a viral RNA-dependant RNA polymerase (ORF1b), and precursor capsid protein (ORF2).

Astroviruses are distinct molecularly from picornaviruses in that they synthesize a subgenomic message during replication and differ from picornaviruses and caliciviruses in that they have a retrovirus-like frame shift signal sequence between ORF1a and ORF1b (19, 21, 27). Currently, only the human astrovirus (HAstV), 2 distinct strains of turkey astrovirus (TAstV), swine astrovirus (SAstV), and avian nephritis virus (ANV) have had their genomes fully sequenced (10, 12–14, 21, 50, 51). The avian astroviruses are molecularly distinct, sharing very little sequence similarity in the different gene segments. However, the turkey astroviruses cluster into a distinct group from ANV.

Similar to the human astroviruses, there is antigenic variation among the TAstVs (19). The prototype TAstV-1 strain was originally identified in the United States in 1985 and is antigenically and serotypically distinct from North Carolina/96, the prototype TAstV-2 isolate. It is evident that even within a single TAstV genotype, there are distinct subtypes. Tang *et al.* demonstrated that the astrovirus isolates TAstV1987 and TAstV2001 are antigenically and serotpically distinct with TAstV1987 being more closely related genetically to the prototype NC/96 (44, 45).

Further, Guy *et al.* demonstrated that a "small round virus" originally identified as an enterovirus is related to TAstV-2 (8). A recent study evaluated the genetic diversity of TAstV-2 isolates collected from across the United States and performed comparative analysis of the polymerase and the capsid genes. These studies clearly demonstrated that even within the more conserved polymerase gene, there is at least 10% nucleotide divergence supporting the assortment of isolates into 2 distinct groups (31). The nucleotide and amino acid sequence variation within the capsid region revealed substantial variation among the isolates. Phylogenetically, the isolates assorted into 9 groups based on greater than 10% nucleotide sequence divergence within groups (31). Whether this sequence variation is simply due to the error-prone nature of the RNA-dependent RNA polymerase, evidence of immune pressure by the host, or is due to actual gene recombination as suggested in Pantin-Jackwood, Spackman *et al.* 2006 is a matter for continued debate.

Susceptibility to Chemical and Physical Agents

Mammalian astroviruses are extremely resistant to inactivation. Similarly, turkey astroviruses are also extremely stable. Astrovirus particles are resistant to inactivation by acidic pH, chloroform, a variety of detergents, heat, ambient temperatures, and lipid solvents (38). Additionally, Kurtz *et al.* (24) demonstrated that astroviruses are resistant to most alcohols, and only 90% methanol inactivates both purified astrovirus and astrovirus in feces.

Turkey astroviruses harvested from the intestines of embryos are very stable. Infectivity can be maintained for several weeks at 4°C. To maintain infectivity for the long term, virus can be stored at –20°C or –70°C. Even in the embryo model, astrovirus is resistant to inactivation with a variety of disinfectants including treatment with phenolics, acidic pH, chloroform, a variety of detergents, heat, ambient temperature, quarternary ammonia, and most alcohols (38). Formaldehyde, b-propriolactone, 90% methanol, and a peroxymonosulfate-containing disinfectant have been used to eliminate infectivity in the embryo model. Inactivation of astrovirus in the laboratory situation can be accomplished with 90% methanol or through the use of a peroxymonosulfate-containing disinfectant (38).

Laboratory Host Systems

Turkey astroviruses can be propagated serially in the yolk sac of 20-day-old turkey embryos or by inoculating 24–25-day-old turkey embryos by the amnionic route (3, 16–21). At 5 days postinoculation (dpi), the intestines and bursa can be isolated for virus purification by cesium chloride or for use as viral stock. In 75–80% of specific-pathogen-free (SPF) embryos inoculated with turkey astrovirus, the intestines are distended, thin-walled, and fluid-filled by 5 dpi. The astrovirus can be purified from the fluid as well as from the embryo intestines. This pathogenic effect is not observed in commercial embryos, although there is astrovirus replication. Astrovirus infection does not result in embryo mortality. To date, replication of turkey astrovirus in cell culture lines has been unsuccessful, even in the presence of exogenous trypsin.

In contrast, chicken astroviruses (CAstV) can be cultivated in cell culture (2). The CAstV isolates replicate well in primary chick embryo liver and LMH (chicken heptocellular carcinoma cell line) cells producing a marked cytopathic effect (CPE) after four-to-five passages. CAstVs replicate poorly in chick embryo fibroblasts and chick kidney cultures initially, but after several passages will replicate in chick kidney inducing CPE.

Pathogenesis and Epidemiology

In commercial flocks, astroviruses have been isolated from turkey poults experiencing viral enteritis. Clinical signs of disease usually develop between 1 and 3 weeks of age and generally last 10–14 days (34). They vary somewhat, but typically include diarrhea, listlessness, litter eating, and nervousness. Severity ranges from mild to moderate with only slight mortality. Morbidity, occurring as decreased growth (stunting), is of greatest concern.

Experimentally, turkeys infected with TAstV-2 developed a profuse, watery diarrhea by 2 days post infection, which continued through 12 days post infection (18, 29, 34). Morphologically, intestines of infected poults were 3 to 5 times larger than their control counterparts and appeared dilated, distended, and fluid-filled by 3 days post infection (3). TAstV infection resulted in an overall growth depression of infected birds, possibly as a consequence of decreased absorption in infected birds, by 5 days post infection and throughout the experiment (18). When SPF poults were given an inoculum containing only astrovirus, they absorbed significantly less D-xylose compared with uninoculated control poults. Commercial poults inoculated with astrovirus had decreased intestinal maltase by 3 days postinfection. The decrease in specific maltase activity in astrovirus-infected poults was transient, returning to normal by 10 days postinfection (11, 48).

Histological and Gross Changes

At necropsy, characteristic pathologic changes were dilated ceca containing yellow, frothy contents, and gaseous fluid; loss of tone (gut thinness); and hyperemia of the intestinal tract. The pathogenesis of diarrhea associated with astrovirus infections has been at least partially attributed to the osmotic effect of undigested, unabsorbed disaccharides (and other nutrients) attracting water to the intestinal lumen.

Studies in the mid-1990s demonstrated that astrovirus infections of poults induced histopathologic lesions of the small intestine characterized by mild crypt hyperplasia, resulting in increased crypt depth and area (47). Histopathologic changes were noted in the proximal jejunum as early as 1 day postinfection, with all portions of the small intestines affected by 5 days postinfection. Unlike some other intestinal viral infections, astrovirus infections do not induce villous atrophy. In-situ hybridization studies with a probe specific to TAstV-2 demonstrated that replication was restricted to the intestines (see Fig. 12. 11).
12.11. *In situ* hybridization demonstrating the location of TAstV-2 replication in the intestine of poults 3 days post infection.

Replication was detected in the upper regions of the small intestine by 24 hpi (3). Individual degenerating enterocytes were apparent along the basal edge of villi by 2 dpi and continued through day four. By day five, mild shortening of the villi was observed (3) as well as occasional clusters of necrotic enterocytes along the villous base, correlating with infection (18). TAstV-2 was localized primarily to the large intestine by day 7 pi. Replication peaked at 3 to 5 days post infection and TAstV-2 was infrequently observed at time points later than 9 days post infection (3). Although replication was limited to the intestine, infections (18) TAstV-2 was isolated from the bursa, thymus, spleen, kidney, skeletal muscle, pancreas, and plasma (18). Overall, TAstV-2 infection, as shown in Figure 12.12, was associated with mild histopathology and little cell death as measured by TUNEL (18).

The lack of an inflammatory response may result from the increase in transforming growth factor–beta (TGF-ß), a potent suppressor of inflammation, in infected intestines. Intriguingly, the histopathology observed in the young turkey model is similar to that observed in human infection (39). These results suggest that astrovirus-induced diarrhea is due to a mechanism other than destruction of the intestinal epithelium or eliciting an inflammatory response and raise the question of how astroviruses induce diarrhea. Preliminary data suggests that astrovirus infection results in increased paracellular permeability and changes in ion regulation resulting in diarrhea (30).

Immune Response

Although viral replication was limited to the intestine, infectious TAstV-2 virus was isolated systemically and a transient viremia was observed 3 dpi (18). TAstV-2 infected turkeys also demonstrated a transient, localized growth depression of the thymus, which manifested by 5 days post infection and resolved by 12 days post infection (18). The effects of astrovirus on the immune response and the mechanism of viral clearance are under investigation (16).

Qureshi *et al.* demonstrated that the responsiveness of peripheral blood lymphocytes (PBLs) isolated from astrovirus-infected poults was significantly reduced as compared to control birds up until 7 dpi (33). Further, they reported that astrovirus infection caused a transient decline in circulating CD4- CD8+ lymphocyte populations (32, 33). This is in contrast to a separate study demonstrating that astrovirus infection had no effect on T-cell populations and that virus-specific antibodies were not substantially altered in response to TAstV-2 (17). Further, neutralizing antibodies to TAstV-2 have not been isolated from infected poults. To date, studies suggest that the innate immune response may be important for controlling primary astrovirus infection. During infection, macrophages are induced to produce nitric oxide (NO) in a replication-independent manner. In turn, NO inhibits viral replication both *in vitro* and *in vivo* suggesting an important role in control (17). An additional control mechanism appears to be the induction of type 1 interferon (IFN). Like many other viruses, type 1 IFN inhibits astrovirus replication *in vitro* and *in vivo* and astroviruses have evolved mechanisms to inhibit IFN production during infection to allow viral spread (30).
12.12. TAstV-2 infection results in minor histopathologic changes (B) as compared to mock-infected poults (A).

Diagnosis

Historically, immune electron microscopy was the primary method for identifying astroviruses from fecal and/or intestinal samples. This procedure is done by diluting the fecal/intestinal sample with sterile diluent such as phosphate-buffered saline (pH 7.2) to make a working solution. The diluted sample is thoroughly mixed by using a homogenizer or vortex mixer and sonicated. Particulate matter and bacteria are removed by centrifugation at 500 $\times$ g for 20 minutes and filtering the resulting supernatant fluid through a 450 nm porosity membrane filter. The filtrate is incubated with an appropriate dilution of antiserum containing astrovirus antibodies. Following incubation, the sample is pelleted by ultracentrifugation, negatively stained with phosphotungstic acid, and observed by EM. Aggregates of astrovirus can be observed easily at 330,000–50,000$\times$ magnification. Although astroviruses have star-shaped morphology, only a small percentage of particles display this characteristic. It is quite difficult to diagnose astrovirus infections accurately without IEM. A definitive diagnosis of astrovirus infection is made by recognizing aggregates of typical astrovirus particles in the IEM preparation. In the author's experience, turkey astroviruses only occasionally display nonspecific agglutination; therefore, one must rely on IEM for aggregation of particles (Fig. 12.10).

Recently, several diagnostic tests have been developed that specifically detect the distinct TAstV strains. Two antigen-capture enzyme-linked immunosorbent assays (AC-ELISAs) were developed that could detect TAstV-1 and TAstV-2 strains in intestinal homogenates. The basis of the assay is a capture antibody, which is coated on a 96-well plate, intestinal homogenates from suspect flocks are added, and the presence of TAstV antigen is detected with a second specific antibody. The assay was unable to detect virus in fecal or non-intestinal tissue homogenates, but detected virus in intestinal homogenates with a titer of 5 x 10^2 egg infectious dose 50 (43). Because there is no "gold standard" test for TAstVs, the authors were unable to test the specificity and sensitivity of the AC-ELISA.

Several reverse-transcriptase polymerase chain reaction (RT-PCR) tests have been developed to identify astrovirus in feces or intestinal homogenates (20, 43). This procedure is completed by pooling the feces or lower intestines from 3–5 birds per flock and either isolating RNA directly or passaging filtered fluids one time through embryonated turkey eggs. The RNA from the field sample or from the isolated embryo intestines then is subjected to RT-PCR using oligonucleotide primers specific to 2 different genes of the viral genome, a conserved region and a diverse region. The use of primers from 2 different regions of the virus allows the identification of distinct astrovirus genotypes. Through the development of this test, it is possible to distinguish the astrovirus that circulated among commercial turkey flocks in the 1980s from the more recent NC96 strain. The RT-PCR test will also detect the presence of astrovirus as early as 1 day postinfection. The sensitivity, specificity, and cost of the RT-PCR test has been greatly improved by the development of several real-time RT-PCR assays (RRT-PCR) (17, 42). RRT-PCR amplifies viral nucleic acid similar to standard RT-PCR, but the product is detected in "real time" with a sequence-specific probe labeled with fluorescent dyes. RRT-PCR is commonly used in human diagnostic laboratories and now serves as the "gold standard" test for numerous viral pathogens.

Differential diagnosis of astrovirus infections in turkey poults needs to include infectious, parasitic, and noninfectious agents that can cause enteric disease. Cultures for enteropathogenic bacteria, such as *Salmonella* spp. and *Campylobacter* spp., should be done. Smears or tissue sections should demonstrate protozoa. Other enteric viruses need to be excluded including coronaviruses, reoviruses, rotaviruses, and toroviruses. Differential diagnosis of several viral enteric pathogens can now be accomplished by multiplex RT-PCR or RRT-PCR (40, 42, 46). These assays differentiate turkey astrovirus, turkey coronavirus, and turkey reovirus in intestinal homogenates. The rapid advances in diagnostic technology make it probable that we may one day have an affordable enteric pathogen chip capable of rapidly identifying the causative agent(s) of infectious enteritis in poultry.

Treatment, Prevention, and Control

No vaccines, chemotherapeutics, or other measures are reported to be efficacious for control and/or prevention of astrovirus infections. Generally, good management practices emphasizing cleaning, disinfecting, litter management, and resting of facilities between flocks are recommended. Astrovirus infections have, however, continued to be problematic for some producers with modern facilities using high standards of management, suggesting that contemporary management practices may not have been entirely effective.

Avian Enterovirus-Like Viruses

J. S. Guy, M. S. McNulty and C. S. Hayhow

Introduction

A number of enterovirus-like viruses (ELVs) have been identified in avian species. The term enterovirus-like is applied to these viruses, as they have not been fully characterized; definitive classification awaits further biologic, physicochemical, and molecular characterization. This section addresses those ELVs identified in domestic poultry, other than duck hepatitis virus types 1 and 3 (see Chapter 13), and turkey viral hepatitis virus (see Chapter 14).

The economic significance of avian ELVs is not yet known. No evidence suggests that they are transmissible from avian species to humans or other mammals. The extent, if any, to which they spread among different species of domesticated poultry is unknown.

Etiology

Classification

Enteroviruses comprise one of nine genera within the family Picornaviridae (40). Members of the Picornaviridae contain a single molecule of infectious, positive sense, single-stranded RNA, 7–8.8 kb in size. Genera within the family Picornaviridae are distinguished *inter alia* by their sensitivity to acid, buoyant density of the virion in CsCl, and clinical manifestations in the affected host. Members of the genus *Enterovirus* are stable at acid pH, have a density of 1.30–1.34 g/mL in CsCl, and they replicate primarily in the intestinal tract (21, 40). Most avian ELVs have been classified on the basis of size, morphology, cytoplasmic replication in enterocytes, and resistance to acid pH. However, it is emphasized that these biological criteria are insufficient for definitive classification. This is borne out by nucleotide sequence analyses of genomic RNA, and antigenic analyses, of some avian viruses that possess these biological criteria. Avian encephalomyelitis virus, a virus that initially was considered to be an enterovirus, has been shown to share a high level of deduced amino acid sequence identity with hepatitis A virus (24, 43). Based on these findings, avian encephalomyelitis virus has been provisionally classified as a tentative species in the genus *Hepatovirus* in the family Picornaviridae (40). Similarly, nucleic acid sequence analyses of other viruses—avian nephritis virus and two viruses initially thought to be turkey ELVs—have identified these viruses as members of the family Astroviridae (14, 15, 20, 22, 32, 40, 45, 46). Based on antigenic analyses, it is likely that several viruses initially identified as chicken ELVs will be reclassified in the future as astroviruses, as these viruses have been shown to share antigenic relationships with avian nephritis virus (4, 10, 29, 42). Furthermore, given the extent of antigenic variation exhibited by astroviruses, some of the ELVs that are antigenically unrelated to avian nephritis virus may also be reclassified at a future date.
12.13. Spherical, 18–27 nm enteroviruslike viruses (ELVs) detected in feces of young turkeys with enteric disease, sodium phosphotungstate.

Morphology

Picornavirus virions are icosahedral (T = 1), nonenveloped, and 22–30 nm in diameter. The virion lacks obvious surface structure, and no surface projections exist (21, 40) (Fig. 12.13). The sizes described for most avian ELVs fall within a 22–30 nm range, although a range of 18–24 nm was described for a U.S. turkey ELV (41).

A turkey ELV isolate was determined to have a buoyant density of 1.33 g/mL in CsCl (18).

Chemical Composition

Only limited information is available regarding the chemical composition of avian ELVs. Information on the genome structure of ELVs is available only for a single U.S. isolate from turkeys (18). This virus was shown to possess a single-stranded RNA genome of approximately 7.5 kb. No information is available regarding avian ELV proteins.

Virus Replication

Replication of turkey ELVs has been investigated by both immunohistochemistry and thin-section EM (19). Virus replication
12.14. Degenerating enterocyte containing cytoplasmic crystalline arrays of enteroviruslike viruses (ELVs).

was shown to occur in the cytoplasm of intestinal enterocytes. Crystalline arrays composed of small, round virus-like particles approximately 23 nm in diameter (Fig. 12.14) were observed (19); an earlier study (41) described particles of 17.1 nm. Similar findings to the former were reported for chicken ELVs (6, 9, 25, 27). However, in one detailed study (9), membrane-bound cytoplasmic inclusions containing virus-like particles were detected more frequently in mesenchymal cells and macrophages in the lamina propria than in enterocytes. Some chicken ELVs also replicate in the kidney, and have been implicated in the etiology of baby chick nephropathy (37).

A U.S. turkey ELV was shown by immunofluorescence and immunoperoxidase staining procedures to replicate primarily in the jejunum and ileum of experimentally infected poults. The virus replicated preferentially in those enterocytes located halfway between the tip and base of the villus. Viral antigen was found most abundantly in enterocytes situated immediately above crypt openings (17); similarly, antigens of chicken ELVs were found mostly in cells at the base of the villi (6).

No information is available concerning transcription and translation of the RNA of avian ELVs.

Susceptibility to Chemical and Physical Agents

Avian ELVs that have been tested have been found to be stable at pH 3 and unaffected by solvents, such as chloroform and ether (25, 27, 28, 39, 42). No information exists about their sensitivity to disinfectants.

Strain Classification

Because of the difficulties associated with growing avian ELVs in cell culture and other laboratory host systems, very little information is available concerning their antigenic relationships. Using cross immunofluorescence, 3 ELVs isolated from chickens, designated EF84/700 (28), FP3 (39), and 612 (25), were found to be antigenically distinct from each other and also from avian encephalomyelitis virus, avian nephritis virus, duck hepati-

tis virus type 1 and duck hepatitis virus type 3 (25, 29). Several ELVs isolated in Japan from chicks with baby chick nephropathy (37) and from broilers with a stunting syndrome (42) had biologic and physical properties similar to the G-4260 strain of avian nephritis virus but were antigenically distinct from avian nephritis virus (36,37). Nucleotide sequence analyses of the genomes of these viruses is needed to determine whether these viruses are enteroviruses or a third serotype of avian nephritis virus (36, 37).

Two strains of turkey ELVs isolated in France were shown to be antigenically unrelated to avian encephalomyelitis and duck hepatitis viruses using cross-neutralization tests (1).

Laboratory Host Systems

Enterovirus-like viruses can be propagated in the laboratory by oral inoculation of neonatal birds of the same species from which they originally were recognized or isolated. Depending on the virus, inoculated birds may develop enteric disease and depressed growth rates. Intestinal contents examined by negative contrast EM 1–3 days postinfection (PI) normally will contain the inoculated virus. Additionally, immune electron microscopy can be used to assist identification of ELVs in intestinal contents of inoculated birds (33, 34, 41). However, caution must be exercised in propagating ELVs in this manner as even specific-pathogen-free birds may be infected with ELVs.

Most chicken ELVs will grow in the yolk sac of 6-day-old embryonated chicken eggs, with approximately 50% of embryos dying within 3–7 days PI. Dwarfing of embryos may also be observed (37). Some of these viruses also can be propagated in the chorioallantoic membrane of embryonated eggs. Immunofluorescent staining of impression smears of yolk sac membranes or cryostat sections of chorioallantoic membrane can be used to confirm virus growth. In addition, some ELVs, for example FP3 and 612, show limited growth in primary cultures of chicken embryo liver or chicken kidney cells. Growth of virus in cell cultures is best detected by immunofluorescent staining (Fig. 12.15), as many of these viruses cause little, if any, cytopathology (4, 25, 29).

Samples of feces or intestinal contents that contain chicken or turkey ELVs also may contain reovirus. Reoviruses normally outgrow ELVs in embryos and cell cultures; thus, their presence interferes with attempts to isolate ELVs.

None of 4 turkey ELVs and 2 pheasant ELVs detected by negative contrast EM in the feces and intestinal contents of birds with enteric disease in the United Kingdom produced a cytopathic effect in primary chicken embryo liver cell cultures. However, 1 turkey virus grew to low titers in embryonated chicken eggs inoculated via the yolk sac (12). Similarly, 2 isolates of ELVs were made in France from turkey intestinal contents following yolk sac inoculation of chicken embryos (1).

An ELV from guinea fowl with transmissible enteritis was propagated successfully following inoculation of 7-day-old guinea fowl embryos via the yolk sac; however, embryo mortality and lesions were inconsistent. This virus also grew in primary cultures of guinea fowl embryo brain cells; no cytopathic effect was evident, but the presence of virus was demonstrated by inoculation of guinea fowl embryos and 1-day-old guinea fowl (31).
12.15. Immunofluorescent staining of chicken embryo liver cell culture infected with enteroviruslike virus (ELV) (612 isolate). ×450.
12.16. Specific immunofluorescence in epithelium of jejunal villus of chicken infected with enteroviruslike virus (ELV) (612 isolate). ×450.

Pathogenicity

The pathogenic role of avian ELVs requires further clarification. Although field and experimental evidence suggests that they may cause enteric disease in young turkeys, chickens, and guinea fowl, and nephropathy in baby chicks, additional studies are needed to define their importance.

Pathobiology and Epidemiology

Incidence and Distribution

Examination of feces using negative contrast electron microscopy (EM) has led to the discovery of ELVs in a number of avian species. The presence of ELVs in intestinal contents of young turkeys and chickens was described in the United Kingdom in 1979 (26). Subsequently, ELVs were identified in the feces of turkey poults in the United States (33, 34, 35), Italy (31), and France (1); in chickens in Belgium (5), the United States (11), Malaysia (3), South Africa (25), Italy (31), Holland (38), and Germany (38); in guinea fowl with transmissible enteritis in Italy (23, 31) and France (2); and in partridges (13) and pheasants (12) in the United Kingdom. In addition, ELVs have been found in feces and enterocytes of cockatoos and galahs with enteric disease in Australia (30, 44) and in the gut contents of ostriches showing signs of enteritis in South Africa (8). Based on these findings, it is likely that avian ELVs have a worldwide distribution.

Natural and Experimental Hosts

Infections with ELVs have been described in turkeys, chickens, guinea fowl, partridges, pheasants, ostriches, and psittacine species. The majority of naturally occurring infections in domes-

tic poultry have been identified in young birds during the first few weeks of life. However, a chicken ELV was isolated from the meconium of a dead-in-shell chicken embryo (39), indicating that infection with these viruses may occur in adulthood.

Transmission, Carriers, and Vectors

The principal site of replication of ELVs is the small intestinal epithelium (Fig. 12.16); some chicken ELVs also replicate in the kidney (37). Thus, infection most likely is spread horizontally through ingestion of infected feces, but other routes of spread cannot be ruled out. Isolation of a chicken ELV from meconium of a dead-in-shell chicken embryo indicates that this virus is vertically transmitted (39); it is likely that other ELVs also are transmitted in this manner. Additionally, evidence indicates darkling beetle larvae may act as mechanical vectors for turkey ELVs (7).

Clinical Signs

The main clinical signs associated with naturally occurring ELV infections in domestic poultry are diarrhea, decreased feed efficiency, and uneven growth. Increased mortality also may occur. Disease is most frequently seen in birds in the first few weeks of life. Enteric disease has been reproduced experimentally in neonatal birds inoculated orally with ELVs.

In 3- or 4-day-old specific-pathogen-free turkeys experimentally infected with a U.S. turkey ELV, depression, watery droppings, and pasted vents were observed. Signs were first evident 3–4 days PI. Similar signs occurred in poults inoculated at 2, 3, and 4 weeks of age. Decreases in body weight gain also were observed. ELVs were detected in greatest numbers in the intestinal

contents of inoculated turkeys at 3 and 4 days PI but were present in some birds up to 14 days PI (17, 19, 41).

Abnormal feces and transient stunting of growth of variable severity were observed in broiler chickens dosed orally with ELVs (5, 25, 29). Specific-pathogen-free chicks inoculated orally with Japanese ELVs showed diarrhea and variable mortality (up to 53.3%), dying between 2 and 6 days PI (37).

An ELV isolated from guinea fowl with transmissible enteritis in Italy suppressed weight gains of commercial guinea fowl when they were inoculated orally at 1 day of age (31).

A naturally occurring syndrome associated with ELV infection in young galahs and sulfur-crested cockatoos was characterized by intractable profuse diarrhea, wasting, and death (30, 44).

Pathology
Gross lesions in turkeys experimentally infected with a U.S. turkey ELV consisted of thin-walled, dilated ceca filled with yellow, foamy fluid and extreme paleness of the serosa of the gastrointestinal tract; catarrhal secretions were detected in the small intestines. Morphometric studies indicated varying degrees of shortening of the villi and elongation of crypts along the length of the small intestine (17, 19, 41). In naturally occurring infections in turkeys, ELVs usually occur as a component of mixed infections. Interestingly, poults experimentally infected with a combined turkey ELV/group A rotavirus inoculum were more severely affected in terms of clinical signs, body weight gain, and lesion severity than poults that received either inoculum alone (17).

Chicks experimentally infected with Japanese ELVs and that died 2–6 days after inoculation showed microscopic changes characteristic of baby chick nephropathy (i.e. nephrosis and visceral urate deposition) (37). Chicks experimentally infected with ELVs from broilers in Belgium with a runting syndrome had pale small intestines with watery and sometimes filamentous contents of the small intestine and ceca (5).

In a naturally occurring syndrome associated with ELV infection in young galahs and sulfur crested cockatoos, the intestine was dilated with mucoid fluid and gas, and the walls appeared thickened. Microscopic lesions in the intestine consisted of villus atrophy and fusion, elongation of the crypts of Leiberkuhn, marked epithelial cell proliferation in the crypts and shortened villi, with inflammation of varying severity (30, 44).

Thin section EM has revealed the presence of intracytoplasmic, crystalline arrays of particles resembling enteroviruses in the enterocytes of infected chickens (6, 27) and cockatoos (30, 44).

Pathogenesis of the Infectious Process
The nature of the microscopic lesions in the small intestine of affected birds suggests that infections with ELVs produce malabsorption and diarrhea due to destruction of small intestinal villus epithelial cells. Measurement of absorption of D-xylose from the intestines of experimentally infected turkey poults confirmed that a transient malabsorption was present in poults inoculated at 3 days of age, but not in poults inoculated at 2 weeks of age (17). However, it also has been suggested that the turkey ELV exerts its effects by altering the cellular physiology of the villus epithelial

cells, altering the normal intestinal flora, or through a systemic mechanism (as evidenced by a transient lymphopenia) (41).

Replication in other organs, such as the kidneys, also may contribute to the pathogenesis of these viruses.

Immunity
The development of active immunity to ELV infections has not been investigated. Similarly, the extent to which passively acquired maternal antibodies provide protection from these infections is unknown.

Diagnosis

Isolation and Identification of Causative Agent
Diagnosis of ELV infections in avian species most commonly is accomplished by EM examination of droppings or intestinal samples. ELVs have been identified using both direct and immune EM procedures. For direct EM, droppings or intestinal contents are prepared as suspensions (10–20%) in phosphate-buffered saline and centrifuged at 800 x g for 20 minutes to remove large particulate material. The supernatant fluid subsequently is centrifuged at 15,000 x g for 20 minutes in a benchtop centrifuge, and the resultant pellet is resuspended in approximately 500 μL distilled water and 100 μL 2% phosphotungstic acid. After mixing, the material either is sprayed onto formvar-filmed copper grids, or a drop of the material is placed on the grid for 1–3 minutes and removed by blotting on bibulous paper. ELVs also may be detected in droppings or intestinal contents using immune EM (34); however, this procedure requires availability of specific antisera.

Confirmation that particles observed by EM are animal viruses is achieved by isolating the viruses in turkey or chicken embryos or in cell cultures as described previously. Antigenic characterization of the isolate is dependent on the availability of serogroup-specific antisera. Yolk sac membranes or chorioallantoic membranes from inoculated embryos may be prepared as impression smears or cryostat sections and examined by immunofluorescent staining using serogroup-specific antisera. This serologic procedure will distinguish between isolates of known serogroups and aid in the identification of new serogroups.

An antigen-capture enzyme-linked immunosorbent assay (ELISA) was described for detection of turkey ELV in turkey intestinal contents (16). The procedure was shown to be a rapid, highly sensitive, and specific method for diagnosis of the virus.

Serology
Antibodies to ELVs have been detected by serum-neutralization and indirect immunofluorescence tests (6, 29, 37); however, because virus isolates and reference antisera are not widely distributed, routine serologic diagnosis is not recommended. However, serology is useful to determine the status of specific-pathogen-free birds with respect to ELV infections.

Differential Diagnosis
Enteric disease associated with ELVs needs to be distinguished from similar conditions caused by other enteric viruses, such as

rotavirus, astrovirus, and coronavirus; clinical signs and lesions are not pathognomonic. However, mixed infections of ELVs and other enteropathogens occur commonly, and it may be difficult to identify the relative importance of each constituent of mixed infections.

Intervention Strategies

The role of ELVs as avian pathogens has not yet been fully defined; consequently, no specific therapeutic or prophylactic measures are available. Given the importance of some of the conditions with which avian ELVs have been associated, it would be prudent to develop better diagnostic methods for these viruses in order to investigate their epizootiology and pathogenicity more fully.

Turkey Torovirus Infection

D. L. Reynolds and A. Ali

Introduction

Toroviruses are classified in the order Nidovirales and the genus Torovirus of the family Coronaviridae (13, 15). Comparative genomic analysis has provided evidence to suggest that toroviruses should be a subfamily of Coronaviridae or perhaps their own family within the Nidovirus order (14). The first torovirus to be classified, the Berne virus, was isolated and identified from a horse during the early 1980s and is the only torovirus that has been propagated in cell culture (equine dermal cells) (15, 33). Since then, toroviruses have been detected in cases of diarrhea / enteritis from humans, dogs, cattle (Bovine breda 1 and breda 2 viruses) and pigs (12, 16–19, 23, 24, 28, 29, 34). More recently, an enteric virus formerly known as stunting syndrome agent (SSA) has been detected in young turkeys with diarrhea (2). This virus now has been determined to be a torovirus. The relationship between the turkey toroviruses and toroviruses from other animal species have not been determined. Additionally, the economic impact of torovirus infection(s) on the turkey industry has not been established.

History

Stunting syndrome (SS) is a condition of young poultry characterized by diarrhea, poor weight gain, and suboptimal performance (11, 22, 24, 35). In poults, the condition has also been referred to as malabsorption syndrome, poult enteritis, turkey viral enteritis, etc. (24). A number of infectious agents (including viruses, bacteria, and parasites) and noninfectious etiologies have been associated with this condition (24). In the early 1990s, the disease was reproduced in turkeys under laboratory conditions. Subsequently, a disease model was developed using an inoculum containing the etiologic agent (now known as turkey torovirus) (10). Using this laboratory model, stunting syndrome of turkeys was characterized. It was found that poults with stunting syndrome had decreased weight gain, diarrhea, decreased disaccharidase activity, and poor feed conversion (9–11). The etiologic agent was isolated and identified several years following the characterization of the disease (2). Stunting syndrome of turkeys is caused by a virus initially referred to as the stunting syndrome agent (SSA). Further characterization of the SSA revealed physicochemical properties consistent with toroviruses (5). Additionally, it was found that the SSA was antigenically and genomically different from other known avian pathogens including enteric coronavirus, infectious bronchitis, and Newcastle disease virus (6). It was revealed that the SSA genomic sequence is very similar to the polymerase protein gene of Berne virus—a member of the genus Torovirus (Ali and Reynolds, unpublished data). Based on the physicochemical properties and this recent genomic sequence information, the SSA is being referred to as turkey torovirus.

Incidence and Distribution

Little information is available concerning the prevalence of torovirus in turkeys and other avian species. A direct and indirect immunofluorescence assay to detect toroviral antigens (in the intestinal tissue) and antitorovirus serum antibodies, respectively, was developed (27) and was used in a survey of turkey flocks in
12.17. Composite of four electronmicrographs of turkey torovirus. Note the virus envelope with peplomeres and the various morphology of the nucleocapsid that is dependent on its orientation. Size of particles vary from 60 to 95 nm.

the United States (26). The results of this study indicated that about 30% of turkeys experiencing enteric disease (i.e., stunting syndrome) were positive for torovirus. Additionally, antitorovirus serum antibodies were detected from turkey flocks in Israel. These results provided evidence that turkey torovirus occurs in other countries and continents beyond the United States.

The enteric disease caused by turkey torovirus infection usually occurs during the first 3 weeks of life in turkey poults. The older turkeys are susceptible to infection, but the weight loss and enteric disease is mild or asymptomatic.

At present, it is not known whether torovirus infected turkeys become carriers and shed virus following infection or whether egg transmission occurs. Additionally, the mechanism(s) by which the turkey torovirus is maintained in the environment is also not known. Chickens and chicken embryos are resistant to infection with turkey torovirus.

Etiology

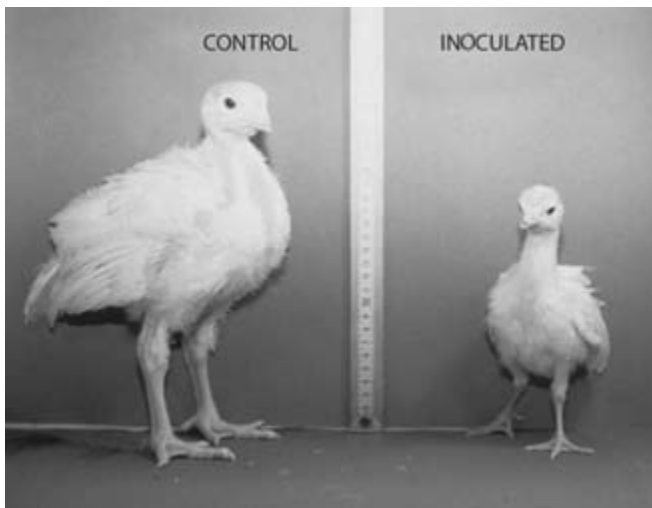
Turkey torovirus is an enveloped virus that is about 60–95 nm in diameter when examined with transmission electron microscope (2). Morphologically, the nucleocapsid appears as dumbbell-shaped, kidney-shaped, or comma-shaped depending on its orientation and is surrounded with a membrane containing peplomers (Fig. 12.17).

Turkey torovirus agglutinated rat erythrocytes at 4°C and at room temperature but did not agglutinate erythrocytes from chickens, turkeys, rabbits, mice, guinea pig, cats, horses, dogs, sheep, and cattle. Turkey torovirus lost its infectivity after treat-

ment with ether but was stable at acidic pH (pH 3.0) for 1 hour at 37°C. The virus is inactivated at pH 10.0. Turkey torovirus was resistant to treatment with sodium deoxycholate and phospholipase C. Treatment of turkey torovirus with trypsin, chymotrypsin, and pancreatin resulted in the enhancement of viral infectivity. The purified viral genome is sensitive to treatment with RNase enzymes and appears to be polyadenylated at its 3′ end (5). Partial sequence data of the turkey torovirus genome indicated that it is related with the polymerase protein gene of Berne virus, a member of the genus Torovirus (Ali and Reynolds, unpublished data).

Turkey torovirus was propagated in primary culture of turkey intestinal epithelial cells (1, 2). The virus can also be propagated in 23–24-day-old turkey embryos when inoculated via the amniotic route (3). Torovirus replication in turkey embryos was limited to the intestinal tract. Virus replication in the intestines was detected by immunofluorescence and reverse transcription-polymerase chain reaction (RT-PCR). Torovirus replication in embryos causes accumulation of excessive amounts of fluid within the lumen of the intestine (Fig. 12.18), decrease in intestinal maltase activity and a decrease in the absorption of D-xylose by the intestine.

Pathogenesis and Epidemiology

Turkey torovirus is known to infect turkeys. Chickens are refractory to infection with the virus. The clinical disease caused by torovirus is observed during the first few weeks of life. Turkeys older than 4 weeks are infected with torovirus, but clinical disease is mild or asymptomatic. In torovirus-infected poults, the duration of clinical signs is usually 7–10 days and include diarrhea (loose, frothy droppings containing undigested feed material), listlessness, and litter eating. Decreased weight gain(stunting) and poor feed conversion are of major concern and of economic significance (11). Mortality is generally low, but morbidity is high. Torovirus infected turkey flocks appear uneven in size (Fig. 12.19)


12.19. Turkey poults from the same hatch that had been reared identically. The smaller poult displays the effect of stunting syndrome (i.e. torovirus infection). (Courtesy of Jerry Sell, Iowa State University)

and do not achieve weight gains comparable to uninfected flocks. The intestinal disaccharidase activity and intestinal D-xylose absorption is reduced in infected poults. Experimental studies with turkey torovirus have shown that oral inoculation of day old poults with a gradient purified preparation of virus results in decreased weight gain, diarrhea, decreased intestinal disaccharidase(e.g., maltase, sucrase, etc.) activity and decreased D-xylose absorption (2). The decrease in intestinal maltase activity is detectable at 2–3 days post inoculation and persists for 10–14 days post inoculation. The intestines appear thin-walled and pale. Intestinal contents are watery and contain undigested feed material. The ceca are dilated, and cecal contents are watery, frothy, and brownish in appearance. The disease in poults inoculated with pure virus is of shorter duration and less severe than in poults inoculated with homogenates prepared from the intestines of infected poults. This provided evidence that other factors (i.e., bacteria and other microbes) contribute to the disease (31). Inoculation of turkey embryos (at 23–24 days of embryonation) via the amniotic route with torovirus causes disease that has similarities to natural torovirus infections in poults. Excessive fluid accumulation in the intestines (Fig. 12.18), decreased intestinal maltase activity, and decreased D-xylose absorption are typical (3). Torovirus infected embryonic intestines were thin-walled, pale, and fragile. The intestines were filled with pale-yellow to greenish fluid containing torovirus. The amount of fluid within the intestine increased with time following virus inoculation. Histologically, the changes in the intestinal cells were subtle and may not always be evident. As stated previously, diarrhea was observed in young poults infected with turkey torovirus. Similarly, turkey embryos infected with torovirus exhibited excessive fluid accumulation in the intestines. This fluid accumulation is measured easily (by weighing) and is a useful indicator for quantitating diarrhea. The mechanism(s) of this fluid loss into the intestine by poults and embryos is not understood. One

plausible mechanism of diarrhea from torovirus infection may be from the damage induced to the intestinal epithelium that leads to the accumulation of undigested and unabsorbed feed in the intestinal lumen. This, in turn, can cause an osmotic effect on the movement of water across the intestines leading to fluid loss. It should be noted, however, that intestines observed from embryos inoculated with turkey torovirus exhibit minimal (if any) damage to the intestinal epithelium (i.e., histologically, the intestines appear normal). Additionally, feed material is absent in the intestinal lumen in embryos so there can be no osmotic effect. These observations suggest that an additional mechanism(s) may be involved in fluid loss during turkey torovirus infection. Previous work suggests that immune cells or their products may contribute to the fluid loss during infection with turkey torovirus (4). When turkey embryos were treated with cyclophosphamide to deplete them of their immune cells and these immune cell depleted embryos were infected with turkey torovirus, the embryos secreted significantly less fluid within their intestines than torovirus infected embryos that had intact (normal) immune cells. Additionally, it was also observed that the intestinal epithelial cells from infected embryos had higher levels of mRNA for pro-inflammatory cytokines including interleukin-8, tumor necrosis factor, and macrophages-monocytes inflammatory protein than uninfected normal controls (7). These observations suggest that immune cells are likely to be attracted to the site of virus insult (i.e., the intestine) and these cells or their products play a role in the pathophysiology of torovirus enteric disease. Furthermore, infection of turkey poults and embryos with turkey torovirus lead to activation (increased metabolic activities and increased level of serine esterases-enzymes found in higher concentrations in the cytoplasm of activated cytotoxic lymphocytes) of intestinal intraepithelial lymphocytes. These results further suggest that immune cells, including the intestinal intraepithelial lymphocytes, are activated during infection with turkey torovirus and may contribute to the diarrhea/fluid loss during infection.

The intestinal disaccharidases (e.g., sucrase, maltase, etc.) are also reduced during infection with turkey torovirus in turkey embryos as well as poults. The active disaccharidase enzymes are normally present in the brush border membrane of mature intestinal epithelial cells found at the tip of the villous (30). These enzymes are required for end-stage digestion of disaccharides into final products (respective monosaccharides) before absorption occurs by the epithelial cells. The mechanism(s) of this decrease in enzymatic activity is not known. There is little, or no, loss of mature intestinal epithelial cells during infection with turkey torovirus. During experimental infection of turkey embryos with torovirus, the epithelial cells from control and infected embryos had similar levels of mRNA for sucrase-isomaltase enzyme complex when examined by competitive RT-PCR (4). This observation suggests that the mechanism(s) for the decrease in disaccharidase activity is beyond the post transcriptional level. The mechanism(s) of this blockage is not known. Some lymphokines have been reported to influence the activity of disaccharidases in some cells (20, 21). During our studies where immune cell-deficient turkey embryos (following treatment with cyclophosphamide) were inoculated with the turkey torovirus, there was not a signif-

icant decline in intestinal maltase activity following infection despite virus replication in the intestinal epithelium. It was assumed from these observations that immune cell(s) or their products may also play a role in the mechanism(s) responsible for decreased intestinal maltase activity that was observed following viral infection.

The presence of bacteria in the inoculum containing enteric viral pathogens including turkey torovirus has been reported to increase the severity and duration of enteric disease following infection (31). The identity of bacteria that may be involved in increasing the severity of enteric disease, and the mechanism(s) responsible for their additive effect, are unclear (8). It is also not known whether there is a synergistic effect(s) between other enteric agents (i.e., viruses, parasites, etc.) on the outcome of enteric disease.

Diagnosis

Diagnosis of turkey torovirus infection can be achieved by a number of methods. Direct electron microscopic examination of the cecal contents may be used. However, a number of factors need to be considered when using this technique. Torovirus is a membraned virus; therefore, freezing and thawing of clinical specimens (i.e., intestinal tracts and or feces) generally result in a loss of peplomers, and identification and differentiation (from cell membrane debris) become difficult. Torovirus associates with intestinal epithelial cells and its demonstration from intestines/feces may require concentration from large volumes of clinical specimens. The virus was demonstrated(from 3–9 days post inoculation) in lysed intestinal epithelial cells isolated from infected poults (2). Toroviral antigens were demonstrated from the intestinal epithelium by direct fluorescent antibody (FA) assay (27). The cells containing viral antigens were observed along the middle portion of the villous. The toroviral antigens were demonstrated in the intestinal epithelial cells from 2–12 days postinoculation. Torovirus infections can also be diagnosed by detecting serum antibodies using the indirect fluorescent antibody (IFA) assay. While developing the IFA assay, infected poults were a better source of viral antigen for IFA than infected embryos because the nonspecific fluorescence (i.e., background) was less when using intestines from infected poults than from infected embryos. Turkey torovirus specific antibodies were demonstrated as early as 5 days postinoculation by IFA under experimental conditions. Torovirus specific antibodies have been detected in sera from 25-week-old turkey flocks in field cases.

A reverse transcription-polymerase chain reaction (RT-PCR) assay was developed for turkey torovirus and was used to detect torovirus under experimental conditions (Ali and Reynolds, unpublished data). Further development of this assay may allow for its use in field conditions. Turkey torovirus can be isolated by inoculating turkey embryos (23–24-day old) via the amniotic route (3). The inoculated embryos are incubated for 96 hours and observed for lesions (fluid accumulation in the intestines) and decreased intestinal maltase activity. The torovirus infected intestines (and contents) may need to be blindly passaged a few times in turkey embryos to observe the lesions. The intestinal fluid contains torovirus that can be visualized by direct EM examination. Although cultured, primary intestinal epithelial cells are susceptible to virus replication, these cells may be of limited use for routine isolation of turkey torovirus because of difficulties in maintaining these cells *in vitro* and their extraordinary susceptibility to toxic substances within the inoculum (1).

Treatment, Prevention, and Control

There are no vaccines available to control or prevent infection or disease induced by turkey torovirus. Additionally, because the disease usually occurs within the first 1–2 weeks of life, vaccination after hatching may not have ample time to generate a protective immune response. Age susceptibility with torovirus infection in turkey poults exists (see previous discussion). That is, birds infected within the first few days following hatch develop the most severe form of the disease; whereas, birds infected later in life (i.e., after 4 weeks of age) develop less severe clinical disease or may be asymptomatic. Therefore, prevention and control strategies that are targeted for early protection and prevention will have the greatest impact. Under experimental conditions, the practice of providing artificial passive immunity has proved to be beneficial (25). Poults that received anti-turkey-torovirus antibodies at the day of hatch and were challenged a day later with torovirus gained significantly more weight than challenged poults inoculated with nonspecific antibodies or challenged poults that received no antibodies. The passively administered antibodies were unable to prevent torovirus infection, but the severity and duration of the disease were greatly reduced. Such studies suggest that passive immunity either via the breeder hen vaccination or by artificial means may be a feasible approach for the prevention or treatment of torovirus disease. Good management practices to reduce or eliminate the exposure of poults to torovirus should be followed. The use of enteric antibiotics to lessen the severity and duration of stunting syndrome has been reported (32). Additionally, the use of specific diets or dietary components has been reported to provide beneficial effects (9). It should be noted that these studies were performed with inoculum that contained torovirus and other undefined agents (i.e., bacteria, etc.). The effects of these treatment regiments may not have been on torovirus but most likely on bacteria or other factors that may have contributed to the clinical disease.

Chapter 13
Viral Infections of Waterfowl

Introduction
Peter R. Woolcock

The objective of this chapter is to bring together under one heading the viral diseases that affect waterfowl. This chapter has details on the following diseases:

- Duck hepatitis, a major disease of young ducklings, caused by three different viruses, duck hepatitis virus (DHV) types 1, 2, and 3. Since the last edition new information on the molecular biology of DHV-1 has been reported.
- Duck virus enteritis (DVE), a potential threat to both commercially reared and wild waterfowl. Advances made in the detection of the virus by the use of the polymerase chain reaction (PCR) technique (25), (52) (54) (77) should be a great aid to rapid diagnosis of the disease, particularly in wild and ornamental collections. The use of PCR may also result in a greater understanding of the pathogenesis and possibly latency of this herpesvirus.
- Parvovirus infections of geese and Muscovy ducks. Molecular techniques have shown that although MDPV and goose parvovirus (GPV) are closely related, they are also distinct and, therefore, should be considered as causing separate diseases. Muscovy duck parvovirus (MDPV) has been recognized in the United States (76).
- Goose hemorrhagic polyomavirus (GHPV) is the cause of hemorrhagic nephritis enteritis of geese (HNEG) (24).
- Other virus infections associated with waterfowl will be covered in this Introduction. Viruses that are not necessarily associated with disease in waterfowl but still infect these species will also be included.

Interests in viral infections of waterfowl are more diverse than for poultry and focus on 3 different issues: a) problems associated with raising birds commercially; b) problems associated with wild waterfowl; and c) problems created by migratory waterfowl in the transmission of infectious disease to commercially reared waterfowl and poultry.

RNA viruses associated with waterfowl include Picornaviridae (DHV I & III), Astroviridae (DHV II), Paramyxoviridae (avian

metapneumovirus, avian paramyxoviruses), Orthomyxoviridae (avian influenza), Flaviviridae (West Nile virus), and Reoviridae (Muscovy duck reovirus and goose reovirus); whereas DNA viruses include Herpesviridae (DVE, GHV), Adenoviridae (duck adenovirus), Circoviridae (circovirus-like infection of ducks and geese), Hepadnaviridae (duck hepatitis B virus), Parvoviridae (MDPV and GPV) and Polyomaviridae (GHPV).

Oncogenic viruses of waterfowl are not included in this chapter.

Avian Paramyxoviruses

Avian paramyxoviruses (APMV) types 1, 4, 6, 8 and 9 have been associated with infections in waterfowl, but generally are considered to be apathogenic. Virus isolations from waterfowl have been reported (23), (55), (60) (58), (26), (30), (13). Antibody responses in waterfowl to various AMPVs have also been reported (9), (10), (29), (47).

Chang *et al.* 2001 (14) reported on the complete nucleotide sequencing of a APMV 6 isolated from ducks, that was apathogenic.

An exception to this are reports by Zou *et al*. 2005 (78) and Jinding *et al*. 2005 (36) of an APMV type 1 causing high mortality in geese in China.

APMVs are dealt with in detail in Chapter 3.

Avian Metapneumovirus

Avian metapneumoviruses (aMPV), a relatively newly described group of viruses in the family Paramyxoviridae (53) were first isolated in 1980's (21). They have been of most concern to the turkey industry and were not detected in the United States until 1996 (59). The US turkey isolate of aMPV is designated type C, as it is different from the types A and B found in Europe (57).The isolates from ducks in France (73) have also been assigned to subgroup C and Toquin *et al.* (2006) (74) has shown that the European and American subgroup C viruses belong to different genetic lineages.

In 1999, Toquin *et al.* (73) reported the isolation of a pneumovirus from 42-week-old Muscovy ducks exhibiting coughing for 7 days followed 2 weeks later by an egg drop. Mortality was about 2%. Grossly, the birds showed general congestion and splenomegaly; histologically, tracheitis was also observed. The

virus was isolated from tracheal swabs using Vero cells. After one passage, a cytopathic effect characterized by distended cells detaching from the monolayer and syncytia was observed. Indirect immunofluorescence staining of the culture was positive with a polyvalent antipneumovirus serum prepared in SPF turkeys that had been inoculated simultaneously with 4 aMPV strains. The isolate was confirmed as a pneumovirus by a reverse-transcriptase polymerase chain reaction (RT-PCR) focused on the N gene, which is diagnostic for aMPV, irrespective of the virus subgroup. The authors also showed that using monospecific aMPV antisera in both an ELISA and an indirect IFA, the Muscovy duck virus isolated reacted most strongly with the aMPV Colorado antiserum when compared with antisera against aMPV A, B, and non A-non B. The closeness to the Colorado virus strain was confirmed by RT-PCR because the isolate did not react with G-based primers specific to subgroups A & B. The pathogenicity of the aMPV isolated required further investigation to determine its role in this syndrome because *Reimerella anatipestifer* was also recovered. Jestin *et al*. (35) subsequently has reported that experimental infection of 18-day-old SPF Muscovy ducklings with the aMPV isolate did produce clinical signs that could be correlated with virus isolation from tracheal swabs and preceded any seroconversion.

aMPV RNA has been isolated from the nasal turbinates or swabs of mallard ducks, wild geese and sentinels captured in the north central US (63). The nucleotide and amino acid sequences of the aMPV genes examined had 90–95% identity with isolates from turkeys. It is not clear whether virus was isolated in all these cases. The authors considered that wild birds may well be involved in the spread of the disease in turkeys. McComb *et al*. (45) reported the detection of aMPV viral RNA in choanal-tracheal swabs collected from 8-week-old sentinel ducks (mallards) that were allowed to mingle with wild waterfowl in central Minnesota. In one case, aMPV was isolated from the choanal-tracheal swabs, and the virus had more than 96% predicted amino acid identity with the MN/2A turkey aMPV isolate. The authors (45) also detected aMPV viral RNA in choanal swabs from Canada geese, blue winged teal, and snow geese; however, no viruses were isolated from these birds. They concluded that aMPVs may be more widespread in nature than previously thought.

In an experimental study (48) 10-day-old commercial ducklings were inoculated either orally or oculonasally with a Minnesota turkey isolate of aMPV. The birds remained clinically normal, but at 3–21 days PI, aMPV viral RNA was detected in tissues from inoculated birds. aMPV was also reisolated from the infected ducklings.

aMPV-negative mallard ducks placed next to a turkey farm experiencing a severe outbreak of aMPV infection did not develop clinical disease but infectious aMPV was recovered from choanal swabs after 2 weeks and anti-aMPV antibodies were detected after 4 weeks. This indicated that the aMPV isolates from turkeys and ducks shared a common source and viruses from different species can cross-infect. (61)

Bennett *et al.* 2002 (7) demonstrated the presence of aMPV in wild Canada geese (*Branta canadensis*) and blue winged teal (*Anas discors*) by RT-PCR. By virus isolation aMPV could only be recovered in Canada geese. Thus RT-PCR appears to be more sensitive in detecting aMPV. Using Canada geese isolates Bennett *et al.* 2005 (6) went on to investigate the genomic structure of the virus. All but one of the eight genes were similar to those of a turkey aMPV isolate in terms of size, sequence identity and genome organization. However the attachment gene (G) coding for a 585 aa protein was larger than for any pneumovirus or metapneumovirus, being more than twice the size of G proteins for other subtype C viruses and human metapneumoviruses and more than 170 amino acids larger than the G proteins from aMPV subtypes A, B and D. Although this virus with the large insertion in the G gene was not detected in turkeys, it did replicate in the upper respiratory tract of experimentally challenged domestic turkeys with no clinical signs. This virus could also be horizontally transmitted to naïve turkeys and the infection could induce specific antibody production. The authors suggested that this virus may be a safe and effective vaccine for commercial turkeys.

Shin *et al.* 2001(62) considered ducks could be suspected to play a role as nonclinical carriers of aMPV and serve as a potential source of infection for domestic turkeys.

Avian Influenza Virus

Until recently information on avian influenza in waterfowl was reported as follows: Waterfowl typically do not experience significant disease problems due to avian influenza viruses (AIVs), but infections in these birds are widespread (71). AIVs can be recovered from migratory waterfowl, particularly ducks; at least 30 of 149 species of ducks, geese, and swans have yielded virus but natural infections are usually considered asymptomatic(72).

The picture changed dramatically in late 2002 when HPAI (H5N1) occurred in geese, ducks and swans among other avian species at two waterfowl parks in Hong Kong (18). The range of pathological changes present in the various waterfowl examined in this outbreak resembled those reported generally for HPAI viruses in chickens (72).

Since that outbreak in 2002 H5N1 HPAI, also referred to as "bird flu" has spread through Asia, Europe and parts of Africa.

The role of migratory waterfowl in the spread of H5N1 HPAI has been questioned. Chen *et al.* 2005 (16) described an outbreak in bar headed geese (*Anser indicus*) at Qinghai Lake in Western China in May 2005; more than 1500 birds died.

Hulse-Post *et al.* 2005 (34) reported that the H5N1 HPAI can revert to non-pathogenicity in ducks. Thus wild waterfowl including ducks may appear uninfected by the H5N1 but still shed virus and so continue to circulate the virus. Similar findings were reported by Sturm-Ramirez *et al.* 2005 (69).

There are many reports about the H5N1 HPAI and the role of waterfowl in its transmission; this virus is covered in detail in Chapter 5.

West Nile Virus

West Nile virus (WNV) is a member of the Japanese encephalitis virus antigenic complex of arthropod-borne flaviviruses

(Flaviviridae) that are transmitted through mosquitoes to a variety of mammals and birds (39). The notoriety of this virus has increased since 1999 when an epizootic causing deaths in wild American crows (*Corvus brachyrhynchus)* began in New York (50). This was the first time that WNV had been detected in North America. At the same time, WNV-positive cases occurred in a number of wild bird species, humans, and horses (39, 40, 68) as well as a zoological collection of mammals and birds in New York (12).

Outbreaks of WNV involving ducks and geese have been reported from Israel and Romania (40, 49, 56). In the New York outbreak, Steele *et al.* (68) examined birds from two wildlife facilities in the city, which had either died or were euthanatized and were suspected of being infected with WNV. Lesions seen in emaciated Anseriformes included brain hemorrhages, splenitis, splenomegaly, nephritis, and congestion in the kidneys. Three ducks were involved in this study, 1 mallard and 2 bronze-winged ducks. In the mallard, abundant antigen was demonstrated by immunohistochemistry in the brain, heart, liver, kidney, and pancreas and to a lesser extent in the adrenal gland and intestine. Virus in excess of 10^2 pfu/0.2 ml was isolated from brain, heart, spleen, liver, and kidney; virus was also demonstrated by RT-PCR in these same tissues. Only immunohistochemical testing was performed on the tissues from the bronze-winged ducks, but results obtained were not dissimilar to those in the mallard.

Calle *et al.* (12) reported that in the 1999 outbreak in New York an Abyssinian blue-winged goose (*Cyanochen cyanopterus*), a roseybill duck (*Netta peposcaca*), and a domestic goose (*Anser anser*) showed asymptomatic seroconversion to WNV, and in the domestic goose and trumpeter swan (*Cygnus cygnus buccinator*) morbidity and recovery were recorded. No deaths were recorded in any of the birds.

The New York isolates of WNV yielded an E gene nucleotide sequence that was extremely homologous to that from the WNV isolated from a goose in Israel in 1998 and also from a 1996 Romanian isolate(40, 42).

In an experimental study, Swayne *et al.* (70) reported WNV replication in 2-week-old goslings following s/c inoculation. A viremia was detected between 1–5 days PI; virus could be detected in plasma diluted up to 1:10^6. All the experimentally infected goslings developed clinical signs, typified by depression, weight loss, and decreased activity; one bird developed neurological signs. Microscopic lesions seen in the infected birds were encephalitis and myocarditis. Virus was recovered from the brain and the heart. Viral antigen was demonstrated by immunohistochemistry in the heart, brain, pancreas, and kidney and in autonomic ganglion cells of the intestine (varied from bird to bird). These authors concluded that the disease was a threat to goslings; the high virus titers in the blood suggested that goslings could be an amplifying host and, thus, infect permissive mosquito vectors; the virus was transmitted by contact between goslings in close association.

Bird to bird transmission of West Nile virus in geese has been proposed by Austin *et al.* 2004.(1) They investigated an outbreak on a multiage farm with multiage flocks in Manitoba, Canada. The level of seroconversion in these flocks exceeded that which would have been expected by mosquito transmission alone. In another study Banet-Noach *et al.* (4) showed direct (non-vector) transmission of WNV in geese. They mixed a group of 10, 3-week-old s/c inoculated geese with 20 healthy geese of the same age in an insect-proof room. All geese in the inoculated group produced antibodies, 8 became viremic and 5 died between 7–10 days PI. Virus was shed via the cloaca and oral cavity by 3 geese. Two of the contact birds died on days 10 and 17 pi and WNV was recovered from another 3 birds. The authors claim these findings strongly suggest that horizontal transmission can occur in commercial flocks and may be aggravated if cannibalism and feather picking of sick birds occurs.

RT-PCR procedures for detecting WNV have been described (8, 40, 56).

Muscovy Duck and Goose Reoviruses

Muscovy duck reovirus infections have been described (37, 43). In France, it is considered to be a major virus disease of Muscovy ducks (41). In 2-4-week-old ducks, the disease is acute; morbidity is high; and mortality can reach 10%. Clinical signs include apathy, with diarrhea and difficulties in moving. Grossly, dead birds showed fibrinous pericarditis, marbled spleen, and enlarged friable livers (43, 44). Microscopically, the pericarditis consisted of an infiltration of mononuclear inflammatory cells in the serous membrane associated with a fibrinous exudate. In the liver, there were necrotic foci or infiltrations of lymphocytes and plasmacytes in the portal region. In the spleen, reticulosis, depletion of lymphoid nodules, and focal necrosis were evident. The synovial sheath of the leg tendons had an exudative inflammation (44).

Cross neutralization tests have demonstrated the Muscovy duck reovirus to be antigenically distinct from the chicken reovirus S1133 (28).

A reovirus has also been reported recovered from a mallard (46).

Palya *et al.* 2003 (51) reported on a disease in young geese caused by a reovirus. The disease was characterized by splenitis and hepatitis with miliary necrotic foci during the acute phase and epicarditis, arthritis and tenosynovitis during the subacute/chronic phase. Although in earlier reports reoviruses had been repeatedly recovered from geese they had never been associated with disease. The disease occurred most frequently in 2–20-week-old goslings and Banyai *et al.* 2005 (5) investigated the genetic variability among goose reoviruses (GRV). The S4 genome segment of five GRVs shared substantial structural similarity with Muscovy duck reovirus (DRV). The authors consider GRV and DRV to belong to a species distinct from others established within the subgroup 2 of orthoreoviruses.

Hollmen *et al.* 2002 (31) reported the isolation of a reovirus from common eider ducks (*Somateria mollissima)* in Finland. The virus was isolated from the bursa of Fabricius in Muscovy duck embryo fibroblasts, but not in SPF chicken eggs. Mallard ducklings challenged with this virus seroconverted. No deaths were recorded but at necropsy focal hemorrhages were observed in the liver, spleen and bursa of Fabricius of some of the birds. The polyvalent eider reovirus serum obtained from the experi-

mental mallards did not inhibit the growth of avian arthritis virus (S1133) in Muscovy duck embryo fibroblasts. The relationship of this reovirus to DRV and GRV has not been reported.

Goose Herpesvirus (GHV)

In Australia, a herpesvirus has been implicated in a peracute disease of domestic geese that caused 97% mortality over a 24-day period (38). Clinical signs and gross pathology were similar to those seen with DVE infections. Histologically small button ulcers and large plaques overlying lymphocyte aggregates were present on the mucosa of the small intestine of affected birds. Small white foci of necrosis and focal hemorrhages were seen in the livers. Numerous intranuclear inclusion bodies were observed microscopically in the hepatocytes. A herpesvirus was isolated in various primary chicken and duck embryo cell cultures. This virus was not neutralized by antiserum to DVE virus. In experimental transmission studies, the virus caused 100% mortality in adult domestic geese, 50% mortality in 1-day-old commercial ducklings, and 25% mortality in 4–6-week-old commercial ducklings (38). However, Gough and Hansen (22) reported that Pekin ducks are not susceptible to GHV.

In cross-protection studies, Gough and Hansen (22) showed that mortality in DVE-vaccinated geese, Muscovy ducks, and Pekin ducks challenged with GHV was 100, 50 and 0%, respectively. Conversely, in geese, Muscovy ducks and Pekin ducks immunized with inactivated GHV, 100% mortality was recorded in the geese and Muscovy ducks and 80% in the Pekin ducks following challenge with DVE virus. Using cross-neutralization tests in cell cultures, they compared GHV with 5 other avian herpesviruses—namely, DVE/goose, DVE/Muscovy, infectious laryngotracheitis virus, Pacheco's herpesvirus, and falcon herpesvirus. No significant cross neutralization was reported, confirming that GHV is antigenically distinct from DVE viruses. Using restriction endonuclease analysis, a comparison of the genome of GHV with 3 different strains of DVE virus confirmed that GHV is completely different from the DVE viruses. By PCR using two different sets of DVE-specific primers, the GHV was shown to be different from 3 DVE virus strains.

Adenoviruses

Duck adenovirus 1, also known as group III avian adenovirus, egg drop syndrome-1976 virus, avian adenovirus EDS, and egg drop syndrome virus (NCBI & ICTV database), is a member of the genus *Atadenovirus* species duck adenovirus A. Ducks and geese are assumed to be the natural hosts of this virus, but there is no evidence of disease in waterfowl associated with this virus.

Aviadenoviruses have also been reported isolated from a mallard (46) and a Muscovy duck (11). In Muscovy ducks, mortality occurred, but there were no attempts to reproduce the disease with the isolated adenovirus tentatively named duck adenovirus 2.

Unclassified Adenoviruses

Hollmen *et al.* 2003 (32) reported the isolation of an adenovirus from long-tailed ducks (*Clangula hyemalis)* collected during a die-off in the Beaufort Sea off the north coast of Alaska. The authors reproduced the disease experimentally in long-tailed ducks inoculated with the isolated virus; no mortality was recorded but clinical signs included gastrointestinal disease including watery feces and blood in the feces. Challenged ducks seroconverted. The virus could not be neutralized by reference antisera to group I, II or III avian adenoviruses and so may represent a new serotype.

Hollmen *et al.* 2003 (33) also reported on an adenovirus associated with impaction of the posterior small intestine with mucosal necrosis and the cause of death in 10 male common eider ducks (*Somateria mollissima*) in the northern Baltic Sea near Finland. They isolated adenovirus from cloacal swabs from 6 of the birds. The adenovirus could not be neutralized with reference antisera to group I, II or III avian adenoviruses. The virus caused clinical signs of illness and gastrointestinal pathology in an experimentally infected mallard duckling.

Cheng *et al.* 2001 (17) reported attempts to characterize a virus causing enteritis in goslings in China. They identified an adenovirus, and named the virus new gosling viral enteritis virus (NGVEV).

For more information, see Chapter 9, "Adenovirus Infections."

Circovirus-like Infection of Ducks and Geese

Soike *et al.* (67) first reported in 1999 the presence of circovirus-like particles, approximately 15 nm in diameter, by negative stain EM in bursal, splenic, and thymic tissues from a flock of Czech hybrid geese with a history of increased losses and runting. Since then a virus has been isolated from two female mulards showing characteristic signs of circovirus infection (66). This duck circovirus (DuCV)has been shown to be closely related phylogenetically to goose circovirus (GoCV), but is still distinct (27).

Avian circovirus infections which occur in the first months of life are characterized by developmental and/or feathering disorders. The virus invades the lymphoid tissues and leads to immunosuppression, growth retardation and an increased probability of secondary infections, such as *Reimerella anatipestifer* and *Aspergillus* sp. In geese the only apparent gross lesions in 2-week-old and 9-week-old birds were a cloudiness of the air sacs (67). Histopathological changes were evident in the lymphoreticular tissue; lymphocytic depletion and histocytosis were most apparent in the bursa of Fabricius. Basophilic globular inclusions were found in the cytoplasm of medullar and cortical bursal follicular cells and bursal epithelial cells. Ultrastructural examination of these inclusions revealed paracrystalline or multilayered arrays or randomly arranged complexes of isometric viral particles approximately 14 nm in diameter. In naturally infected commercial Muscovy, mule and Pekin ducks, and white Roman geese in Taiwan, the mainly 4–6 week old birds had clinical signs of loss of wing and body feather, necrosis of feather follicles and stunted growth. Grossly the most common lesion was polyseroritis in particular in the pericardial cavity and over the surface of the liver; a cheese like mass within the air sacs was often observed (15).

Smyth *et al.* 2005 (64) investigated a circovirus infection in geese by *in situ* hybridization using a GoCV DNA probe, which showed that circovirus DNA could be demonstrated in the bursa of Fabricius, spleen, thymus, bone marrow, liver, kidney, lung and heart, indicating that the infection can be multisystemic.

Diagnostic tests for GoCV and DuCV are mostly PCR based. Ball *et al.* 2004 (2) reported a PCR and dot blot hybridization test to diagnose GoCV in Hungarian geese. Fringuelli *et al.* 2005 (19) described the development of both conventional PCR and real time PCR to diagnose DuCV. Chen *et al.* 2006 (15) reported a PCR that could detect and differentiate duck and goose circovirus infections.

Glavits *et al.* 2005 (20) investigated an outbreak of West Nile fever in a goose flock in Hungary; they found histologically in addition to the changes attributable to WNV changes more characteristic of a circovirus. Both virus infections were diagnosed by RT-PCR and PCR, respectively, but neither virus was isolated.

A duck circovirus (DuCV) was detected by PCR in bursal and thymic samples from Pekin ducks from New York. The birds exhibited bursal and thymic atrophy, as well as arthritis caused by *Staphylococcus aureus* (3). This is the first report involving Pekin ducks.

Miscellaneous Viral Infections

Tsai *et al.* (75) reported that 77.3% of 611 ducks and 70.9% of 542 geese in Taiwan were positive for antibodies to Japanese encephalitis virus.

Smyth and McNulty (65) reported on a transmissible disease of the bursa of Fabricius in ducks but could not identify a causative agent.

Duck Hepatitis

P. R. Woolcock

Introduction

Duck hepatitis (DH) is a highly fatal, rapidly spreading viral infection of young ducklings characterized primarily by hepatitis. It can be caused by any of three different viruses, namely duck hepatitis virus (DHV) types 1, 2, and 3. DHV types 2 and 3 were first recognized as separate entities because they induced hepatitis in DHV type 1-immune ducklings. Duck hepatitis is of economic importance to all duck-growing farms because of the high potential mortality if not controlled. The three virus types are not known to have any public health significance. For other reviews of DHV types 1 and 3 see Calnek (15) and for DHV type 2 see Gough and Stuart (48).

In addition to the three viruses that are etiologically associated with liver disease in ducks, a member of the hepadnavirus group

(hepatitis B viruses) is also found in wild and domestic ducks. Although the duck hepatitis B virus is not known to cause disease or lesions in ducks, it is briefly described in a separate section at the end of this chapter.

Duck Hepatitis Type 1

History and Distribution

An acute disease of ducklings, characterized by enlarged livers mottled with hemorrhages, was observed in 1945 by Levine and Hofstad (73). The disease affected ducklings during the 1st wk of age, and death was rapid after signs were observed. While the disease could be transmitted in ducklings, no agent was isolated. During the spring of 1949, Levine and Fabricant (72) studied a highly fatal disease, which is now known as DH type 1, in young white Pekin ducks on Long Island, New York. The disease spread rapidly; before the summer was over, practically all 70-odd duck farms in the area had suffered losses. At first, ducks 2–3 wk old were succumbing. On severely affected farms, mortalities up to 95% were not uncommon in some broods. Successive lots of ducks almost invariably became infected. Later, occasional broods would escape with little mortality. It is estimated that 15% of the total number of ducklings started for that year died from the disease—a total of 750,000 birds. The disease has also been diagnosed in other duck-raising areas of the United States. Duck hepatitis type 1 is worldwide in distribution (107); the most recent reports of new isolations include China (50) and Korea (90).

Etiology

DHV type 1 was first isolated in chicken embryos by Levine and Fabricant (72). No serologic relationship was demonstrated between this virus and that causing duck plague (duck virus enteritis); likewise, no neutralization of DHV type 1 occurred when tested with convalescent serum from cases of human and canine virus hepatitis (28). DHV type 1 contains RNA and has been classified as a picornavirus (106). It bears no relationship to the hepadnavirus infection caused by duck hepatitis B virus (DHBV) as described by Mason *et al.* (82). Duck hepatitis B virus has been found in domestic ducks in China and the United States.

Morphology

DHV type 1 has been estimated to be 20–40 nm in size (97). Richter *et al.* (98) observed 30 nm particles in thin liver sections by electron microscopy (EM). Tauraso *et al.* (106) confirmed the size to be less than 50 nm by filtration studies.

Biologic Properties

Fitzgerald and Hanson (32) were unable to demonstrate hemagglutination of chicken, duck, sheep, horse, guinea pig, mouse, snake, swine, and rabbit red blood cells (RBCs) by cell culture-grown DHV type 1.

Cell cultures infected with DHV type 1 failed to hemadsorb green and rhesus monkey, hamster, mouse, rat, rabbit, guinea pig,

human O, goose, duck, and day-old chicken RBCs. High-titered virus suspensions would not hemagglutinate RBCs of the same species when tested at a pH range of 6.8–7.4 and at temperatures of 4, 24, and 37°C (106).

Resistance to Chemical and Physical Agents

DHV type 1 is resistant to ether and chloroform, relatively heat stable, and capable of survival for long periods under usual environmental conditions.

DHV type 1 resisted treatment with ether or fluorocarbon (91), chloroform, pH 3 and trypsin (106), and 30% methanol or ammonium sulfate (53). Using cell culture-grown virus, Davis (20) reported that DHV type 1 resisted pH 3 for 9 hr, but longer exposure (48 hr) reduced virus titer. The virus was not inactivated by 2% lysol or 0.1% formalin (6); 15% creolin, naphthalysol, or xylonaphtha; or 20% anhydrous sodium carbonate (92). Complete inactivation was reported with 1% formaldehyde or 2% caustic soda within 2 hr at 15–20°C, 2% calcium hypochlorite within 3 hr at 15–20°C (92), and 3% chloramine in 5 hr or 0.2% formalin in 2 hr (27). Haider (51) reported complete virus inactivation with 5% phenol, undiluted Wescodyne (an inorganic iodine solution), and undiluted Clorox (sodium hypochlorite solution).

Heating the virus at 50°C for 1 hr had no effect on virus titer (106). Most of the virus was inactivated at 56°C after 30 min (53). Asplin (6) reported, however, that it would survive at 56°C for 60 min but not at 62°C for 30 min. Dvorakova and Kozusnik (27) reported that 23 hr were required for complete inactivation at 56°C. DHV type 1 survived for 21 days at 37°C (91). Heat stability was unaffected by 1 M divalent cation (Mg^{2+})(110). Davis (20), using cell culture-grown type 1 virus, showed that it had a half-life of 48 min at 50°C, but that the presence of molar NaCl, Na_2SO_4, $MgCl_2$, or $MgSO_4$ protected the virus from inactivation at that temperature.

Under more natural environmental conditions, the virus survived at least 10 wk in uncleaned infected brooders and for longer than 37 days in moist feces stored in a cool shed (6). At 4°C, the virus survived over 2 yr (6), (27) and at –20°C for as long as 9 yr (53).

Variability

Viruses differing, or serologically distinct, from DHV type 1 have been recognized as causes of hepatitis in ducklings and have been reported from India (95) and Egypt (104). The Indian isolate is known to be distinct from DHV type l, but its relationship to the other DHV types is unknown.

A variant strain of DHV type 1, named DHV type 1a, has been described by Sandhu *et al.* (102). The origin of the virus is unknown, but all known isolates can be traced back to a single location. With the use of cross-neutralization tests in embryonating chicken eggs, they showed, with somewhat variable results, a partial cross-reaction between types 1 and 1a. They also showed partial cross-protection in passively immunized ducklings challenged with each of the viruses. Woolcock (see (124) had also reported differences between these two viruses in plaque-reduction assays in duck embryo kidney cells. Both DHV type 1 and DHV type 1a are serologically distinct from DHV type 3.

Laboratory Host Systems

Embryos

Levine and Fabricant (72) were the first to propagate the virus in the allantoic sac of 9-day-old chicken embryos. From 10 to 60% of the embryos died by the 5th or 6th day and were stunted or edematous (Fig. 13.1A). Hwang and Dougherty (63) passaged a DHV type 1 strain as two lines in 10-day-old chicken embryos. The serially passaged lines became nonpathogenic for newly hatched ducklings at the 20th and 26th transfers. The virus titer in chicken embryos was $1–3 \log_{10}$ lower than when grown in ducklings.

Hwang (55) developed a chicken embryo lethal strain of DHV type 1 by serial embryo passages. Using a homogenate of dead embryos and chorioallantoic membrane (CAM) in embryonic fluid, mortality reached 100% at the 63rd passage. More consistent results were obtained when 5- to 7-day-old embryos were inoculated via the yolk sac.

Toth (108) found titers of 80th passage-adapted virus to be highest at about 53 hr postinoculation (PI): embryo, $10^{7.50}$; CAM $10^{5.79}$; and amnioallantoic fluid $10^{3.62}$. A high-titer live vaccine could be harvested from all these parts 53–69 hr PI. Essentially similar results were reported by Pan (87).

Mason *et al.* (81) noted a somewhat higher titer of attenuated DHV type 1 in chicken embryos that reached a peak (10^8) in 48 hr. The latent period was between 6 and 24 hr.

Goose embryos were found to be susceptible to the virus, and embryo deaths occurred 2–3 days after allantoic inoculation (4).

Cell Cultures

Various attempts to grow and assay DHV type 1 in cell cultures of duck and chicken embryo origin have been described (32), (34), (57), (65), (81), (91). Maiboroda (76) followed development of DHV type 1 in monolayers of duck kidney cells with a direct fluorescent antibody (FA) technique. Fluorescence was observed after 8 hr, reached a maximum after 2–4 days, and was confined to the cytoplasm. Cytopathic effects (CPE) (rounding of cells) and maximum virus titers occurred after 2 days. Maiboroda and Kontrimavichus (77) produced growth and CPE in goose embryo kidney cells. Kurilenko and Strelnikov (71) reported similar results in piglet kidney cell culture. Davis and Woolcock (23) showed that attenuated DHV type 1 grew in embryo cell cultures of goose, turkey, quail, pheasant, guinea fowl, and chicken origin, while virulent virus strains grew to varying degrees in only guinea fowl, quail, and turkey embryo cells. Golubnichi *et al.* (42) reported successful growth and a high level of cytopathogenicity in duck embryo fibroblasts inoculated with chick embryo-adapted DHV type 1. They recommended this procedure for vaccine production and virus neutralization (VN) tests.

Woolcock *et al.* (121) described a plaque assay for attenuated DHV type 1 in primary monolayers of duck embryo kidney (DEK) cells. The concentration of fetal calf serum in the overlay medium affected plaque size. Subsequently, Chalmers and Woolcock (17) demonstrated that several mammalian sera had an inhibitory effect on the virus, which was nonspecific and only occurred when the serum was in direct contact with the virus. The virus-inhibitory substance in fetal calf serum ap-peared to be present in the albumin fraction. There was no or minimal inhibitory effect in sera from ducks or chickens. Woolcock (116) reported plaque assays for both virulent and attenuated DHV type 1 in primary duck embryo liver (DEL) cells and compared the results of *in vitro* assays with those obtained *in ovo* and *in vivo*. Kaleta (66) described a microneutralization assay using attenuated DHV type 1 in primary DEK cells; Woolcock (117) modified this assay to monitor immune responses to vaccines.

Pathogenicity

Asplin (5) and Reuss (96) reported loss of pathogenicity of DHV type 1 for ducklings after chicken embryo passages. Hwang (55) found one virus strain to have lost its pathogenicity for ducklings after 20 or more passages in chicken embryos. He also found that the same strain had lost its pathogenicity for ducklings after the sixth passage in duck embryo fibroblasts, but the virus retained its pathogenicity for chicken embryos (56).

Hwang and Dougherty (63) reported that chicken embryo-passaged strains, while nonpathogenic for ducklings, did multiply in the tissues but at a lower titer than field strains. Field strains were found in fairly high concentrations in duckling brain; chicken embryo-passaged strains could not be detected or were present in low concentrations in the brain.

A similar attenuation of pathogenicity has been reported when DHV type 1 was passaged in duck embryos (11). Embryo passage-attenuated DHV type 1 strains are still capable of causing very mild and transitory histologic changes after inoculation (101), (105), and reversion to virulence occurs after back-passage in young ducklings (122), (123).

When Kapp *et al.* (67) encountered heavy losses from DH type 1 in several flocks of ducklings 3–4 wk old, they suspected inadequate rations as contributory causes. This was borne out experimentally when eight of nine 3-wk-old ducks that had been fed the farm ration died after virus exposure. No mortality occurred in controls on normal feed. It was concluded that faulty diet had impaired liver function, which predisposed ducklings to hepatitis at an unusually advanced age.

Friend and Trainer (35, 37, 38) fed low levels of polychlorinated biphenyl, DDT, and dieldrin to mallard ducklings for 10 days; 5 days later, birds were infected with DHV type 1. Birds receiving toxic substances had significantly higher mortality than controls not previously fed the chemicals. It appears that inadequate diet or ingestion of toxic substances exacerbates pathogenic effects of the virus.

Lu *et al.* (74) reported an outbreak of infectious-bill-atrophy syndrome in ducklings in Taiwan, which they believe was caused by a parvovirus infection in association with DHV. The exact role of DHV in this syndrome was not clearly defined.

Sandhu *et al.* (102) reported that the pathologic responses to DHV types 1 and 1a were similar.

Pathogenesis and Epidemiology

Natural and Experimental Hosts

In naturally occurring outbreaks, DH type 1 occurred only in young ducklings. Adult breeders on infected premises did not be-

come clinically ill and continued in full production. Field observations indicated that chickens and turkeys were resistant. Rahn (94), however, found that day-old and wk-old poults exposed to DHV type 1 developed signs, lesions, and neutralizing antibody. Poults, after either oral or intraperitoneal exposure, had mottled livers and enlarged gall bladders and spleens. DHV type 1 was isolated from livers up to 17 days after oral exposure of day-old poults. Schoop *et al.* (103) and Reuss (97) failed to infect chickens experimentally. Reuss could not transmit the disease to rabbits, guinea pigs, white mice, or dogs. Asplin (6) reported that young chickens can contract an inapparent infection and pass it on through contact with other chicks. Experimental infections in goslings (4) and mallard ducklings (36) have been reported. In experimentally exposed birds, no mortality occurred in chicks, Muscovy ducklings, or pigeon squabs; low mortality occurred in young turkeys and quail, while high mortality occurred in young pheasants, geese, and guinea fowl. All exposed birds became infected with DHV type 1 (61).

Transmission, Carriers, and Vectors

Under field conditions, DH type 1 spreads rapidly to all susceptible ducklings in the flock. Although high mortality and rapid spread of the disease on farms indicate extreme contagiousness, occasional exceptions have been observed. In one pen, 65% of the ducks died, while in an adjoining pen separated only by a 14-in. curb, mortality was negligible.

The first efforts to transmit the disease to small groups of three or four caged ducklings by injection and feeding of egg-propagated virus were not successful. In another experiment, with tissues from a naturally occurring outbreak, some ducklings became infected. Transmission was most easily accomplished by intramuscular (IM) injection and feeding egg-propagated virus and infected organs to larger groups of ducklings (10–20) kept on litter under a hover. The incubation period was 24 hr in most experiments, and nearly all deaths took place by the 4th day. Uninoculated ducklings placed in the same pens with inoculated birds contracted the disease and died somewhat later than injected ducks.

Egg transmission presumably does not take place. Newly hatched ducklings produced by breeders on infected premises remained well when taken where no ducks were being kept. Asplin (5) confirmed this finding.

Priz (93) found that aerosol infection of ducklings with Yagotinski strain of DHV type 1 was lethal.

Hanson and Tripathy (54) reported successful infection with attenuated DHV type 1 by the oral route, although Toth and Norcross (111) suggested that in this case, the portal of entry was really the pharynx or upper respiratory tract, since the virus administered in a capsule failed to produce infection.

Recovered ducks may excrete virus in feces for up to 8 wk PI (97). Asplin (6) reported that there is strong field evidence to incriminate wild birds as mechanical carriers of the virus over short distances. He also suggested the possibility that an unknown host acting as a healthy carrier might be responsible for new outbreaks at great distances. However, Asplin (8) found no serologic evidence of DHV type 1 in VN tests of sera from 520 wild aquatic fowl of six species. These negative results were fortified by failure of Ulbrich (113) to find VN antibodies in 36 wild ducks (four species) taken from ponds where DH type 1 had occurred in domestic ducks. In addition, all of 153 wild duck embryonated eggs from an infected area were susceptible to experimental infection.

Of possible significance in the epizootiology of the disease is the report of Demakov *et al.* (25) indicating that brown rats (*Rattus norvegicus*) could act as a reservoir host of DHV type 1. Ingested virus remained alive in the body up to 35 days and the virus was excreted 18–22 days PI. Serum antibodies were also present 12–24 days PI.

Vectors are not known to be a factor in transmission of DH type 1.

Signs

Onset and spread of DH type 1 are very rapid, with practically all mortality occurring within 3–4 days. Affected ducklings at first fail to keep up with the brood. Within a short time, they stop moving and squat down with eyes partially closed. Birds fall on their sides, kick spasmodically with both legs, and die with heads drawn back (Fig. 13.1B). Death occurs within an hour or so after signs are noted. During the height of severe outbreaks, the rapidity with which ducklings die is astonishing.

Farmer *et al.* (29, 30) described duck fatty kidney syndrome and focal pancreatic necrosis, which were considered to be aspects of DH type 1. Between 1978 and 1983, losses up to 30% were recorded on certain duck-rearing farms in the United Kingdom. Two age groups, 1–2 wk and 4–6 wk old, were affected despite routine vaccination with type 1 vaccine. Gross lesions were characterized by pale swollen livers and kidneys, and swollen mottled spleens. Histologic evidence was indicative of DH type 1. Despite vaccination with attenuated DHV type 1, and the age of the older group of birds, the authors suggested that this syndrome was a manifestation of DH type 1. They have acknowledged, however, that DHV type 2, which was subsequently diagnosed in East Anglia (45, 46), may have played a role in this syndrome.

Morbidity and Mortality

Morbidity is 100% and mortality is variable in young ducklings infected with DHV type 1. In some broods less than 1 wk old, mortality may reach 95%. In ducklings 1–3 wk of age, mortality may be 50% or less. In ducklings 4–5 wk of age, morbidity and mortality are low or negligible.

Gross Lesions

Principal lesions due to DHV type 1 are found in the liver, which is enlarged and contains punctate or ecchymotic hemorrhages (Fig. 13.1C). Frequent reddish discoloration or mottling of the liver surface is seen. The spleen is sometimes enlarged and mottled. In numerous cases, the kidneys are swollen and renal blood vessels congested.

Histopathology

Microscopic changes in uncomplicated, experimentally induced DHV type 1 infections have been studied (28). Primary changes

in the acute disease consisted of necrosis of hepatic cells (Fig. 13.1D); survivors with more chronic lesions showed widespread bile duct hyperplasia (Fig. 13.1E). Varying degrees of inflammatory cell response and hemorrhage occurred. Regeneration of liver parenchyma was observed in ducklings that did not die. Ten-day-old chicken embryos inoculated with DHV type 1 were killed and examined histologically at 12-hr intervals for periods up to 10 days PI (33). Histologic changes included proliferation of granulocytes in various organs, focal necrosis of the liver, bile duct hyperplasia, and subcutaneous edema. Inclusion bodies were not found. Six-day-old ducklings were infected intranasally and intramuscularly with DHV type 1 and killed 14–24 hr later. Their livers were examined by EM. One hr after infection, there was an occasional breakup of glycogen within the liver cells. Spherical particles 100–300 nm in diameter and of unknown origin were visible. Changes seen in peracute cases were degenerative, and there was extensive cell necrosis after 24 hr. Virus-like particles were detected at 1 hr and 18–20 hr PI (1).

Adamiker (2) examined spleen and muscle of ducks infected with DHV type 1 by EM. The spleen showed regressive changes from the 6th hr PI and became necrotic by the 24th hr. There were degenerative changes in the nuclei of plasma cells that may have been caused by the virus. Virus particles were not identified. Only slight changes were seen in muscles.

Biochemical Effects

Ahmed *et al.* (3) reported that in clinical cases of DH type 1, there were lower serum levels of total protein and albumen and elevated levels of alkaline phosphatase, glutamic pyruvic transaminase (GPT), bilirubin, and creatinine. Mennella and Mandelli (83) noted that serum levels of GPT and glutamic oxaloacetic transaminase were increased in relation to severity of infection. Buynitzky *et al.* (12, 13) indicated that even in clinically inapparent DHV type 1 infection in mallards, liver enzyme patterns were altered, with a consequent alteration in metabolism of DDT. This may partially explain the interrelationship between chlorinated hydrocarbons and DH type 1 (35, 37, 38).

Immunity

Recovery from DH type 1 results in solid immunity and VN antibodies in the serum. Active immunity can be induced in adult ducks by injection of certain strains of virus (6). Some strains require repeated injections to obtain high levels of antibody (96). Passive immunity can be conferred to ducklings by injection of serum from recovered or immunized birds. Passive antibodies may also be transferred through yolk to hatched ducklings to protect them. Malinovskaya (79), investigating the antibody response to DHV type 1 vaccine in breeder ducks and 7-day-old ducklings, showed by a passive hemagglutination (HA) test that duck serum contained more 7S antibodies (cysteine sensitive) than 19S antibodies (cysteine resistant). Decline of the 7S antibodies halved the hemagglutination-inhibition titers in 43% of serum samples taken 3–7 days PI. In ducklings experimentally infected between 3 and 21 days of age, the main type of antibody response was 19S during the ensuing 20 days; but in ducklings infected at 30 days of age, 19S antibody was formed first, but 7S

antibody began to appear after 15 days. Davis and Hannant (22) reported that VN antibody was present 4 days postvaccination of 2-day-old ducklings. The antibodies were shown to be in the macroglobulin and 7S fractions by Sephadex G200 chromatography and had γ or ß$_2$ mobility by immunoelectrophoresis.

Diagnosis

Virus Isolation and Identification

The presence of DHV type I may be confirmed by one or more of the following procedures Woolcock (119, 120):

- Inoculation, subcutaneously (SC) or intramuscularly (IM), of the isolate into 1-to-7-day-old DHV type I-susceptible ducklings. The characteristic clinical disease should follow, with deaths often occurring within 24 hours. Ducklings should show the gross pathology attributable to DHV type I. The virus should be reisolated from the livers to confirm the diagnosis.
- Inoculation of serial dilutions of the liver homogenate into the allantoic sacs of embryonated duck eggs (aged 10–14 days) from a DHV type I-free flock, or chicken eggs (aged 8–10 days). DHV type I-infected duck embryos should die within 24–72 hours; chicken embryos are more variable and erratic in their response and usually take 5–8 days to die. The allantoic fluid is opalescent or a pale greenish-yellow. Gross pathological changes in the embryos include stunting and subcutaneous hemorrhages over the whole body, with edema, particularly of the abdominal and hind limb regions. The embryo livers may be swollen, red and yellowish in color, and show necrotic foci. The liver lesions and embryo stunting become more apparent in embryos that take longer to die.
- Inoculation of primary cultures of duck embryo liver cells (116). Serial dilutions of the liver homogenate containing DHV type I cause a cytopathic effect (CPE) that is characterized by cell rounding and necrosis. When overlaid with a maintenance medium containing 1% agarose (wt/vol), the CPE gives rise to plaques approximately 1 mm in diameter.

A rapid and accurate diagnosis of DH type 1 can be made using the direct FA technique on livers of naturally occurring cases or inoculated duck embryos (76), (114).

Virus isolation and identification procedures have been previously reviewed (51, 110).

Serology

Serologic tests have not been useful in diagnosing acute outbreaks of DHV type 1. However, from the time the virus was first recognized (72), the VN test has been used for other purposes: virus identification, titration of serologic response to vaccination, and epidemiologic surveys.

Hwang (58) described an accurate, reproducible DHV type 1 neutralization test in chicken embryos. Modifications of this procedure were described (47, 111). Haider (51) described several modified VN tests in duck embryos or ducklings, and Golubnichi *et al.* (42) described a VN test with virus adapted to tissue culture. Malinovskaya (78) reported that a passive HA test was more

sensitive than the VN test. Ivashhenko (64) examined the use of an indirect HA test for the diagnosis of DHV type 1 and showed a 90% correspondence between indirect HA and VN results.

Murty and Hanson (84) described the use of an agar gel diffusion precipitin (AGDP) test for identification of DHV type 1. Later studies by Wachendorfer (115) and Toth and Norcross (111) claimed that reactions seen by Murty and Hanson were not specific or related to DHV type 1 or antibodies. Zhao *et al.* (125) compared enzyme-linked immunosorbent assay (ELISA), VN, and AGDP for the detection of DHV type 1 antibodies in duck sera. In a report containing several errors, they claimed ELISA and VN to be comparable in sensitivity, but they did not quantitate their VN test results; AGDP was reported to be considerably less sensitive, but exactly what was being measured must be questioned in the light of other reports (111, 115).

Woolcock *et al.* (121) first described a plaque-reduction test for VN antibody. This assay was considerably more sensitive than VN assays in eggs. Chalmers and Woolcock (17) showed that sera collected from 16 uninfected ducks had 50% plaque reduction titers (VN_{50}) ranging between 1:12 and 1:250 with an average of 1:59. They suggested that the maximum VN_{50} titer for negative control serum should be taken as 1:250. Woolcock (116) reported a plaque reduction assay in DEL cells and showed that type 1 virus was only neutralized by type 1 antiserum and not by antisera to type 2 or type 3. He also reported that a VN_{50} of 1:64 in embryonated chicken eggs was equivalent to a VN_{50} in excess of 1:3200 in DEK cells. Kaleta (66) described a microneutralization assay for DHV type 1 in DEK cells. He claimed the assay to be more practical, rapid, and economical than alternative tests but considered the plaque reduction assay more sensitive. Woolcock (117) adapted this microneutralization assay to monitor the VN antibody responses of ducks to vaccines in field and laboratory trials.

Differential Diagnosis

The sudden onset, rapid spread, and acute course of the disease caused by DHV type 1 are characteristic. Hemorrhagic lesions in livers of ducklings up to 3 wk of age are practically pathognomonic. Occurrence of similar disease outbreaks, caused by serologic variants of type 1 virus or by DHV type 2 and DHV type 3, offers the main problem in differential diagnosis.

Chalmers *et al.* (16) reported an outbreak of DHV type 1 associated with *Chlamydia psittaci* in 4- to 6-wk-old birds and suggested a possible synergistic effect as the cause of the persistent 15% mortalities recorded. Gough and Wallis (49) reported DHV type 1 associated with influenza virus in 2- to 5-wk-old mallard ducks reared on a game farm. The DHV type 1 isolated was of low virulence, and it is suggested that the influenza virus may have exacerbated the hepatitis infection.

Other potential causes of acute mortality in ducklings include salmonellosis and aflatoxicosis. The latter disease may cause ataxia, convulsions, and opisthotonos as well as microscopic lesions of bile duct hyperplasia suggestive of DH but does not cause the same characteristic liver hemorrhages. None of the other common lethal diseases of ducks occur frequently in this young age group.

Treatment

As soon as the cause and nature of DH type 1 were recognized by Levine and Fabricant (72), it became apparent that ducklings might be protected by administration of serum from immune ducks. This procedure proved to be highly successful in laboratory experiments and in the field. For many years, the Duck Research Laboratory at Eastport, Long Island, kept a bank of antiserum processed from blood collected at the time of slaughter from recovered birds. Intramuscular injection of 0.5 ml DHV type 1 antiserum into each duckling of a brood at the time of the first deaths in an outbreak was an effective control method.

Rispens (100) suggested passive immunization by injection of yolk from eggs produced by hyperimmune breeder ducks. At the Duck Research Laboratory, Long Island, New York this procedure was modified by substituting yolk from eggs produced by specific-pathogen-free chickens hyperimmunized with DHV type 1.

Prevention and Control

Management Procedures

Duck hepatitis type 1 can be prevented by strict isolation, particularly during the first 4–5 wk. In areas where the disease is prevalent, however, it is very difficult to obtain the necessary degree of isolation.

Panikar (88) and Kaszanyitzky and Tanyi (68) demonstrated the feasibility of eradicating DH type 1 in selected areas where isolation can be achieved. In both studies, vaccination of breeder ducks was used as part of the program.

Immunization

Resistance against DH type 1 may be conferred to ducklings by three methods: injection of immune serum or yolk as described under Treatment; immunization of breeding stock to ensure high levels of passively transferred antibody in the hatched ducklings; and direct active immunization of ducklings with live avirulent strains of DHV type 1.

Attenuated DHV type 1 strains suitable for vaccine use have been produced by passage in chicken embryos (5, 39, 40, 42, 62, 103) or duck embryos (100). Up to this time, various strains of chicken embryo-passaged DHV type 1 have been used most frequently as vaccines.

Davis (21) reported that triple plaque-purified strains of DHV type 1 vaccines could revert to virulence as readily as noncloned virus. This finding has been confirmed with various egg-passage levels of DHV type 1 (118). Davis suggested rapid passage as a method to increase genetic stability.

Breeders. Asplin (5) developed a chicken embryo-attenuated strain of virus for immunizing breeders. The method was to inoculate 0.5 mL undiluted egg-propagated virus IM 2–4 wk before collecting hatching eggs. Reuss (96) found it necessary, with the strain of virus he used, to make repeated injections in breeders to obtain sufficient antibody levels to protect hatched ducklings against challenge with virulent virus. The

optimum age, dosage, route of inoculation, strain of virus, and interval between initial and subsequent vaccinations are not known (6).

Rispens (100) recommended two doses of attenuated virus vaccine administered to breeders at least 6 wk apart; passive immunity was transmitted to progeny for about 9 mo after the second vaccination.

Hwang (59), Rinaldi *et al.* (99), Nikitin and Panikar (85), and Doroshko and Bezrukavaya (26) all confirmed that two or three doses of attenuated virus vaccine were necessary to secure satisfactory levels of protection of progeny. Bezrukavaya (11) secured effective protection by vaccination of breeders with duck embryo-attenuated vaccine. Demakov *et al.* (24) reported that effectiveness of the chicken embryo-attenuated strain was improved by aluminum hydroxide adsorption and a saponin adjuvant. Malinovskaya (80) looked at the effect of chemical stimulators on postvaccinal immunity against DHV type 1 by assaying for passive HA and VN antibodies. Dibazol had no effect, but saponin, methyluracil, and ascorbic acid promoted an accelerated antibody response, which was particularly pronounced 15 days postvaccination.

Golubnichi and Malinovskaya (41) monitored the immune response, following up to three immunizations over a 3-mo period, by assaying HA and VN antibody. The antibody titers in sera of laying ducks necessary to protect their offspring was 1:64 for HA and 1:32 for VN antibodies.

The application of inactivated vaccines also has been investigated. Gough and Spackman (47) reported that effective levels of duckling protection can be secured by administering three doses of inactivated DHV type 1 oil-emulsion vaccine. These workers also reported that live DHV type 1 vaccine at 2–3 days of age, followed by inactivated vaccine at 22 wk, produced significantly higher VN antibody levels than did three doses of inactivated vaccine. Finally, they reported that inactivated vaccine prepared from virus grown in duck eggs gave a better antibody response than virus grown in chicken eggs. Woolcock (117) investigating the use of inactivated DHV type I vaccines in breeder ducks, showed that in order to ensure an adequate immune response to the inactivated virus, it was necessary to prime the ducks with DH type 1-modified live virus (MLV). He showed that ducks primed with MLV at 12 wk of age, and boosted with inactivated DHV type 1 vaccine at 18 wk, developed VN antibody titers 16-fold higher than those in ducks that received only the MLV priming. This level of immunity was sufficient to protect ducklings hatched through a complete laying cycle (8 mo), as demonstrated by challenging progeny with virulent DHV type 1. Inactivated vaccines prepared from MLV grown in embryos or from virulent type 1 virus grown in ducklings were both equally effective. Woolcock (117) also investigated various immunization schedules, using inactivated virus alone, and monitored the VN antibody response of individual ducks in a microtiter assay using primary DEL cells. Only 7 (11%) of 63 ducks developed titers of 6 $\log_2$ or greater, which was considered the minimum protective level, and these responses were only in birds given multiple inoculations of inactivated vaccine.

Ducklings. Asplin (5) used his chicken embryo-attenuated strain of DHV type 1 to vaccinate ducklings by the foot web-stab method. Reuss (96) also reported successful immunization experiments with an attenuated strain.

Newly hatched ducklings injected IM with an attenuated DHV type 1 developed resistance in 3 days (60). Oral exposure required up to 6 days for protection to occur. There was evidence that vaccination would be of benefit even at the start of an outbreak.

Lyophilized, attenuated strains of DHV type 1 induced a considerable degree of protection in day-old ducklings inoculated by the IM, intranasal, or foot-web route (126). Crighton and Woolcock (19) and Gazdzinski (40) also reported successful immunization of ducklings by the (subcutaneous) SC and IM routes, respectively, with chicken embryo-passaged DHV type 1. Golubnichi *et al.* (42) used tissue culture-passaged DHV type 1 for duckling immunization. Effective mass vaccination of ducklings by the aerosol and drinking water routes have been reported (54, 69, 70, 86, 89, 112). Ducklings vaccinated orally at 2–3 days of age did not show an increased immune response when revaccinated at 17 days (9). Balla *et al.* (10) examined administration in the field of DHV type 1 vaccine by SC and drinking water routes. They reported that two doses given in the drinking water at 2–3 days of age were as effective as one dose given orally at 2 days of age.

Balla and Veress (9) examined the antibody response of ducklings of different immune status to SC and oral vaccination with live attenuated DHV type 1. They found that susceptible ducklings and those hatched with maternally derived immunity both responded to vaccination with 1600–9600 EID_{50} given during the first 3 wk of life. The maternally immune birds responded only marginally less. They also showed that a dose of 300–600 EID_{50}/duckling between 2 and 21 days and of 100 EID_{50} at 35 days was sufficient for seroconversion to occur irrespective of the ducklings' immune status. Exposure to an aerosol vaccine for 5–6 min at 2–5 days of age produced a good response in susceptible birds but not in maternally immune ducklings; 30-min exposure to aerosol vaccine gave a good response, which was not boosted by reexposure at 16 days. They did not report any results covering challenge of any of these ducklings with virulent virus. Luff and Hopkins (75) also looked at the effect of maternally derived immunity on vaccination of ducklings with live attenuated DHV type 1. Ducklings were vaccinated when about 12 hr old and were challenged with virulent DHV type 1 at 24 hr, and 3 and 6 days. Their results suggested that partially protective levels of maternally derived antibody did not adversely affect either the speed of onset or the extent of protection afforded by the currently available live vaccine. Unfortunately, findings were limited to the first 6 days of life.

In contrast to the results reported by Luff and Hopkins, field experience has indicated that successful practical duckling vaccination is dependent on the absence of maternal antibodies and is influenced by time and severity of exposure to virulent virus. Vaccination is also less effective when ducklings are exposed to virulent virus early in life, especially in endemic areas and on

heavily infected premises. Judicious application of proper hygiene and sanitation methods could do much to solve this problem.

Duck Hepatitis Type 2

Duck hepatitis type 2, although similar to DH type 1 as a pathologic entity, is caused by an entirely different agent (48). The first report of an outbreak of DH type 2 in ducklings was from Norfolk, England, in 1965 (7). The affected flock had been vaccinated with attenuated DHV type 1. An agent was isolated which was shown, by cross-protection studies in ducklings, to be different from DHV type 1 and was named DHV type 2 (7). The disease disappeared from commercial flocks by 1969 but reappeared in 1983/84 on three farms, again in Norfolk, England (45). Losses in that outbreak varied between 10 and 25% in 3- to 6-wk-old birds, and up to 50% in 6- to 14-day-old birds. Outbreaks on affected farms were often sporadic, affecting some batches of ducks and not others. There are no reports of the disease occurring outside of East Anglia, England, and since the outbreaks in the mid-1980s, there have been no more outbreaks of the disease in that area (44).

DHV type 2 particles have an astrovirus-like morphology and a diameter between 28 and 30 nm as seen by EM (46). Aggregates containing more than 1000 virus particles have been observed in liver suspensions. On this basis, DHV type 2 has been classified as an astrovirus, and it has been suggested that it should be renamed duck astrovirus (43). It has been compared with astrovirus isolates from chickens and turkeys by cross-protection and transmission studies, and found to be antigenically distinct (48). The virus is resistant to chloroform, pH 3.0, trypsin treatment, and heating at 50°C for 60 min. Formaldehyde fumigation and standard disinfection procedures have eliminated the infection from contaminated premises (48).

DHV type 2 replicated in embryonated chicken eggs following several blind passages in the amniotic sac (45). Few embryos died in less than 7 days, but infected embryos appeared stunted and had greenish necrotic livers in which astrovirus-like particles could be demonstrated by EM. Attenuation of pathogenicity occurred after serial passage in chicken embryos (45). Various duck and chicken cell cultures appear to be refractory to infection (45), (116).

Ducks appear to be the only species affected by DHV type 2, and no wildlife reservoirs nor vectors have been detected. All recorded outbreaks have initially involved ducks kept on open fields; therefore, wildfowl, gulls, and other wild birds have been suspected as being vectors (43).

Infection occurs through oral, cloacal, and subcutaneous routes. Deaths occur within 1–4 days, usually within 1–2 hr after the appearance of clinical signs, which include polydypsia with loose droppings, excessive urate excretion, and sometimes convulsions and acute opisthotonos (48). Affected ducks usually die in good condition and both the time of death and the mortality rate (10–50%) depend on the age of the ducks (45). Survivors excrete virus for at least 1 wk after infection (48) and rear normally, with little evidence of retarded growth (45). Mature ducks are refractory to the disease (45).

The target organs for DHV type 2 appear to be liver and kidneys (45). Significantly more virus is present in the liver, which is usually pale pink with multiple, small punctate hemorrhages, often forming confluent bands. The spleen is invariably enlarged and "sago-like" in appearance due to scattered pale foci. Kidneys are often swollen with blood vessels injected and standing out from the pale kidney substance. The alimentary tract is usually devoid of food. Occasionally, small hemorrhages are seen in the intestinal wall and on the heart fat. Microscopic changes in the acute disease are characterized by extensive necrosis of the hepatocyte cytoplasm and bile duct hyperplasia is usually present and widespread.

Gough and Smart (48) found that survivors of DH type 2 were immune to further infection. Detectable antibody levels following infection were shown to be low, using a varying virus-constant serum neutralization test in embryonated chicken eggs (43).

The most reliable diagnostic method for DHV type 2 is EM examination of liver homogenates for the detection of astrovirus-like particles. The virus can only be isolated, with difficulty, following repeated passage in the amniotic sac of embryonated chicken or duck eggs. Inoculation of susceptible ducklings with virus gives a variable response; mortality up to 20% may occur within 2–4 days PI (45, 119, 120).

Inoculation of susceptible ducklings with convalescent serum obtained from DHV type 2-infected ducks has been used successfully to control the disease in the field (48). An experimental live attenuated virus vaccine also protected ducklings from challenge with virulent virus, but this vaccine has never been produced commercially (48).

Duck Hepatitis Type 3

Duck hepatitis type 3 was first reported by Toth (109) who observed hepatitis causing mortality and morbidity in ducklings immune to DHV type 1, on Long Island in the United States. The disease was less severe than DH type 1 and mortality rarely exceeded 30%. Based on differences from both DHV type 1 and DHV type 2, the agent was named DHV type 3 (52). The disease is only known to have occurred in the United States.

Haider and Calnek (52) reported that DHV type 3 contained RNA, based on insensitivity to IUdR, and was resistant to chloroform and pH 3.0 but sensitive to 50°C irrespective of the presence of 1 M MgCl$_2$. Electron microscopy of cultured duck kidney (DK) cells infected with the virus revealed crystalline arrays containing particles about 30 nm in diameter in the cytoplasm. Based on these observations, they suggested that DHV type 3 be classified as a picornavirus, but that it was unrelated to DHV type 1, since no common antigens could be demonstrated in VN and FA tests.

Nine- to 10-day-old duck embryos inoculated onto the CAM were susceptible to DHV type 3 (52). During the first passages embryo deaths were erratic and did not occur until the 8th or 9th day PI, but this was reduced with higher passages. In severely affected embryos, the CAMs were discolored and the surface of the affected areas had a dry crusty or cheesy appearance. Underneath, the CAM was edematous and thickened up to 10

times normal. Embryo lesions included stunting, edema, skin hemorrhages, flaccid appearance, gelatinous fluid accumulations and enlargement of liver, kidneys, and spleen. Attenuation of pathogenicity for ducklings, accompanied by increased pathogenicity for duck embryos, occurred following serial passage in embryonated duck eggs inoculated by the CAM route. Chicken embryos were not susceptible to inoculation with DHV type 3.

Liver and kidney cell cultures of duck embryo or duckling origin were shown to support replication of the virus. This was demonstrated by a direct FA test to show foci of positively infected cells (52). Woolcock (116) reported that the type 3 virus failed to produce plaques in primary DEK and DEL cell monolayers.

DHV type 3 has a low pathogenicity for ducklings experimentally infected, and only ducklings appear to be affected by the virus. Subcutaneous or IM inoculation of liver homogenate from infected ducklings into susceptible day-old ducklings is unreliable. Intravenous inoculation may increase the effectiveness. Mortality and virus yields from liver could be increased if ducklings received two or three doses of cyclophosphamide (2 mg/dose) on days 1–3 and were challenged with virus on the 6th day of age (14).

Ducklings dying from DHV type 3 infection show the typical appearance of type 1 infection, i.e., outstretched legs and opisthotonos (109). Mortality rarely exceeds 30%, but gross pathologic changes are similar to those caused by DHV type 1.

An active immune response to DHV type 3 can be stimulated in adult ducks by inoculation of attenuated virus. This immunity may be passively transferred, via the yolk, to progeny.

DHV type 3 infection may be tentatively identified by inoculation of liver suspension onto the CAM of 10-day-old embryonated duck eggs if embryo lesions and mortality pattern develop as described above (119, 120). Alternatively, virus may be isolated and identified in DK or DEK cultures examined by immunofluorescence 48–72 hr PI, using DHV type 3-specific antiserum. A direct FA test in duckling livers and DEK or DK cells has been described for DHV type 3 (52). A serum neutralization test in embryonated duck eggs is possible. Differential diagnosis is similar to that described for type 1 virus.

Convalescent sera obtained from DHV type 3-infected ducks has been used effectively in the field to control outbreaks. A live attenuated vaccine has been used experimentally in breeder ducks to confer passive immunity to ducklings, but this vaccine has not been available commercially.

Duck Hepatitis B Virus Infection

Duck hepatitis B virus (DHBV) infection is widely distributed in domestic ducks and several species of migratory wild ducks. It is commonly found in the liver and serum. The virus is a small (40 nm diameter) DNA virus belonging to the hepadnavirus group which includes human and woodchuck hepatitis B viruses. In contrast to these mammalian hepadnaviruses, DHBV has not been associated with significant lesions or clinical disease in either chronic congenitally acquired infection or acute experimentally induced infection.

A detailed review of the characteristics of this virus can be found in (31).

Chang *et al.* (18) reported a new avian hepadnavirus infecting snow geese (*Anser caerulescens*). Sequence analysis of the PCR-amplified genome revealed that this virus was distinct from other avian hepadnaviruses.

Duck Virus Enteritis (Duck Plague)

Tirath S. Sandhu and Samia A. Metwally

Introduction

Definition and Synonyms

Duck virus enteritis (DVE) is an acute, contagious herpesvirus infection of ducks, geese, and swans, characterized by vascular damage, tissue hemorrhages, digestive mucosal eruptions, lesions of lymphoid organs, and degenerative changes in parenchymatous organs. Synonyms for the disease are *duck plague*, *eendenpest* (Dutch), *peste du canard* (French), *Entenpest* (German), and *duck virus enteritis* (90). Although Bos (4) first used the term *duck plague*, it was proposed as the official name by Jansen and Kunst in 1949 (39). Subsequently, *DVE*, based on principal features of the disease and to distinguish it from fowl plague, has become the preferred term.

Public Health Significance

DVE is primarily a disease of waterfowl. No known risk to human health has been reported.

Economic Significance

In duck-producing areas of the world where the disease has been reported, DVE has produced significant economic losses in domestic and wild waterfowl due to mortality, condemnations, and decreased egg production. The first outbreak in the United States in 1967 caused losses in excess of $1 million during a 1-year period for the small, but concentrated, duck industry of Long Island, New York (54).

History

In 1923, Baudet (2) reported an outbreak of an acute, hemorrhagic disease of domestic ducks in the Netherlands. Bacterial cultures were negative, and the disease was experimentally reproduced in domestic ducks by injection of sterile filtered liver suspensions. Although presented as a previously unknown viral infection of ducks not infecting chickens, it was concluded the disease was due to a specific duck-adapted strain of fowl plague (avian influenza) virus. Subsequently, more outbreaks were reported in the Netherlands. DeZeeuw (20) substantiated Baudet's findings and speculated the presence of a duck-adapted strain of fowl plague as a predictable cause of the duck virus enteritis. He showed that chickens, pigeons, and rabbits were refractory to experimental infection. DeZeeuw suspected that wild waterfowl were carriers of the disease, as they were found within outbreak areas.

Bos (4) re-examined findings of the earlier workers and observed new outbreaks. He further characterized lesions, clinical

signs, and immune response of ducks by experimental study and was unable to reproduce the disease in chickens, pigeons, rabbits, guinea pigs, rats, or mice. He concluded that the disease was not caused by fowl plague virus, but was a new distinct viral disease of ducks, which he termed "duck plague." This conclusion was based on the high degree of specificity of the agent for ducks, both in experimental and naturally occurring infections, persistence of the disease as a uniform entity in the Netherlands, and the longer incubation period. He differentiated it from Newcastle disease. These observations were further supported by more detailed studies on virus propagation, incidence and distribution, pathology, and immunity (34, 35, 36, 37, 38, 39, 40, 41).

Since the first reports of DVE in domestic and free-flying anseriforms (ducks, geese, and swans) (49, 55), serious outbreaks in migratory waterfowl with high mortality have been reported (22). Outbreaks in zoos and game farm flocks have also been reported (33, 53, 62).

Prior to the 1973 massive outbreak in migratory waterfowl in Lake Andes, South Dakota, the United States Department of Agriculture considered the disease exotic. Because of the high prevalence of DVE in North America the disease is considered enzootic and is reportable. New outbreaks should be reported to the state veterinarian and the federal area veterinarian in charge of the affected state. For a review of the disease in North American waterfowl, see Brand (5).

Etiology

Classification

The causative agent of DVE is a herpesvirus, belonging to the Alpha-herpesvirinae subfamily. Duck enteritis virus (DEV) is nonhemagglutinating (34) and nonhemadsorbing (17).

Morphology

Electron microscopy of virus-infected cells revealed virus particles in both nucleus and cytoplasm (Fig. 13.2) (7). Bergmann and Kinder (3) and Tantaswasdi *et al.* (86) studied structure and maturation of DEV in the cells of infected ducklings. They recorded spherical nucleocapsids about 91–93 nm in diameter with nucleoids (cores) approximately 61 nm in diameter in the nuclei of the host cells. Virus particles about 126–129 nm in diameter, probably the result of the envelopment of nucleocapsids by the nuclear membrane, were seen in the cytoplasm and perinuclear spaces. Larger mature particles varying in size from 156–384 nm in diameter were observed in the tubular system of the endoplasmic reticulum in the cytoplasm. These consisted of enveloped nucleocapsids encased in an osmiophilic matrix and surrounded by an additional membrane. These morphological structures differentiate DEV from other animal herpesviruses (3). In another study, four forms of nucleocapsids were identified in the tissues of infected ducks, which were found in the cytoplasm and nucleus, and measured 42–90 nm in diameter (100). Two types of nucleocapsids were associated with the intranuclear inclusion bodies; round or rod-shaped nucleocapsids containing an electron-dense internal core and nucleocapsids containing electron-dense particles in close proximity to the inner capsid wall, with an elec-
13.2. Thin section of Epon-embedded cells infected 48 hours with Long Island isolate of duck enteritis virus. Virus particles (arrows) appear in several forms in the nucleus (N), cytoplasm (C), and a cytoplasmic vacuole (V). Bar = 1 μm. (7).

tron-lucent cross or pentagonal shape inside. Many nucleocapsids, mature viruses and viral inclusion bodies were observed in the nucleus and cytoplasm of infected cells of liver, small intestine, spleen, thymus and bursa of Fabricius.

Chemical Composition

The virion contains DNA (7). RNase treatment on thin sections had no effect on ultrastructural morphology of the virus, and exposure to DNase led to the removal of the central core without affecting the envelope. Fluorescence of intranuclear inclusion bodies in cell cultures stained with acridine orange was also consistent with the presence of DNA (30). Inactivation by pancreatic lipase indicates that the virions contain an essential lipid (30).

Virus Replication

Development of the virus in cell cultures was studied by electron microscopy and growth curves of intracellular and extracellular virus (3, 7, 86). Examination of thin sections revealed development forms only in the nucleus 12 hours postinoculation. By 24 hours, in addition to viral forms in the nucleus, larger particles with an envelope were observed in the cytoplasm. Virus titrations

of similar cell cultures demonstrated new cell-associated virus 4 hours postinoculation, with maximum titer at 48 hours. Extracellular virus was first detected 6–8 hours postinoculation and reached maximum titer at 60 hours (7). Increased incubation temperatures of tissue cultures (39.5–41.5°C) favored viral replication, especially of less virulent strains (8).

In a susceptible host, virus replicates primarily in the mucosa of the digestive tract, especially in the esophagus, and then spreads to the bursa of Fabricius, thymus, spleen, and liver. The epithelial cells and macrophages of these organs are the principal sites of viral replication (31).

Susceptibility to Chemical and Physical Agents

The virus was found to be sensitive to ether and chloroform (30). Exposing virus for 18 hours at 37°C to trypsin, chymotrypsin, and pancreatic lipase markedly reduced or inactivated it, and papain, lysozyme, cellulase, DNase, and RNase had no effect. Cells treated with DNase showed intranuclear inclusions, but there was marked reduction in fluorescence when stained with acridine orange (30).

Thermal inactivation studies (30) revealed that infectivity was destroyed after heating for 10 minutes at 56°C or 90–120 minutes at 50°C. At room temperature (22°C), infectivity was lost after 30 days. Drying over calcium chloride at 22°C resulted in inactivation after 9 days.

Exposure of the virus for 6 hours at pH levels of 7, 8, and 9 resulted in no loss of titer, but a measurable titer reduction was noted at pH 5, 6, and 10. At pH 3 and 11, the virus was rapidly inactivated. A marked difference in inactivation rates was noted between pH 10 and 10.5 (30).

Strain Classification

Although differences in virulence among DEV strains have been noted, all appear to be immunologically identical (30, 38, 84) and antigenically related (80). The virus is immunologically distinct from other avian viruses, including fowl plague, Newcastle disease, duck hepatitis (4, 17, 39, 56), and other herpesviruses (74).

A herpesvirus was isolated from domestic geese in Australia showing postmortem appearance and histopathological changes similar to those seen in DVE (42). The virus isolate was antigenically and genomically distinct from DEV as shown by protection, serological analysis and genetic characterization by restriction endonuclease digestion and polymerase chain reaction (PCR) assays (26).

Laboratory Host Systems

Duck enteritis virus can be propagated in Pekin duck embryo fibroblasts (98) incubated at 39.5–41.5°C (8) in duck embryo liver or kidney primary cells (25), Muscovy duck embryo fibroblasts (44) and on the chorioallantoic membrane (CAM) of 9–14-day-old embryonating duck eggs (34). The virus can be adapted to grow in embryonating chicken eggs (34) and chicken embryo cell cultures (17); however, they are unsatisfactory for primary isolation. The virus produces cytopathogenic effect in inoculated cell cultures (17,46), and intranuclear inclusions have been ob-
13.3. Inclusion bodies in duck embryo fibroblasts infected with duck virus enteritis. ×10,000 (Plum Island Animal Disease Laboratory).

served in infected chicken and duck embryo cell cultures (29) (Fig. 13.3). Plaque assays have been used to measure virus and neutralizing antibody titers (17). In the presence of complement, antibodies to DEV are capable of lysing infected duck embryo fibroblasts (47).

Pathobiology and Epidemiology

Incidence and Distribution

In addition to the Netherlands, DVE has been reported in China (40) and confirmed in France (23, 59), Belgium (19), India (64, 65), Thailand (68), England (1, 27), Canada (29, 96), Hungary (92), Denmark (69), Austria (66), and Vietnam (94).

In 1967, the first reported outbreak in North America was observed in white Pekin ducks in the concentrated duck-producing area of Long Island (54). In addition, outbreaks in wild, free-flying waterfowl occurred at seven different locations on Long Island, New York (49, 55). The disease has been reported in 21 states, with repeated outbreaks in New York, Pennsylvania (32, 81), Maryland (63), California (83), Virginia, Wisconsin and Texas. An extensive survey for duck enteritis virus (DEV) in North American wild waterfowl failed to detect the virus, indicating that the disease is not enzootic in them (6).

In the Netherlands, a higher incidence of DVE was noted in the spring (35); however, on Long Island, no seasonal increase was noted. In contrast, a higher incidence of DVE in wild, free-flying anseriforms on Long Island was observed in the fall of 1967 (49).

Natural and Experimental Hosts

Natural susceptibility to DVE has been limited to members of the family Anatidae (ducks, geese, and swans) of the order Anseriformes, although the virus can be adapted by serial passage to grow in embryonating chicken eggs and chickens up to 2 weeks of age (37, 38). Natural infections have occured in ducks ranging from 7 days of age to mature breeder. Naturally occurring out-

breaks have occurred in a variety of domestic ducks (*Anas platyrhynchos*), including white Pekin, khaki campbell, Indian runner, hybrids, and native ducks of mixed breeding. Outbreaks are quite common in Muscovy ducks (*Cairina moschata*) (34, 55). In an outbreak reported in Illinois (14), all 625 Muscovy ducks died in a flock of 650 waterfowl consisting of black ducks, rhumen ducks, Pekins, Muscovies and geese. Naturally occurring infections have also been reported in domestic geese (*Anser anser*) (41) and mute swans (43). Gray call ducks have been found to be resistant to lethal infection (91). Outbreaks of DVE in domestic ducks are frequently associated with aquatic environments cohabited by wild waterfowl (20, 55).

Susceptibility of various species of anseriforms to experimental DVE has been studied (91). In addition to domesticated species, mallards (*A. platyrhynchos*), Garganey teal (*A. querquedula*), gadwall (*A. strepera*), European widgeon (*A. penelope*), wood ducks (*Aix sponsa*), shovelers (*Spatula clypeata*), common pochards (*Aythya ferina*), common eiders (*Somateria mollissima*), white-fronted geese (*Anser albifrons*), bean geese (*A. fabalis*), and mute swans (*Cygnus olor*) were susceptible to lethal infection. European teal (*A. crecca*) and pintails (*A. acuta*) were resistant but produced antibodies against DVE as a result of experimental exposure. Mallards were more resistant to lethal effects and were considered a possible natural reservoir of infection. An experimental study (96) showed blue-winged teal (*A. discors*) and Canada geese were extremely susceptible to DEV and experienced high mortalities. Blue-winged teal had few gross lesions at necropsy.

A recent outbreak has been reported in common coots (*Fulica atra*) and crested coots (*Fulica cristata*) belonging to the family Rallidae order Gruiformes (75), but the virus was not isolated or identified. Of the order Charadriiformes, herring gulls (*Larus argentatus*) and black-headed gulls (*L. ridibundus*) were not susceptible to experimental infection and failed to produce antibodies against DEV (91).

The first reported outbreaks of spontaneous DVE in wild waterfowl were diagnosed on Long Island, New York (49, 54). It was detected in mallards, black ducks (*A. rubripes*), a Canada goose (*Branta canadensis*), a bufflehead (*Bucephala albeola*), a greater scaup (*Aythya marila*), and a mute swan.

A major epornitic of DVE occurred at Lake Andes, South Dakota, in 1973, with an estimated loss of 43,000 ducks and geese out of a total population of 100,000 (22). Duck virus enteritis was diagnosed in black ducks, mallards, pintail-mallard hybrids, redheads (*Aythya americana*), common mergansers, common goldeneyes (*Bucephala clangula*), canvasbacks (*Aythya valisineria*), American widgeon (*Mareca americana*), wood ducks, and Canada geese. A study on susceptibility of waterfowl to Lake Andes strain showed that blue-winged teals, wood ducks, and redheads were highly susceptible; muscovies and gadwalls were moderately susceptible; mallards and Canada geese were less susceptible; and pintails were the least susceptible (85).

Transmission, Carriers, and Vectors

Duck virus enteritis can be transmitted by direct contact between infected and susceptible birds or indirectly by contact with a contaminated environment. Because waterfowl are dependent on an aquatic medium to provide a common vehicle for feeding, drinking, and body support, water appears to be the natural means of virus transmission from infected to susceptible individuals. Support for this concept is found in the history of new outbreaks in domestic ducks, which have been limited to birds having access to open bodies of water cohabited by free-flying waterfowl. After infection is established, it can be maintained in the absence of open water or infected birds if susceptible populations are moved onto recently contaminated premises.

New foci of infection may be established by movement of infected waterfowl into susceptible flocks or onto bodies of water previously free of virus contamination. Course and direction of the infection are defined by population densities and rate of transmission between infected and susceptible waterfowl. Population densities in concentrated duck-producing areas encourage rapid spread of DVE, with high mortality. Breeder ducks usually are selected and placed in a defined area and maintained in the same location for the balance of their productive lives. Once a breeder population is exposed, DEV is self-limiting. In contrast, market ducks are progressively moved as they mature and are relocated in areas formerly occupied by the next oldest age group. Infection in market ducklings tends to be a continuous recycling as susceptible birds are sequentially moved to contaminated environments.

Experimentally, DEV can be transmitted via oral, intranasal, intravenous, intraperitoneal, intramuscular, and cloacal routes. Although the intramuscular route of inoculation requires the least amount of virus to kill the inoculated birds, the intranasal and conjunctival routes require more virus, and the oral route requires the most virus (85). Potential transmission by bloodsucking arthropods may be possible during viremia. Although virus has been isolated from an egg removed from the cloaca of an infected domestic duck (37), it has not been recovered from eggs laid during a naturally occurring outbreak. Experimental vertical transmission has been reported in persistently infected waterfowl (9).

A carrier state has been suspected in wild ducks (12, 20, 82, 91). Recovered birds become carriers and shed the virus periodically (11). Like other herpesviruses, DEV latency and reactivation have been blamed for precipitating outbreaks in domestic and migrating waterfowl populations. A recent study has revealed that trigeminal ganglion is the latency site for the virus (79). The virus was reactivated *in vitro* from trigeminal ganglia and lymphocytes. Immunosuppression with corticosteroid was shown to reactivate the virus *in vivo*.

Incubation Period

In domestic ducks, the incubation period ranges from 3–7 days. After overt signs appear, death usually follows within 1–5 days.

Clinical Signs

In domestic breeder ducks, sudden, high, persistent flock mortality is often the first observation. Mature ducks die in good flesh. Prolapse of the penis may be evident in dead mature males. In laying flocks, a marked drop in egg production may be noted during the period of highest mortality.

As infection progresses within a flock, more signs are ob-

served. Photophobia, associated with half-closed pasted eyelids, inappetence, extreme thirst, droopiness, ataxia, ruffled feathers, nasal discharge, soiled vents, and watery diarrhea appear. Affected ducks are unable to stand; they maintain a posture with drooping outstretched wings and head down suggesting weakness and depression. Sick ducks forced to move may show tremors of head, neck and body.

Young ducklings 2–7 weeks of age show dehydration, loss of weight, blue beaks, conjuctivitis, lacrimation, nasal exudate, and often a blood-stained vent.

Morbidity and Mortality

Total mortality in domestic ducks may range from 5–100%. Since the birds showing clinical signs usually die, morbidity closely approaches mortality. Adult breeder ducks tend to experience higher mortality than young ducks. No differences in mortality rates were found in mallard and white Pekin ducks experimently infected with DEV and *Riemerella anatipestifer,* indicating that these organisms do not act synergistically (61). However, mallards immunosuppressed with cyclophosphamide and challenged with a sublethal dose of DEV had higher mortality (24). Secondary bacterial infections with *Pasteurella multocida, Riemerella anatipestifer*, and *E. coli* were often seen in a natural outbreak of a low virulent strain in young ducklings as a result of immunosuppressive effect of the virus (81).

Pathology

The specific pathologic response to DEV is dependent on species affected (49); age, sex, and susceptibility of the affected host; stage of infection; and virulence and intensity of virus exposure (54, 55).

Gross Lesions

Lesions of DVE are associated with disseminated intravascular coagulopathy and necrotic degenerative changes in mucosa and submucosa of gastrointestinal tract in lymphoid and parenchymatous organs. These collective lesions, when present, are diagnostic of DVE.

Petechial, ecchymotic, or larger extravasations of blood may be found on or in the myocardium and other visceral organs and their supporting structures, including the mesentery and serous membranes. On the epicardium, especially within coronary grooves, closely packed petechiae give the surface a red "paintbrush" appearance (Fig. 13.4A). The latter lesion is observed more frequently in mature breeder ducks than in young ducklings. When heart chambers are exposed, endocardial mural and valvular hemorrhages may also be observed.

Surfaces of liver, pancreas, intestine, lungs, and kidney may be covered with petechiae. In mature laying females, hemorrhages may be observed in deformed, discolored ovarian follicles, and massive hemorrhage from the ovary may fill the abdominal cavity. Lumina of intestines and gizzard are often filled with blood. The esophageal-proventricular sphincter appears as a hemorrhagic ring.

Specific digestive mucosal lesions are found in the oral cavity (12), esophagus, ceca, rectum, and cloaca. Each of these lesions

undergoes progressive alterations during the course of the disease. Initially, macular surface hemorrhages appear, which are later covered by elevated, yellow-white crusty plaques. Subsequently, the lesion becomes organized into a green superficial scab devoid of its former hemorrhagic base. Lesions range in size from approximately 1–10 mm in length. In the esophagus and cloaca, lesions may become confluent; however, close inspection will often reveal their composite structure. In the esophagus, macules occur parallel to longitudinal folds. When macular concentrations are numerous, small lesions may merge to form larger ones covered with a patchy diphtheritic membrane (Fig. 13.4B). In young ducklings, individual lesions in the esophagus are less frequent; sloughing of the entire mucosa is more common, and the lumen becomes lined with a thick yellow-white membrane. Oral erosions can be found at openings of sublingual salivary gland ducts in chronically infected waterfowl (12). Meckel's diverticulum may be hemorrhagic and contain a fibrinous core (72).

In ceca, macular lesions are singular, separated, and well defined between mucosal folds. The external surface of affected ceca often presents a barred, congested appearance.

Rectal lesions are usually few in number with greatest concentration at the posterior portion of the rectum, adjacent to the cloaca.

In the cloaca, macular lesions are densely packed; initially, the entire mucosa appears reddened. Later, individual plaque-like elevations become green and form a continuous scale-like band lining the lumen of the organ.

All lymphoid organs are affected. The spleen tends to be normal or smaller in size, dark, and mottled (Fig. 13.4E). The thymus is atrophied and has multiple petechiae (Fig. 13.4F) and necrotic focal areas on the surface and cut section and is surrounded by clear yellow fluid that infiltrates and discolors subcutaneous tissues of the adjacent cervical region from the thoracic inlet to the upper third of the neck. The latter lesion is of importance in meat inspection and is easily detected when the opened neck of the carcass is observed on the processing line. The bursa of Fabricius is intensely reddened during early infection (Fig. 13.4C). The exterior becomes surrounded by clear yellow fluid that discolors adjacent tissue of the pelvic cavity. When the lumen of the bursa is opened, pinpoint yellow areas are found in an intensely hemorrhagic surface. Later, walls of the bursa become thin and dark, and the bursal lumen is filled with white coagulated exudates (Fig. 13.4C). Intestinal annular bands appear as intensely reddened rings visible from external and internal surfaces. Yellow pinpoint areas can be observed on the mucosal surface. Later, the entire band becomes dark brown and tends to separate at its margins from the mucosal surface. The multifocal necrosis of gut-associated lymphoid tissue causes ulceration covered by fibrinous pseudomembranes (Fig. 13.4D).

During early stages of infection, the entire liver surface has a pale copper color with an admixture of irregularly distributed pinpoint hemorrhages and white foci (Fig. 13.4E), giving it a heterogeneous, speckled appearance. Late stages of infection are characterized by dark bronze or bile-stained livers without hemorrhages; the white foci are larger and appear more distinct on the darker background.

Although these lesions are consistent with DEV infection, each age group responds distinctively. In ducklings, tissue hemorrhages are less pronounced and lymphoid lesions are more prominent. In mature domestic ducks with naturally regressed bursa of Fabricius and thymus, tissue hemorrhages and reproductive tract lesions predominate.

In geese, intestinal lymphoid disks (51) are analogous to annular bands in ducks. In a single Canada goose, lesions of the intestinal lymphoid disks resembled "button-like ulcers" (50). Similar intestinal lesions have been observed in an outbreak of DVE in Canada and Egyptian geese. In swans, diphtheritic esophagitis is a consistent lesion (43).

An outbreak caused by a low virulent strain of DEV in commercial 2–6-week old white Pekin ducklings produced atypical gross lesions, including diphtheritic membranes under the tongue and in nasal and infraorbital sinuses. Esophageal mucosa had a few necrotic plaques, and cloacal mucosa was covered with necrotic greenish diphtheritic membranes. No lesions were seen in the intestines including annular bands. Thymus and bursa were atrophied and hemorrhagic (Fig. 13.4F), and the bursal lumen was filled with cheesy exudate. An experimental study showed that the bursal atrophy could last for at least 39 days postinfection; however, the thymus recovered after 10 days of infection (81).

Microscopic Lesions
The initial lesion occurs in the walls of blood vessels. Smaller blood vessels, venules, and capillaries, instead of larger blood vessels, are more markedly involved. The endothelial lining is disrupted, and connective tissue of the wall becomes less compact, with visible separations at points where extravasations of blood pass from the lumen through the thin ruptured wall into surrounding tissues.

Hemorrhages are especially pronounced in certain locations: interlobular venules of the proventriculus, hepatic and portal venules at the margins of liver lobules, venules in the spaces between lung parabronchi, capillaries within intestinal villi, and star-shaped intralobular renal hemorrhages.

As a result of vascular damage, affected tissues undergo progressive degenerative changes. Microscopic changes can be found in any visceral organs including those without gross lesions.

Digestive lesions appear initially as hemorrhages of capillary arcades of submucosal papillae or folds. Hemorrhages become larger and confluent, elevating and separating the overlying mucosa. The affected epithelium above the hemorrhage becomes edematous, necrotic, and raised into the lumen above normal adjacent mucosal surfaces (Fig. 13.4G). Later, margins of necrotic epithelium separate to define the borders of elevated plaques. There is necrosis and degeneration of stratified squamous epethelium of the esophagus and cloaca (71). Eosinophilic intranuclear and cytoplasmic inclusions have been seen in epithelial cells (81, 86).

Hemorrhage from venules and capillaries fills lymphoid tissue within intestinal annular bands or lymphoid disks and lymphoid tissue of the esophageal-proventricular sphincter and spleen. Lymphocytes undergo karyorrhexis and pyknosis. Fragments of lymphocytes appear everywhere and are engulfed by phagocytes.

In addition to cellular debris and hemorrhage within lymphoid follicles, marked swelling of reticulum cells occurs, and their cytoplasm becomes subdivided and condensed into spherical and oval pale-staining bodies. Reticulum cells rupture and discharge their cytoplasmic contents into tissue spaces. An intranuclear inclusion body and delicate nuclear membrane and cell wall are the remaining vestiges of reticulum cells.

Intestinal lymphoid lesions become large hemorrhagic infarcts. A layer of free blood separates lymphoid tissue from the mucosa, which undergoes coagulation necrosis. The necrotic mucosa forms a pseudomembrane higher than adjacent normal intestinal mucosa.

In the small intestines, sheets of epithelial cells are displaced from the surface of villi, many of which are broken and cast into the lumen. Abundant blood and cellular debris fill the lumen.

Within the bursa of Fabricius, submucosal and interfollicular capillary hemorrhages are found. There is a severe depletion of lymphocytes in the follicles, many of which have empty hollow cavities in the medulla. Corticomedullary epithelial cells, capillary networks, and large phagocytic cells containing fragmented lymphocytes form the circumference around these cavities. Severe depletion of lymphocytes in the follicles occurs, which is replaced by eosinophilic material mixed with heterophils. There are occasional mononuclear cells that contain intranuclear inclusions. Bursal epithelial cells are hypertrophied with vacuolated cytoplasm and contain both intranuclear and intracytoplasmic inclusions (81).

In the thymus, free blood fills interfollicular spaces. Coagulation necrosis of central medullary reticulum cells and destruction of cortical lymphocytes are pronounced.

In mature female breeder ducks, congestive, hemorrhagic, and necrotic alterations occur in the oviduct. Follicles may be misshapen and blood stained. In the ovary of immature female breeder ducks, focal intestinal hemorrhages from capillaries and venules may be found.

In mature breeder drakes, focal capillary hemorrhages occur in interstitial tissues between seminiferous tubules. In parenchymatous organs such as liver, pancreas, and kidneys, hemorrhages and focal necrosis are found surrounding blood vessels.

Within necrotic foci in the liver, hepatic cords show a variety of changes including detachment and disassociation of hepatocytes from each other and their surrounding structure. A few necrotic liver cells become swollen or subdivided and discharge their cytoplasmic contents through a ruptured cell surface and are represented only by intranuclear inclusion bodies. Focal areas of necrosis may be filled with fibrin (Fig. 13.4H). Similar, but more limited, changes occur in pancreas and kidney (52).

Immunity
Active
Active immunity has been demonstrated following the use of a modified live-virus vaccine (37) and inactivated tissue culture vaccine (80). It is assumed that both humoral and cell-mediated immunity are involved in protection (48, 89). Field observations suggest that recovered birds are immune to re-infection with DEV.

Passive

Maternal immunity has been reported in ducklings, but it declines rapidly. Progeny of vaccinated breeder ducks with a live-attenuated virus vaccine are fully susceptible. However, ducklings from breeders that had been vaccinated and challenged with a virulent virus were fully protected at 4 days of age, and less than 40% were protected at 13 days of age (88). In an experimental study (10), superinfection of persistently infected mallard ducks resulted in death, indicating that protection against mortality was dependent on the route of exposure, strain of the initial virus, and strain of superinfecting virus.

Diagnosis

Isolation and Identification of DEV

Although a presumptive diagnosis can be made on the basis of gross and histopathologic lesions, isolation and identification of DEV confirms the diagnosis even in the absence of typical lesions. Samples recommended for virus isolation are liver, spleen, bursa, kidneys, peripheral blood lymphocytes (PBL) and cloacal swabs. Virus isolation is carried out by inoculation of susceptible 1-day-old Muscovy, white Pekin ducklings, or onto CAM of 9-14-day-old embryonating duck eggs. Characteristic lesions and mortality in inoculated ducklings are highly suggestive of DVE. Virus can also be isolated and propagated in white Pekin or Muscovy duck embryo fibroblasts, and primary cell culture of liver and kidney. Virus identification is carried out by virus neutralization assay in embryonating duck eggs or cell culture using DEV-specific antiserum.

Conventional polymerase chain reaction (PCR) assay is used for detection of DEV DNA in tissue samples and in cell culture (28, 67, 70). Recently, a quantitative real-time PCR assay has been developed that may be useful for rapid diagnosis and detection of DEV DNA in acute and latent stages of infection (99). Latex agglutination test was claimed to be as sensitive as duck embryo inoculation and virus neutralization in the detection of viral antigens (15). Restriction endonuclease analysis could be a possible test for differentiation of DEV strains (93).

Serology

Increase in virus neutralization (VN) titers following convalescence from DVE will demonstrate progress of the disease within a flock. A VN index of 1.75 or more indicates infection with DEV (16). A VN index of 0–1.5 has been found in sera of domestic and wild waterfowl not exposed to the disease. The use of chicken embryo-adapted virus in chicken eggs for VN studies is safer and more convenient than the use of field-strain viruses inoculated onto the CAM of duck eggs (16). Immunofluorescence tests can be used to detect viral antigens in cell cultures or tissue sections (21, 78). Other serologic procedures for detecting antibodies include a microtiter plate isolation and neutralization test using duck embryo fibroblasts (97), a reverse passive hemagglutination test (18), and enzyme-linked immunosorbent assay (ELISA) (45, 77). A Dot-ELISA and passive hemagglutination assays have been developed for detection of DEV antibodies, however, the specificity and sensitivity of these two assays were shown to be moderate (60).

Differential Diagnosis

Differential diagnosis requires consideration of other diseases producing hemorrhagic and necrotic lesions in anseriforms. In domestic ducks, common diseases producing such changes are duck virus hepatitis, fowl cholera, necrotic enteritis, coccidiosis, and specific intoxications. Although Newcastle disease, fowl pox, and fowl plague are reported to produce similar changes in anseriforms, these diseases have been infrequently reported.

Intervention Strategies

Management Procedures

Prevention is achieved by maintaining susceptible birds in environments free from exposure to the virus. These measures include the addition of stock known to be free from infection and avoiding direct and indirect contact with possibly contaminated material. Introduction of the disease by free-flying anseriforms and contaminated aquatic environments must be prevented. All possible measures should be taken to prevent dissemination of virus by free-flowing water. After DVE has been introduced, control can be effected by depopulation, removal of birds from the contaminated environments, sanitation, disinfection, and vaccination of all susceptible ducklings.

In countries where the disease is not enzootic and is truly exotic, measures should be taken to further prevent entry and dissemination into geographic areas known to be free from DVE. This would include specific examination to prevent importing infected anseriforms. Accordingly, there would be surveillance of ornamental bird collections, zoos, and domestic growers of anseriforms. Efforts should be made to provide efficient detection of DEV by laboratory workers and waterfowl specialists so that its presence, status, and importance can be better defined.

Vaccination

Vaccination has been used as a preventive measure and also for controlling disease outbreaks.

Inactivated vaccines have been tried but have not been as efficacious as modified live-virus vaccines (13). However, an inactivated tissue culture-grown virus vaccine has been shown to provide protection against the virulent strain (80). This vaccine could be used in domestic and captive waterfowl without the risk of introducing a live virus.

A chicken embryo-adapted DEV strain, avirulent for domestic ducks, has been developed and used extensively with good success in the Netherlands (37). This vaccine strain has also been used to prevent and control DVE outbreaks on commercial duck farms and captive waterfowl collections in the United States and Canada (62, 76). The vaccine can be used in the face of an outbreak, as it provides protection immediately after vaccination due to an interference phenomenon (36, 73). It should be noted, however, that birds in the period of incubation may not be protected. A naturally apathogenic and immunogenic strain of DEV was reported to be successful for active and passive immunization of ducks (57, 58).

Attenuated live virus vaccine is administered by subcutaneous or intramuscular routes in domestic ducklings more than 2 weeks

of age. Normally, the breeding flocks are vaccinated. Flocks maintained for more than a year are revaccinated annually. Apparently, vaccinated ducklings do not excrete inoculated virus to a degree that would be sufficient to bring about contact immunization (38, 87).

Treatment

There is no specific treatment for infection with DEV.

Hemorrhagic Nephritis Enteritis of Geese (HNEG)

J-L. Guérin

Introduction

Hemorrhagic nephritis enteritis of geese (HNEG) is one of the major diseases of geese in Europe. HNEG had been named for a long time "young geese disease", or "late form of Derzsy's disease," by confusion with goose parvovirus infection. According to its etiology, a more relevant denomination should be "goose polyomavirosis." This systemic, frequently lethal disease is also the only polyomavirus infection described to date in a poultry species.

Public Health Significance

Polyomaviruses are supposed to have a very narrow host range (20). This is supported by recent evidence of co-divergence of mammalian and avian polyomavirus with their respective hosts (13). HNEG is therefore supposed to have no public health im-plication.

History

HNEG was first described in 1969 in Hungary (2), where occur-rence of field cases was always associated with administration of serum—collected from convalescent flocks formerly affected by Derzsy's disease—to young geese, in order to confer to them pas-sive immunity. No spontaneous case of HNEG has been reported so far in this country. HNEG was described a few years later in Germany (17), then in France (18, 22), where it evolved with a sporadic pattern, except epizootics in the late 80's and since 1997 (5). For many years, HNEG was suspected to correspond to a late evolution of Derzsy's disease. Actually, since hyperimmune sera against goose parvovirus or duck hepatitis virus did not protect goslings from HNEG, it appeared clearly that HNEG agent was a distinct virus (10). Etiology of HNEG was clarified lately by Guérin *et al.* (6), exactly 30 years after the first clinical report.

Etiology

Classification

The agent of HNEG, namely goose hemorrhagic polyomavirus (GHPV), is member of the Polyomaviridae family and Polyomavirus genus (6). The budgerigar fledgling polyomavirus (BFPyV) is the prototype avian polyomavirus, infecting psittacines, falconiforms and passerines (3, 4, 8, 15).

Morphology

Virus particles are naked, spherical and show icosahedral syme-try. Their size ranges from 40 to 50 nm in diameter (6). Buoyant density of virions is of 1.20 g.cm^{-3} in sucrose gradient (6), which corresponds to 1.34–1.35 g.cm^{-3} in CsCl.

Chemical Composition

GHPV genome is a circular, double stranded DNA of 5256 pb. Genome organization of all polyomaviruses shares common fea-tures, with a set of early genes encoding polymerases (t and T antigens) and late genes, encoding structural proteins: VP1, the main capsid protein, and two other structural proteins, VP2 and VP3 (9). As for avian polyomaviruses, an additional VP4 has been evidenced, the precise functions of which still remain to be clarified (9).

Virus Replication

Replication of GHPV occurs in the nucleus: observations of in-fected cells show a huge concentration of viral material in the nu-cleus, either in culture cells or tissues of infected goslings (Fig.13.5) (6). Virus is easily detected in the nuclei by immunoflu-orescence, using serum of geese recovering from HNEG (Fig. 13.6). Releasing of virions implicates disruption of cell membrane.

Susceptibility to Chemical and Physical Agents

GHPV shows a great resistance to heating: virus is still fully vir-ulent after a 2 hours incubation at 55°C (6). The virus also is re-sistant to freezing-thawing cycles and to lipids solvents: treat-ment with 1% phenol has no effect on its viability (10). The other avian polyomavirus, BFPyV, is mostly sensitive to chloride de-rived products (16).

Strain Classification

Genetic variability among field isolates has not been assessed so far. Nevertheless, polyomavirus genomes are supposed to be highly conserved: all the variants of BFPyV isolated from psittacines, falconiforms or finches share more than 99% nu-

13.6. Immunostaining of goose polyomavirus in kidney cell culture. Intranuclear replication is evidenced by indirect immunofluorescence, using isothiocyanate fluoresceine-labelled antibody.

cleotide identity (14). Phylogenic analysis of GHPV confirmed that VP1 is remarkably conserved among isolates from different countries (12). No cross-neutralization experiment has been performed so far on GHPV field isolates.

Laboratory Host System

HNEG is successfully reproduced by parenteral inoculation on 1-day-old goslings. Death occurs between 6 to 8 days post-inoculation, with a peracute evolution. Goslings are susceptible to inoculation by either subcutaneous or intraperitoneal routes. All attempts to adapt the HNEG virus to duck fibroblasts or embryos remain unsuccessful (6, 7). Goose fibroblasts are also refractory to virus replication (6). Propagation of GHPV on goose embryos has been reported: 14-day-old goose embryos inoculated onto the chorioallantoid membrane (CAM) died from 8 to 10 days post-infection, with lesions similar to those described in goslings (1). Virus propagation can be accomplished by propagation on epithelial primary cells derived from 1-day-old gosling kidneys. A cytopathic effect appears by day 5 post-inoculation: granulations and vesicles are distinguished in the cytoplasm, followed by budding of the cell, and finally cell detachment from the monolayer (6). Cell-based dilution titration procedures are seldom done, since cytopathic effect appears late after infection. Alternatively, detection and quantification of virus yields from cell cultures could be assessed by quantitative real-time PCR (7).

Pathobiology and Epidemiology

Incidence and Distribution

Until now, HNEG has been described in Hungary, Germany and France (2, 5, 17, 18, 22). Occurrence in other countries seems likely, although there's no published report confirming this clearly. Cases are frequently observed in winter, probably due to climatic conditions or weakness of the goslings hatched from light-conditioned breeders (5, 7).
Natural and Experimental Hosts

HNEG has only been described to date in growing geese. Unapparent infections have been evidenced in migrating wild geese (7). Other waterfowl species, such as mule or Muscovy ducklings are clinically refractory to GHPV inoculation (7). Actually, reproduction of HNEG signs in ducklings, reported in 1970 by Szalai and Bernath (21) could never be confirmed. In the same way, no HNEG-like syndromes have ever been observed in Pekin, mule or Muscovy ducks.

Transmission, Carriers, Vectors

Infected birds excrete amounts of virus in their droppings, resulting in dissemination of contagious material in the environment, and easy direct and indirect contaminations. Vertical transmission of the virus through the egg has never been confirmed so far but can not be excluded. The experimental infection of goose embryos has been evidenced, but it does not formally demonstrate a field occurrence of vertical transmission (1). No biologic vector seems to be involved in GHPV transmission.

Incubation Period

Incubation period is mostly age dependent. Inoculation of day-old goslings results in death within 6 to 8 days. In contrast, in 3-week-old goslings, incubation lasts for up to 15 days (12). After 4 weeks, inoculation results mostly in non-clinical infection. Actually, although clinical signs rarely start before 5 or 6 weeks of age, contamination likely occurs early in life, as observed for other polyomaviruses (15).

Clinical Signs, Morbidity, and Mortality

HNEG has been described in goslings from 4 to 10 weeks old. In affected flocks, morbidity ranges from 10 to 80% and death is the most common outcome (5). Clinical signs develop only few hours before death: birds sit alone, away from the flock, stay in a coma and die (2, 10). Nervous signs, such as opistothonos, are

13.7. Gross lesions in a 10-day-old gosling infected with goose polyomavirus. Note edema, gelatinous ascites, and swelling of kidneys.

13.8. Microscopic lesions in a follicle of cloacal bursa. Severe lympholysis in the center of the follicle and in cortical foci (arrow). H & E, ×150.

quite only observed after experimental or iatrogenic infections of goslings (5). Chronic evolution of the disease leads to urate deposits on viscera and in joints, resulting in lameness. In these late forms, mortality may be limited to few birds every day, up to the age of 12 weeks.

Pathology

Necropsic findings include edema of subcutaneous connective tissues, gelatinous ascites, inflammation of the kidneys (Fig. 13.7) and less frequently, hemorrhagic enteritis. Renal dysfunction leads to an increase of blood uric acid concentration (17): geese which die after a chronic evolution show visceral gout and urates in the joints (10, 11, 19). Histopathologically, the most obvious features are (i) an interstitial nephritis and necrosis of the kidney tubular epithelium (10, 11) and (ii) a moderate to severe lymphocytosis in cortical and medullar regions of follicles of the cloacal bursa (Fig. 13.8), suggestive of B-lymphocyte depletion (6, 11). Gross lesions of enteritis are associated with necrosis of intestinal epithelium. Hemorrhagic foci are also observed in most tissues, particularly in acute infections (11, 12). No inclusion could be detected in tissues of birds diagnosed with HNEG (6, 11). Electron microscopy examination of infected tissues shows aggregated virions in nuclei (Fig. 13.5) and large vesicles of dense material, including optically clear centers, in the cytoplasm of about 20% of the infected cells, either in culture cells or goose tissues (6).

Pathogenesis of the Infectious Process

During the course of infection, GHPV seems to replicate first in endothelial cells, nuclear enlargement of endothelial cells and arteriolitis being the first lesions noticed (11, 12). These histological findings suggest a selective tropism for endothelial cells, which might be of great relevance in pathogenesis of HNEG.
Endothelial cells are indeed known to play a critical role in many biological pathways, resulting in vascular dysfunctions as ascites or edema. Another main target of GHPV is lymphoid cells: virions are observed in many bursal lymphoid cells and cloacal bursa systematically shows a significant lympholysis, whereas thymus lymphoid cells are less or not affected. This feature is fairly relevant with the well documented tropism of polyomaviruses to B-lymphocytes (20) and suggests an immunodepressive effect of unapparent infections.

Immunity

Immunological aspects of HNEG have so far received little attention. Neutralizing antibodies are detected in previously infected birds and their transmission to the progeny seems very efficient, since goslings hatched from infected breeders are refractory to experimental infections with huge viral load (7, 21). Duration of immunity has not been determined.

Diagnosis

Isolation and Identification of Causative Agent

GHPV can be detected in clinical material of birds putatively diseased, or in long-time, nonclinical carrier geese. Isolation could be based on either kidney cell culture (5) or goose embryos inoculation (1), but these methods are time consuming and seldom can be applied to routine diagnostic of HNEG. Detection of GHPV genome is therefore a more reliable way to detect the virus: PCR detection of DNA extracted from infected tissues (liver, spleen, kidney) with primers designed on VP1 gene is efficient and reliable (6). In non-apparent carriers, PCR assays can be advantageously performed on blood samples, spleen or cloacal swabs (7). Serology appears of poor interest to detect infection by a polyomavirus, since serologic response is greatly variable; in contrast, virus persists in infected birds for months, if not years (17).

Differential Diagnosis

Lesions of ascites, subcutaneous edema, visceral urates, nephritis in 4- to 10-week-old goslings are suggestive of HNEG. Similar lesions may however be associated with goose parvovirus. Histopathological, virological or serological procedures may be helpful in clearing etiology. Actually, HNEG is probably underdiagnosed, related to confusion with Derzsy's disease.

Intervention Strategies

Management Procedures

Goose polyomavirus spreads from carriers and clinically affected birds, mostly by fecal route (5, 10). Disinfection procedures should be thoroughly observed: complete removal of organic material, followed by the use of an appropriate disinfectant is required to prevent or interrupt a disease outbreak. Chloride derived products are considered efficient to inactivate polyomaviruses, but are particularly sensitive to the presence of organic debris (16). Since infected birds have a viremia, needles used for administration of vaccines should be sterilized between uses. Though transmission of HNEG virus through the egg is not clarified, sanitary rules should be respected in the hatchery, so as to limit early contamination of goslings, before they reach the farm. When goslings are infected by the virus, occurrence of clinical signs may greatly depend on management failures, resulting in chill and/or stress. In the same way, oil-adjuvanted vaccines should be administered with extreme caution to flocks affected by the disease.

Vaccination

Management procedures are unlikely to be sufficient for the control of HNEG infection. Vaccination of breeders could be indicated to provide maternal immunity to goslings, when they are critically sensitive to virus contamination (5). An inactived vaccine is currently under trials (7). The experimental vaccination schedule relies on (i) administration to breeders before each laying period and (ii) vaccination of growing goslings, so as to induce an active immunization covering the whole economic life of birds.

Treatment

There is no effective treatment. Prevention of stress may be helpful in preventing non-clinically infected birds from developing HNEG.

Parvovirus Infections
Richard E. Gough

Introduction

Goose parvovirus (GPV) infection, variously known as Derzsy's disease, so-called goose influenza, goose or gosling plague, goose hepatitis, goose enteritis, infectious myocarditis, and ascitic hepatonephritis, is a highly contagious disease affecting young geese and Muscovy ducks (*Cairina moschata*). The diverse names given to the condition reflect the multiple pathological features of the disease. Depending on the age of affected goslings the disease may be present in either acute, subacute, or chronic forms (12, 67, 73). The acute form of the disease can result in 100% mortality in goslings under 10 days of age. An antigenically distinct parvovirus causing up to 80% mortality in Muscovy ducklings has also been reported from various countries. This strain of Muscovy duck parvovirus (MDPV) is much less pathogenic than goose parvovirus (28). Apart from geese and Muscovy ducks, the disease has not been reported in other avian species or mammals, including humans.

Economic Significance
In countries where geese and Muscovy ducks are farmed intensively the disease is of serious economic significance. Vaccination of breeding stock has significantly reduced the impact of the disease. However, in areas such as China where goose farming contributes to the rural economy and also provides a source of feathers and down for clothes and bedding, losses due to GPV can have a more profound social impact.

Public Health Significance
There are thought to be no public health risks associated with parvovirus infection of geese and Muscovy ducks.

History

The first detailed description of a serious disease of goslings, which occurred in China in 1956 and was later shown to be caused by a parvovirus, was reported by Fang and Wang in 1981 (22) and later confirmed by Zheng *et al.* (92). During the 1960's a similar disease was reported from many European countries, including Poland (83), W.Germany (54), Hungary (51), Bulgaria (2), Holland (10), France, USSR, and Czechoslovakia (16). Initially, many authors referred to the disease as "goose influenza," which caused some confusion as this name had originally been used for a disease of geese thought to be caused by a hemophilic bacterium (16). To distinguish the two diseases it was suggested that the "new" disease be known as "so-called goose influenza" (19). During the following years the disease was reported from all the major goose and Muscovy duck farming countries of Europe and a variety of names were given to the condition.

Although several viruses had been implicated, it was not until 1971 that Schettler (75) confirmed that the disease was caused by a parvovirus. In 1978 it was recommended that the disease be called goose parvovirus (17). Formerly, parvoviruses originating from geese and Muscovy ducks were thought to be antigenically closely related. However, following the emergence of a more virulent Muscovy duck strain of the virus, studies using virus neutralisation and molecular analysis have demonstrated significant differences between parvovirus isolates from geese and Muscovy ducks (3, 7, 56, 91).

Etiology

During the past 20 years several etiological agents have been proposed for the disease. Some early reports attributed the disease to reoviruses (14, 18, 21). It was also suggested that adenoviruses were the etiological agents as they were frequently isolated or detected from outbreaks of disease in goslings (13, 38, 68). However, in subsequent, more detailed studies, it has been confirmed that the etiological agent is a parvovirus (12, 15, 29, 49, 52, 75).

Classification
The virus was originally classified as an autonomous parvovirus belonging to the family *Parvoviridae*. More recently molecular studies have indicated that GPV is more closely related to the human *Dependovirus* genus (6, 90). No antigenic relationship with chicken or mammalian parvoviruses have been demonstrated (15, 45, 64).

Morphology
Intact virions are unenveloped and hexagonal in shape (Fig. 13.9) with an estimated 32 capsomeres and a diameter of 20–22nm (15, 29, 49, 75). The density of the virus in cesium chloride is approximately 1.38g/ml (42, 75).

Chemical Composition
Goose parvovirus, like its mammalian counterparts, has a single-stranded DNA genome (49), 5–6 kilobases in length (56, 90). Analysis of goose isolates from Bulgaria and Russia demonstrated four viral proteins with molecular weights of 88, 77, 65 and 60kD respectively (1). Similar results have been reported from Japan and Hungary using Muscovy duck parvoviruses (81, 90). Unlike several mammalian parvoviruses, haemagglutination activity, using a variety of red blood cells under different conditions, has not been demonstrated with goose parvoviruses (75).

Virus Replication
The replication of GPV has not been investigated in detail although *in vitro* studies by Kisary and Derzsy (49) have shown that viral replication takes place in the nucleus. Electron microscopy (EM) studies by Bergmann (4) have demonstrated the presence of large aggregates of parvovirus in the nuclei of cells from the heart and bursae of infected goslings. Like other parvoviruses that are able to replicate without the presence of a
13.9. Electron micrograph of purified goose parvovirus. A. Purified virions. B. Virions in the feces of a naturally infected 10-day-old gosling, showing intact and hollow (arrow) particles.

helper virus, GPV is dependent on cells actively synthesizing DNA for its replication cycle (44). It has been demonstrated that the replication of GPV under *in vitro* conditions is enhanced in the presence of a human helper-dependant adeno-associated type 2 virus (62).

Susceptibility to Chemical and Physical Agents

Goose parvovirus is very resistant to chemical and physical inactivation. Gough *et al*. (29) reported no loss of titer when the virus was heated at 65°C for 30 min. These authors also found that the virus was stable at pH 3.0 for 1hr at 37ºC. Schettler (75) tested an isolate against a variety of chemicals under different conditions and detected no significant loss of activity. However, following treatment with 0.5% formaldehyde infectivity was completely destroyed (75).

Strain Classification

The results of early studies using cross-neutralisation and gosling-protection tests suggested that several serologically distinct strains of the virus existed (20). However, at the time of these studies the etiology of the disease had not been confirmed; later work showed that several of the virus strains used were contaminated with reoviruses (21). Subsequent studies showed that parvoviruses from both geese and Muscovy ducks were antigeni-

cally closely related (26, 31, 41). Later studies with Muscovy duck isolates using cross neutralization, restriction endonuclease and molecular analysis identified significant differences between the genomes of MDPV and GPV (7, 9, 36, 82, 91). A more recent investigation described the isolation and characterization of a parvovirus from Muscovy ducks in Pennsylvania, USA associated with between 10 and 40% mortality. This isolate showed only about 85% identity with other goose and Muscovy duck parvoviruses in a conserved region of the genome, compared to over 99% and 95% identity among previously sequenced MDPV and GPV isolates (69)

Laboratory Host Systems

Goose parvovirus has only been isolated in embryonated goose or Muscovy duck eggs or primary cell cultures prepared from the embryos. It is essential that the embryonated eggs are obtained from unvaccinated flocks known to be free of parvovirus antibodies. Isolated virus has been cultivated in an embryonic goose fibroblast cell line (CGBQ).

Pathobiology and Epidemiology

Incidence and Distribution

Waterfowl parvoviruses have been reported from all the major goose and Muscovy duck farming countries of Europe, including

the former USSR and Israel. The disease has also been reported from the People's Republic of China and several of its autonomous regions, Taiwan, Vietnam, Japan and the USA (69, 86). There have been unconfirmed reports of outbreaks in Muscovy ducks in South America. A disease with similar clinical and post mortem features has also been reported from Canada, although parvoviruses were not isolated (70).

Natural and Experimental Hosts

Geese, Muscovy ducks and some hybrid breeds are the only species in which natural clinical disease has been observed. All breeds of domestic geese are susceptible and the disease has also been reported to occur in Canada geese (*Branta canadensis*) and snow geese (*Chen hypoborea atlantica*) following accidental infection (74). In a serological survey in wild geese in Germany 48% of the bean geese (*Anser fabalis*) and white-fronted geese (*Anser albifrons*) tested had significant neutralising antibody to GPV (34). Other breeds of domestic poultry and ducks appear refractory to experimental infection (29,35).

Age of Host Commonly Affected

The disease is strictly age dependant; thus, 100% mortality may occur in goslings under 1 wk of age, with negligible losses occurring in 4- to 5-wk-old birds. However, while older geese do not show clinical signs of infection, they respond immunologically (19, 26, 43). Similar findings apply to the clinical disease in Muscovy ducks (35, 53, 94).

Transmission, Carriers, Vectors

Infected birds excrete large amounts of virus in their faeces resulting in a rapid spread of infection by direct and indirect contact. The most serious outbreaks occur in susceptible goslings following vertical transmission of the virus. In older birds that become subclinically infected, a latent infection may become established. These birds may then act as carriers of the disease and transmit the virus through their eggs to susceptible goslings or ducklings in the hatchery (16, 46). No biological vectors have been identified.

Incubation Period

In susceptible goslings the incubation period is age dependent. Experimental infection of day-old goslings with GPV results in the appearance of clinical signs 3–5 days later. In 2- to 3-wk-old birds the incubation period may vary between 5 and 10 days (46, 73).

Clinical Signs

The clinical signs in susceptible goslings and ducklings also vary according to the age of the birds. In birds under 1 wk of age the course of the disease may be very rapid with anorexia, prostration, and death occurring within 2–5 days. In older birds, or those with variable levels of maternally derived antibody, the disease follows a more protracted course with the appearance of characteristic clinical signs. Initially, affected birds exhibit anorexia, polydipsia, and weakness with a reluctance to move. There is a nasal and ocular discharge in many birds with associated headshaking. The uropygial glands and eyelids are often red and swollen, and a profuse white diarrhoea is evident in many birds. Examination of the birds at this stage may reveal a fibrinous pseudomembrane covering the tongue and oral cavity. Survivors from the acute phase may develop a more prolonged disease characterised by profound growth retardation, loss of down around the back and neck, and marked reddening of the exposed skin. There may be an accumulation of ascitic fluid in the abdomen, which causes goslings to stand in a "penguin-like" posture.

In a comparative pathological study in domestic goslings and Muscovy ducklings strains of GPV caused severe disease in both goslings and Muscovy ducklings, whereas a strain of MDPV caused no clinical signs or pathological lesions in inoculated goslings (24).

Morbidity and Mortality

Mortality sometimes reaches 100% in goslings infected in the hatcheries. In 2- to 3-wk-old birds mortality levels may be below 10% although morbidity levels may be high. Complicating factors such as poor management and secondary bacterial, fungal, or viral infections may influence the final mortality levels (46, 52). Goslings over 4 wk of age rarely show clinical signs although a "late form" of the disease has been described in goslings 1–3 months of age (12). Geese and Muscovy ducks of all ages respond immunologically to parvovirus infection without necessarily showing clinical signs (43).

Pathology

Gross Lesions

In acute cases of parvovirus infection, with a short clinical course, lesions are commonly found in the heart, which has a pale myocardium characteristically rounded at its apex (Fig. 13.10). The liver, spleen, and pancreas may be swollen and congested (16). A variety of other gross lesions may also be present in cases with a more prolonged clinical course. Typically, a serofibrinous perihepatitis and pericarditis are present with large volumes of straw-coloured fluid in the abdominal cavity. Pulmonary edema, liver dystrophy, and catarrhal enteritis may also be present. Less frequently, haemorrhages in the thigh and pectoral muscles may be seen. Diptheritic and ulcerative lesions may be observed in the mouth, pharynx, and esophagus, depending on the presence of secondary invaders.

Microscopic

Detailed histopathology studies of both GPV and MDPV infection by a number of workers have produced similar findings (11, 63, 65, 66). The main lesions reported were pronounced degenerative changes in myocardial cells with associated loss of striation, fatty infiltration (Fig. 13.11), and the presence of scattered Cowdry type-A intranuclear inclusions. Similar histological changes were also found in intestinal and smooth muscle cells. In liver the predominant lesions were degeneration of hepatocytes with vacuolation and fatty infiltration. Small, eosinophilic inclusion-like bodies were sometimes seen in the cytoplasm of the vacuolated hepatocytes. Changes in the pancreas consisted of shrunken, necrotic acinar cells with fatty infiltration. Some lym-

13.11. Liver section from a 10-day-old gosling infected with goose parvovirus showing widespread vacuolation and degeneration of hepatocytes.

13.10. Postmortem appearance of a 12-day-old gosling infected with goose parvovirus showing hydropericardium and ascites. The liver is coated with a fibrinous membrane.

phoblastic processes were occasionally observed in the spleen, bursa of Fabricius, and thymus, together with marked vacuolation of the kidneys. In Muscovy ducklings muscle fiber degeneration, mild sciatic neuritis and polioencephalomyelitis has also been reported (24). The pathological features will vary depending on the age of the birds at the time of infection.

Pathogenesis of the Infection Process
Detailed studies on the pathogenesis of waterfowl parvovirus are not available. In horizontal transmission, ingestion of virus-contaminated feed and water is of prime importance (46). Initially, virus replication occurs in the intestinal wall and then enters the blood stream. Following a viremia, virus reaches the liver and heart where the most severe pathological changes occur (46). It has been suggested that an enteric form of GPV exists (24).

Immunity
Passive Immunity
Adult breeding geese and Muscovy ducks that have been naturally infected with parvovirus, either during the rearing phase or as adults, transfer maternal antibody of the IgG type via the egg yolk

to their progeny (18, 27, 35). This passively acquired antibody may persist at a relatively high level until about 2wk of age (43).

Humoral Immunity
The primary humoral response of geese to parvovirus infection is characterised by the initial production of IgM and then IgG-type immunoglobulin (43). Using virus-neutralisation (VN) and agar-gel precipitin tests to measure parvovirus antibodies in the sera of geese that had survived the disease, high and persistent levels of antibody were detected for up to 80 months after infection. The progeny of these geese were also found to be fully resistant to experimental challenge up to 4 wk of age (27). The results of studies by Kisary (43) suggested that goslings are not fully immunocompetent until 20 days of age.

Active Immunity
Cell Mediated Immunity
Cell mediated immunity is not thought to play a significant role in immunity to waterfowl parvovirus.

Diagnosis

Isolation and Identification of the Causative Agent
Waterfowl parvovirus can be isolated from a variety of suitable postmortem specimens following inoculation of 10- to 15-day-

old embryonated goose or Muscovy duck eggs via the allantoic cavity. Embryo mortality occurs 5–10 days post inoculation with haemorrhages and ochre-colored livers. The virus can also be isolated in primary cell cultures of goose or Muscovy duck embryos. Isolation of the virus is facilitated by inoculating cultures before they reach confluency (49). The virus produces a well-defined cytopathic effect (CPE) 3–5 days postinfection, although several blind passages may be required before a detectable CPE is observed, particularly when attempting to isolate MDPV. In haemotoxylin-eosin stained infected cultures Cowdrey type-A intranuclear inclusions and syncytium formation are often present (49, 77). The presence of the virus can be confirmed by electron microscopic examination of infected cell cultures, even though gross cytopathic changes are absent, or neutralisation with specific parvovirus antiserum (28).

Direct Detection of Viral Antigen
Immunofluorescence has been used to detect the presence of viral antigen in goslings (1), embryonated goose eggs (85) and infected cell cultures (75). Other methods have also been developed, including immunoperoxidase techniques (71), antigen-capture enzyme-linked immunosorbent assays (ELISA) (40) and reverse indirect haemagglutination test (87). A digoxigenin-labelled DNA probe technique has been described for the detection and identification of MDPV (57).

An agar gel diffusion technique has been described using rabbit anti-goose parvovirus serum to precipitate parvovirus in the allantoic fluid of infected goose embryos (5).

Electron Microscopy
Goose parvovirus virions have been detected by EM in the faeces of goslings showing clinical signs of goose parvovirus (25) and in ultrathin sections of heart and bursa of Fabricius from infected goslings (4). An immune EM (IEM) technique has also been developed and evaluated for the detection of parvovirus. The technique, utilizing GPV monoclonal antibodies, detected parvovirus virions in the organs of goslings and cells of infected goose and duck embryos (1)

Molecular Identification
Various polymerase chain reaction (PCR) techniques have been developed to detect both GPV and MDPV. Primers have been designed from conserved regions of the VPI, 2 and 3 genes that encode for the capsid proteins, and can be used to differentiate strains of GPV and MDPV following sequencing and restriction fragment length polymorphism (RFLP) (69, 76, 80, 82, 91). A PCR detected goose parvovirus DNA in a range of tissues from experimentally infected ducklings from 2 days post inoculation (58). Nucleic acid dot-blotting techniques have also been developed to detect the presence of GPV DNA in a range of tissues from infected geese (89).

Serology
Serologic tests are useful in evaluating the immune status of breeding flocks of geese and Muscovy ducks and their progeny. The presence or absence of parvovirus antibody in breeder geese will determine the susceptibility of the progeny. Serology is also a useful diagnostic tool in confirming recent outbreaks of the disease in goslings and Muscovy ducklings. Demonstration of yolk-derived antibody in eggs will also provide information on the levels of maternal-derived antibody in the offspring.

Virus Neutralisation
The most widely used method is the VN test in embryonated goose or Muscovy duck eggs or primary cell cultures, to detect the presence of GPV-neutralizing antibodies (28). Cross neutralisation tests can be used to differentiate between GPV and MDPV antibodies (3). A duck embryo-adapted GPV strain has also been used for VN tests in Pekin duck embryonated eggs (30). Titres of 1/16 or greater are considered positive for GPV antibodies.

Agar Gel Precipitation
Though less sensitive than the VN test the agar gel precipitation (AGP) test is a useful method for testing large numbers of sera for the presence of parvovirus antibodies. The test does not differentiate between antibodies produced against parvovirus derived from geese or Muscovy ducks (26, 60).

Other Serologic Tests
Enzyme-linked immunosorbent assays (ELISA) have been developed to detect goose parvovirus antibodies in both geese and Muscovy ducks (33, 36, 55). A blocking ELISA, incorporating anti-goose parvovirus-goose IgG, has been developed and compared to other serologic tests (40). The results showed that the method was rapid, reliable, easily standardised, and correlated well with a virus-neutralisation test. This type of ELISA has also been used to detect MDPV antibodies and a good correlation was reported between ELISA values and protection to challenge (40). Problems may arise from this type of test if non-specific-pathogen-free geese are used in the production of serum and immunoglobulin G for use in the ELISA. Other serological techniques that have been developed include the spermagglutination-inhibition test (61), a plaque reduction assay (78) and indirect immunofluorescence (81). A Western blotting assay on sera from infected goslings and Muscovy ducklings using purified antigens from the capsid and non-structural proteins of waterfowl parvoviruses has also been described (84).

Differential Diagnosis
Formerly, parvoviruses originating from geese and Muscovy ducks were thought to be antigenically closely related. However, following the emergence of a more virulent Muscovy duck strain of the virus, studies using VN, restriction endonuclease analysis and molecular sequencing of the virus genome have demonstrated significant differences between GPV and MDPV isolates (7, 28, 69).

A digoxigenin-labelled DNA probe has been developed for the detection of MDPV. The assay proved sensitive for detecting strains of parvovirus and differentiating isolates from vaccine-derived strains (57).

Avian adenovirus-associated viruses are defective par-

voviruses that may be associated with adenovirus infections. In the absence of a helper adenovirus these parvoviruses are unable to replicate under *in vitro* conditions.

Very few other pathogens of goslings and Muscovy ducklings exist that show the strict age-relatedness of waterfowl parvoviruses. The herpesvirus of duck viral enteritis produces disease with high mortality in geese and ducks of all ages. Isolation and identification of the causal virus will clearly differentiate it from parvoviruses. Duck hepatitis viruses also cause fatal diseases in ducks under 6 wk of age. However, these viruses are not pathogenic for geese or Muscovy ducks.

Hemorrhagic nephritis and enteritis of geese (HNEG) affects geese from 4 to 20 wk of age. The disease was first reported from particular regions of France in the 1970's and was referred to as the late form of Derzsy's disease (47). More recent studies suggest that HNEG is associated with an avian polyomavirus (28). A disease of 2–8-wk-old Muscovy ducklings called virus K disease of the Muscovy duck has been described (23). The etiological agent is thought to be a reovirus and it does not cause disease in geese.

Pasteurella anatipestifer and *Pasteurella multocida* organsims may also cause high mortality in goslings and Muscovy ducklings. Treatment of birds with appropriate antibiotics and culture of the etiologic agent in suitable media will enable differentiation from waterfowl parvovirus.

Intervention Strategies

Management Procedures

Because many outbreaks of waterfowl parvovirus are directly attributed to transmission of the disease by congenitally infected birds during hatching, the practice of incubating and hatching eggs that have originated from different breeding flocks should be discouraged. Only eggs from known parvovirus-free flocks should be incubated together and good hatchery hygiene should be maintained.

On farms where outbreaks of the disease have occurred, the practice of breeding from parent stock that have survived the disease when young should also be discouraged, as these birds are potential carriers of the virus. All contact birds, whether young or adults, should be serologically tested in order to identify which birds have been infected horizontally. Positive reactors should be removed from the flock as these birds may also become carriers of the virus.

Vaccination Strategies

Because the disease is confined to young geese or Muscovy ducklings, control measures have been developed to provide adequate immunity during the first 4–5wk of life. Some of the early outbreaks of GPV occurring in China in 1962 were controlled by the use of hyperimmune serum in newly hatched goslings (22). Serum therapy was widely used when the disease subsequently appeared in Europe, using serum produced in hyperimmunized geese (16, 32, 35, 72). However, passive immunization was found to be expensive and time consuming, particularly as two doses of serum were often required to produce adequate immunity (50).

Active immunization of adult breeding geese and Muscovy ducks with virulent virus has also been reported (35). The results showed that good protection was transferred to the progeny via the egg yolk.

One of the first vaccines against GPV was developed in China, and during the period 1962–79 about four million female geese were vaccinated (22). The virus was attenuated following multiple passages in embryonated goose eggs and good protection to challenge was recorded in the progeny goslings. Other vaccines have been developed by attentuation of the virus in goose or Muscovy duck embryo cell cultures, for use in breeding geese and goslings (39, 50, 59, 88, 93). Duck embryo-adapted GPV vaccines have also been shown to induce a good immune response in goslings and breeder geese (8, 30).

Inactivated vaccines have also been used in flocks of breeding geese and Muscovy ducks inducing high levels of immunity (37,79). Bivalent vaccines have also been developed containing both GPV and MDPV antigens.

Future Developments

Recombinant vaccines formulated in oil emulsion have been evaluated in goose and Muscovy duck laying flocks. The authors report that the progeny of the vaccinated breeders were fully protected against goose parvovirus (48).

Chapter 14
Other Viral Infections

Introduction
Y. M. Saif

This chapter has traditionally included viral infections that did not fit into virus groupings used in a given edition. Yet, the grouping of viral infections into different chapters has changed in the different editions for a variety of reasons. Avian encephalomyelitis is presented in this edition as a subchapter instead of its earlier status as a stand-alone chapter in recognition of its rare occurrence in commercial poultry. Hepatitis E infections are presented as a completely new subchapter replacing two earlier subchapters, "Big Liver and Spleen Disease," and

"Hepatitis Splenomegaly Syndrome." These two subchapters were included in Chapter 34, "Emerging Diseases of Complex or Unknown Etiology," of the 11th edition. Consensus now is that these two conditions are the same clinical enteritis. In addition, the work of Meng *et al.* has elucidated the etiology of the condition being a hepatitis E virus.

The etiology of proventriculitis in chickens continues to be elusive, and in this edition, it is presented in Chapter 33, "Emerging Diseases of Complex or Unknown Etiology."

Miscellaneous Herpesvirus Infections
J.P. Duchatel and H. Vindevogel

Introduction

Herpesvirus infections have been described in several species of domestic and wild birds including pigeons (10, 38), psittacine birds (32), falcons (24), owls (4), cormorants (13), cranes (5), storks (19), and bobwhite quail (18).

All herpesvirus strains isolated from pigeons in Belgium, France, Australia and Czechoslovakia have been found to be antigenically similar and to possess the same cultural characteristics (3, 17, 21, 38, 39). Therefore, only one pigeon herpesvirus type, pigeon herpesvirus 1 (PHV1) appears to exist. However, following Kaleta (17), various breeds of racing and show pigeons may harbor two serologically different herpesviruses and some isolates may contain small- and large-plaque variants.

PHV1 is antigenically different from turkey herpesvirus, Marek's disease virus, infectious laryngotracheitis virus, and duck virus enteritis herpesvirus (25, 27). It can also be clearly distinguished from the psittacine herpesvirus (Pacheco's disease virus) based on antigenic composition and plaque size in cell culture (49).

Conversely, PHV1 cannot be serologically distinguished from the falcon (FHV) and the owl (OHV) herpesviruses, and it remains to be established whether these three herpesviruses are different

isolates of the same virus (24, 25). All other herpesviruses isolated from wild birds differ antigenically from each other and from other avian herpesviruses except for the bobwhite quail herpesvirus and the crane herpesvirus, which are serologically related (18).

This subchapter will cover PHV1 infections in pigeons and will briefly mention pseudorabies virus infections that can be experimentally induced in pigeons and young chickens.

History

The first observation of intranuclear inclusion bodies in the liver of pigeons, probably associated with PHV1 infection, was reported in 1945 (33). Since 1967, PHV1 has been isolated from diseased pigeons in numerous countries (9, 38).

Incidence and Distribution

The suspected geographic distribution of PHV1 is worldwide. The virus has been isolated in the United Kingdom (8), Czechoslovakia (21), Australia (3), Belgium (43), Hungary (37), Germany (14), France (23) and Italy (56). Infection has also been observed in the United States (27). In Europe, the vast majority of pigeons are infected, since more than 50% of them possess specific antibodies (16, 22, 38, 50). In Belgium, the presence of PHV1 was demonstrated in 60% of dove-cotes where pigeons

were permanently affected with respiratory disease, and PHV1 could be isolated from the pharynx of 82% of pigeons affected with acute coryza (38, 51).

Etiology

Belonging to the family of *Herpesviridae* (most probably alpha), PHV1 is called *Columbid herpesvirus 1* in the new nomenclature. It possesses the morphology and has the physico-chemical properties of a typical herpesvirus (58).

All avian cell cultures tested to date were susceptible to PHV1, but the cytopathic effects varied (7,44,45). In chicken embryo fibroblast (CEF) cultures, the most consistent change is an increase in the size of cells with syncytia containing two to four nuclei. Initial alterations consist of margination of chromatin and the appearance of Cowdry type-A intranuclear inclusion bodies 10 hr after inoculation. Viral antigen is first detected in the nucleus and later throughout the cytoplasm. Virus can be detected by 12 hr, and peak titers are reached by 36 hr after inoculation (44). The baby hamster kidney cell line (BHK) is also susceptible to infection with PHV1, but all the other mammalian cell lines tested so far have been refractory to the virus (45).

Plaques develop in cultures overlaid with carboxymethylcellulose, agarose, or specific antiserum (42, 43). Virus multiplication in cell cultures is inhibited by trisodium phosphonoformate (28, 29, 38) and acycloguanosine (35). Extracellular virus can be protected by the addition of 5% dimethylsulfoxide to the medium before freezing (43).

Pathogenesis and Epidemiology

Natural and Experimental Hosts

The pigeons seem to be the natural host of PHV1 with virus infection remaining latent (38). PHV1 has been isolated from budgerigars (*Nymphicus hollandicus*) accidentally infected after close contact with pigeons (46). Pigeons are susceptible to experimental infection by pharyngeal painting, which causes a mainly localized disease (42, 48), or by the intraperitoneal route, causing a systemic infection (10). Systemic infections can also be produced in budgerigars (*Melopsittacus undulates*) by intranasal inoculation of the virus (39). Chickens, ducks, canaries and hamsters are resistant to infection (10, 38, 40).

Transmission

Susceptible pigeons can be infected through direct contact with infected birds. Egg transmission of PHV1 seems unlikely (41). Mature pigeons in infected flocks are asymptomatic carriers of the virus, and some of them may shed virus from time to time (48).

The vast majority of latently infected mature pigeons re-excrete virus in their throat during the breeding season and during squab gorging (60). They are, therefore, able to transmit directly the infection to the squabs soon after hatching. Although the squabs become infected, they are protected from the disease by maternal antibodies acquired through the egg yolk. Therefore, most of the squabs themselves become asymptomatic carriers after this initial infection (41). The virus has been isolated by us from the cloacal bursae and the kidneys of 12-day-old pigeons.

Incubation Period, Shedding, and Latency

Virus excretion begins 24 hr after inoculation and persists at a high titer for a minimum of 7–10 days in inoculated squabs. Typical lesions appear 1–3 days after infection when viral excretion reaches its peak. Mild episodes of recurrence, without clinical signs, occur spontaneously. High titers of specific antibodies do not prevent these recurrences, and, conversely, recurrent episodes are not more frequent when the animals are nearly devoid of specific antibodies. Pigeon herpesvirus 1 re-excretion can also be provoked by cyclophosphamide (Cy)-treatment of pigeons and this period of re-excretion may be accompanied by lesions (48).

Distribution of Pigeon Herpesvirus 1 in the Host

In classic PHV1 infection, virus generally remains localized in the upper respiratory and digestive tracts. However, naturally occurring experimental pharyngeal infection may be followed by viral dissemination throughout the body, with viral localization and development of lesions in organs such as trachea, spleen, liver, kidney, and brain (6, 8, 41, 42). Indeed, during the primary infection and during episodes of re-excretion following Cy-treatment, a transient viremia may occur (42). Moreover, PHV1 can be transmitted from cell to cell in the presence of high titers of specific antibodies (42). Thus, PHV1 can be spread either by tissue contiguity or by viremia, especially when pigeons are immunodepressed (38).

As about 65% of racing pigeons are infected with circovirus (11, 12, 34) and suffering from immunodeficiency, PHV1 is now a major viral infection associated with high morbidity. PHV1 DNA has been detected in 7/45 liver samples from pigeons with symptoms of circovirus infection from 5 of 15 lofts (26).

Signs

In the acute form of the disease, pigeons sneeze frequently and show conjunctivitis, and nostrils become obstructed with nasal mucus and moisture. Caruncles, which are normally white, turn yellow-gray.

In the chronic form, sinusitis and intense dyspnea may be observed if the primary viral infection is complicated by *Trichomonas columbae* or secondary mycoplasmal or bacterial invaders (*Mycoplasma columbinum, Mycoplasma columborale, Pasteurella multocida, Pasteurella hemolytica, Escherichia coli, Staphylococcus ß-hemolysin, Streptococcus ß-hemolytic)* (30, 38).

Morbidity and Mortality

Clinical disease is observed principally following primary infection of young pigeons not protected by maternal antibodies and in virus carriers in which the infection is complicated by virtue of debilitating factors (41).

Pathology

Gross Lesions

The mucous membranes of the mouth, pharynx, and larynx are congested and, in severe cases, covered with foci of necrosis and small ulcers. The mucous membrane of the pharynx may be coated with diphteritic membranes. When the viral infection is

generalized (viremia), foci of necrosis can be observed in the liver. If the initial infection becomes complicated by bacterial infections, the trachea may be obstructed by caseous material and some birds may show airsacculitis and pericarditis (pigeons chronic respiratory disease) (38).

Histopathology

Multiple foci of necrosis are observed in the pharyngeal stratified squamous epithelium and in the salivary glands. Foci contain cells at different stages of degeneration and necrosis, and intranuclear inclusions are present in adjacent epithelial cells. Large foci may extend and form ulcers. Similar foci of necrosis can also be observed in the laryngeal and tracheal epithelium (42).

In generalized infections, pigeons presenting with hepatitis consistently have intranuclear inclusion bodies in many hepatic cells widely spread throughout the organ (8, 42, 43). Lesions have also been described in the pancreas and the brain (6, 8, 10).

Immunity

Neutralizing antibodies appear in squabs at the end of the first week following infection. Importance of these antibodies is difficult to evaluate with regard to re-emergence of active infection (48), but when acquired passively in the form of maternally derived antibodies, they are protective for squabs (41). As a herpesvirus infection, it might be presumed that cell-mediated immunity is important in PHV1 infections.

Diagnosis

Isolation and Identification of Causative Agent

Pigeon herpesvirus 1 can be easily isolated in CEF cultures from pharyngeal swabs of infected pigeons ; also, but with more difficulty, from internal organs such as trachea, lungs, or liver. Isolates should be characterized by immunological means such as immunofluorescence (38, 47).

A PHV1 polymerase chain reaction (PCR) amplifying a 242 base pair product of the DNA-dependent DNA polymerase gene has been described (26).

Serology

Specific antibodies can be titrated by virus-neutralization tests or by indirect immunofluorescence and can be detected by counter-immuno-electro-osmophoresis (38, 47).

Differential Diagnosis

Clinically acute PHV1 infection disease may be confused with Newcastle disease virus infection (lentogenic pneumotropic paramyxovirus 1 strains), and chronic PHV1 infection complicated by secondary bacterial invaders must be distinguished from the diphteroid form of poxvirus infection (57, 59). A diagnosis of PHV1 infection requires virus isolation or serological evidence; however, both techniques may fail to demonstrate PHV1 infection in individual pigeons, the first because the animal may not be actively excreting virus and the second because of an absence of seroconversion in a latent carrier. For these reasons, several animals from the same dove-cote must be simultaneously examined (38, 47).

Treatment, Prevention, and Control

After primary infection, pigeons become asymptomatic carriers and may re-excrete virus. Chemotherapy trials with trisodium phosphonoformate and acycloguanosine failed to prevent infection (28, 29, 35, 52). Vindevogel *et al.* (53, 54, 55), therefore, compared the ability of inactivated (in oil adjuvant), or attenuated vaccines to prevent clinical disease, the carrier state, and virus re-excretion. Both types of vaccine were able to reduce primary viral excretion and clinical signs of challenge. Nevertheless, neither attenuated nor inactivated vaccines were able to prevent appearance of carriers since most of the pigeons re-excreted virus after Cy-treatment. Vaccination did, however, help to prevent viral re-excretion, thereby helping to control viral dissemination.

Pseudorabies Infection of Birds

Pseudorabies virus [*Sus herpesvirus 1* (SHV1)] produces a generally mild disease in swine, its natural host, but a fatal disease in cattle. Other animals found infected in nature are dogs, cats, sheep and rats (20, 23). The virus multiplies very well in chicken embryo fibroblast cultures (2).

Experimentally, SHV 1 can infect chickens, chicken embryos, and pigeons (15, 20, 36). Chicken embryos succumb with encephalitis after inoculation on the chorioallantoic membrane, as do 2-day-old chicks after being inoculated subcutaneously (1). Adult chickens, however, are resistant to subcutaneous inoculation (31).

Toneva (36) attenuated a strain of SHV 1 by serial passages in pigeons combining intramuscular and subcutaneous routes of inoculation (pigeon strain 80). Inoculated pigeons developed classic symptoms of encephalitis, i.e. torticollis, and disordered balance. The SHV 1 pigeon strain 80 is avirulent for rabbits, mice, guinea pigs and piglets after subcutaneous injection but remains lethal after intracerebral inoculation.

Avian Nephritis

Tadao Imada

Introduction

Avian nephritis, caused by an astrovirus, is an acute, highly contagious, typically subclinical disease of young chickens that produces lesions in the kidneys.

The causative agent, avian nephritis virus (ANV), was first isolated in chicken kidney cell (CKC) cultures from the rectal contents of apparently normal, 1-wk-old broiler chickens in Japan in 1976 (46). It has been shown to be an astrovirus, which is distinct from avian encephalomyelitis virus, duck hepatitis viruses, and turkey astrovirus, based on pathologic (9, 18), immunologic (3, 22, 23, 27, 42), and genomic (14, 15,20) criteria. ANV is the first astrovirus that was not identified by the morphological but by genomic analyses (14). The pathogenicity of this virus was established by experimental infection of chickens and chicken embryos. As the isolation and identification of this virus was a little bit difficult, there have been a few reports on the disease associated with this virus infection in the field (19, 36, 42), the economic importance is not well known, and public health significance is not known. Lately, more information about avian astroviruses has been published (1, 16, 17).

Incidence and Distribution

The true incidence and distribution of the disease are not well known owing to the transient, usually subclinical nature of the in-

fection and the difficulties with virus isolation. Runting and diarrhea in young chickens associated with an enteroviruslike particle serologically identical or related to ANV, but different biologically, have been reported in some countries (4, 6, 7, 8, 22, 24, 25, 33, 40). Avian nephritis virus has been shown to be widely distributed in chicken flocks in Japan (10, 43, 45), some European countries (3, 5, 32), and several specific-pathogen-free (SPF) flocks (3, 26, 32) by serology. Antibody to ANV has been also detected in turkeys in Northern Ireland and England (3, 32). Recently, the ANV gene has been validated on the case of acute nephritis and gout in Hungary (19).

Etiology

Classification and Morphology

Avian nephritis virus is classified as a new genus member of the family *Astroviridae* based on the following properties: 1) the ANV genome consists of approximately 7,000 nt with three Open Reading Frames (ORFs), ORF 1a, 1b, and 2 (Fig. 14.1). ORF 1a encoded a 3C-like serine protease motif, whereas the ORF 1b encoded a viral RNA-dependent RNA polymerase motif, and a ribosomal frameshift motif was also present between the two ORFs. On the other hand, ORF 2 of ANV, which may encode the capsid precursor polyprotein, encoded a product with 26% amino acid homology to those of human astrovirus (HAst). As shown for the HAst, ORF 2 of ANV is likely expressed from subgenomic-size RNA, which was detected in the ANV-infected cells, as well as genomic-size RNA. The genome organization of
14.1.   Schematic representation of the ANV (G-4260 strain) genome. Open boxes, PRFs. The locations of three ORFs, predicted transmembrane helices (MB), protease (Pro), nuclear localization signal (NLS), ribosomal frameshift structure (RFS), RNA-dependent RNA polymerase (Pol), and stem-loop II-like motif (s2m) are indicated. Numbering is according to the ANV genomic sequence (accession no. AB033998).

ANV is apparently identical to that of HAst; 2) ANV differs from previously described mammalian astroviruses in that trypsin is not required for growth in tissue culture. Trypsin-dependent replication of astroviruses *in vitro* is a very specific feature; 3) ANV was genetically distinct from other astroviruses; 4) replication in the cytoplasm; 5) diameter of 28 nm; 6) resistance to ethyl ether, chloroform, trypsin, and acid (pH 3.0); 7) relative heat lability; and 8) partial stabilization at 50°C by molar magnesium chloride (2, 14, 21, 46).

It is quite difficult to differentiate this virus from small round viruses, especially from picornavirus morphologically (16, 21).

Laboratory Host Systems
Chicken Embryos
When inoculated with ANV by the yolk sac route, 6-day-old embryos died 3–14 days postinoculation (PI). They manifested hemorrhage and edema of the whole body at 3–6 days PI and stunting at 7–14 days PI. When inoculated by the chorioallantoic membrane (CAM) route, high virus doses killed all embryos, but low virus doses allowed some infected embryos to hatch normally. In these eggs, the CAM showed edematous thickening or pocks at the inoculation site, and the embryos were stunted. Embryos inoculated by the allantoic cavity route sometimes became infected, but no virus was detected in allantoic fluids (8, 12).

Cell Culture
The representative strain (G-4260) of ANV grew in CKC with round cell-type cytopathic effect (CPE) and maximum virus titers at 24 hr PI (46). It did not grow in duck embryo fibroblasts, duck embryo kidney cells, or some established mammalian cell lines (HeLa, Vero, MDBK, PK-15, and MDCK). But the ability of ANV to replicate and to show CPE *in vitro* may be influenced by the conditions of the cell cultures and the strains of ANV (3, 6, 8, 27, 42). It has been shown that the chick embryo liver cells

cultures and LMH cells, a chicken heptocellular carcinoma cell line, are suitable for chicken astroviruses isolation and propagation (1).

Pathogenicity
Young chickens are the only animals known to develop clinical disease and distinct kidney lesions when exposed to ANV. Field viruses exhibit different degrees of pathogenicity in chickens. There are indications that different serotypes, and even strains with the same serotype, can vary in their ability to produce illness and death (6, 8, 9, 19, 34, 38, 39, 40, 42). Avian nephritis virus had no apparent effect on egg production or egg quality in laying hens (13). It had been reported that infectious bursal disease virus infection and cyclophosphamide treatment enhanced the pathogenicity of ANV in chickens (30, 31).

Pathogenesis and Epidemiology
Natural and Experimental Hosts
Infection has been recognized in chickens, and antibodies to ANV were detected in turkey flocks. Attempts to establish active infection in other animals have not yet been carried out. Chickens of all ages may be infected, but it has been observed that 1-day-old chicks are the most susceptible (8, 11, 29). Transmission readily occurs by direct or indirect contact (11). Egg transmission has been suggested on the basis of field observations (3, 42), and the virus can be isolated from chicks hatched from artificially infected embryonating eggs (12). In experimentally infected chicks, the virus was first detected in feces 2 days PI, with maximum virus shedding at 4–5 days PI. The virus is widely distributed, with maximum titers in the kidney and jejunum and lower titers in the bursa of Fabricius, spleen, and liver. The virus was consistently isolated from kidney, jejunum, and cloaca, but not from brain and trachea during the first 10 days PI (9).

The only clinical sign of ANV infection in 1-day-old chicks is
14.2. Visceral urate deposits in a chick that died 10 days postinfection. Chalklike urate crystals were deposited on the surface of the peritoneum and liver, although those on the surface of the liver were mostly removed during necropsy. The heart is white due to heavy urate deposits on the epicardium.

14.3. Degenerated proximal convoluted tubules containing acidophilic granules (*arrows*) in epithelial cell cytoplasm, and lymphocytic infiltration in interstitium, 5 days postinfection. H & E, ×300.

transient diarrhea, but not all chicks show this sign. Weight gain is depressed between 7 and 14 days PI. At necropsy at 4–21 days PI, mild to severe discoloration and swelling in the kidneys are observed, and in dead chicks within 2 weeks PI, visceral urate deposits (Fig. 14.2) are observed (7, 9, 18, 28, 29, 34, 35, 37). It has been reported that the concentration of serum uric acid or plasma urate value of ANV-infected 1-day-old chicks is transiently higher than that of uninfected chicks (28, 29, 30, 31, 37, 39).

Mortality may be influenced by the virulence of the ANV strain, strain of birds, and experimental conditions (8, 34, 39, 44).

Under field conditions, clinical signs associated with this virus infection in broiler chickens have varied from none (subclinical) to outbreaks of the so-called runting syndrome and baby chick nephropathy (7, 10, 19, 22, 24, 36, 40, 42, 46). Nothing is known about clinical signs in turkeys.

Histopathology

Histopathologic lesions in the kidneys of experimentally infected chickens have been studied (8, 11, 12, 13, 18, 28, 29, 30, 31, 34, 35, 37, 38, 40). The primary changes consisted of necrosis and degeneration of epithelial cells of the proximal convoluted tubules with infiltration of granulocytes. The degenerating epithelial cells had acidophilic granules of various sizes in the cytoplasm (Fig. 14.3). Also, there was interstitial lymphocyte infil-

tration and moderate fibrosis. In later stages, at 14–28 days PI, lymphoid follicles developed. Avian nephritis virus particles and viral antigens were demonstrated by electron microscopy in the degenerating epithelium (Fig. 14.4) and immunofluorescence (IF), respectively. Specific viral antigens were recognized by IF also in the jejunum, but distinct microscopic lesions were not observed in the small intestine. The chicks that died revealed many urate tophi in the serosa and parenchyma throughout the body, including the kidneys.

Diagnosis

Isolation and Identification of Causative Agent

For isolation of the virus from infected chickens, suspensions of either the kidneys or the rectal contents made in cell culture medium can be used as inoculum. After freezing and thawing three times, and centrifuging to remove the large tissue particles, the supernatant fluid is inoculated onto monolayers of CKCs or injected by the yolk sac route into 6-day-old embryonating eggs that originated from an SPF flock with no antibody to ANV (44,

14.4. Crystalline array of virus particles in the cytoplasm of a kidney epithelial cell, 3 days postinfection. ×30,000.

46). In infected CKC cultures, round cell-type CPE, without hemagglutinin, develops within 72 hr PI. There may be difficulties associated with isolation of enteric viruses in cell cultures (see Chapter 12, Diagnosis).

In embryonating eggs, infected embryos display hemorrhage and edema or stunting. Virus isolates may be further characterized by filtration through 50-nm-porosity membrane filters, or by inoculation of 1-day-old chicks with a 50% suspension of tissues harvested from embryos, followed by examination for lesions in the kidneys 3–7 days PI.

The IF technique is a useful diagnostic procedure, because this technique could detect group antigens of ANV. Viral antigens can be detected in the early acute phase of the disease by staining infected kidneys with specific anti-ANV fluorescent antibodies. This technique can also be used to detect viral antigens in cell cultures and embryos. In CKC infected with ANV, lumpy and granular antigens are seen in the cytoplasm as early as 12 hr PI.

For confirmation and direct demonstration of ANV infection, nucleic acid-based methods can be used. RT-PCR method could detect the regions of the viral protease, polymerase, and capsid genes specifically (1, 14, 19)(see Chapter 3, Diagnosis).

Serology

Chickens recovered from naturally occurring and experimental infections manifest an immunologic response that can be measured with a conventional virus-neutralization test, the indirect IF test, and enzyme-linked immunosorbent assay (ELISA) (5). It has been reported that there are at least two serotypes of ANV in the field (8, 38, 40, 42).

Differential Diagnosis

Certain nephrotoxic strains of infectious bronchitis virus (IBV) cause interstitial nephritis. It would be difficult to separate the two conditions on the basis of the histologic lesions (41). These cases may be differentiated from ANV infections by the fact that with infectious bronchitis there are some changes in the trachea, and infections in kidneys are usually preceded by respiratory signs. When nephritis is noticed in especially young chickens, it is necessary to isolate the causative agent or conduct serologic tests. The possibility that the two diseases may occur simultaneously in a flock should not be overlooked.

Treatment, Prevention, and Control

There is no specific treatment. Additional knowledge is needed to formulate measures for prophylaxis and control. It is important to know if the flocks are infected or not in view of the possible economic implications for the poultry industry.

Arbovirus Infections

James S. Guy and Mertyn Malkinson

Introduction

The term *arbovirus*, an abbreviation of *arthropod-borne-virus*, is used to describe a virus that replicates in a hematophagous (bloodsucking) arthropod and is transmitted by bite to a vertebrate host. Taxonomically, the term has been used to group those viruses that share the property of transmission by arthropod vectors. The most recent edition of the *International Catalog of Arboviruses* (60), published in 1985, lists 504 recognized arboviruses; however, an additional 30 arboviruses have been officially recognized since that publication (61). Over 100 arboviruses have been isolated from avian species or ornithophilic arthropod vectors. However, only five arboviruses—eastern equine encephalitis (EEE) virus, western equine encephalitis (WEE) virus, Highlands J (HJ) virus, West Nile (WN) virus and Israel turkey meningoencephalitis (IT) virus have been identified as causes of disease in domestic poultry and farm-reared game birds.

Public Health Significance

Eastern equine encephalitis virus, WEE virus and WN virus are zoonotic agents and potential causes of significant neurological disease in human beings; these infections may progress to paralysis, convulsions, coma and death. The case fatality rate for EEE virus in human beings is 50–75%, and survivors often have permanent neurological sequelae (mental retardation, seizures, impaired motor activity, impaired speech and hearing) (90). Western equine encephalitis virus and WN virus are less severe, with most infections being subclinical. The case-fatality rate in human beings for WEE virus and WN virus is approximately 3–7% and 4–11%, respectively (68, 90). For WN virus infections, it has been estimated that approximately 20% of human infections result in symptomatic illness, and about 1% lead to encephalitis, meningitis, or acute flaccid paralysis (126).

Human infection usually is acquired by mosquito bite; laboratory and clinically acquired infections are rare. However, care should be taken to avoid contact or droplet exposure when handling suspect infected birds or performing necropsies. HJ virus and IT virus are not believed to be pathogenic for human beings.

Etiology

Classification

The arboviruses comprise a large, diverse group of viruses, with members in 12 different virus families; however, only the Togaviridae and Flaviviridae contain viruses that cause disease in poultry and game birds. The main characteristics of the Togaviridae and Flaviviridae are presented below.

Togaviridae
Togaviruses are spherical enveloped viruses approximately 70 nm in diameter (Fig. 14.5). The genome consists of a single mol-
14.5. Negative-contrast electron micrograph of eastern equine encephalitis virus. ×150,000.

ecule of positive-sense, single-stranded RNA of 9.7 to 11.8 kilobases (kb), enclosed within a 40-nm diameter icosahedral nucleocapsid (119). Virions are composed of two or three envelope proteins (E1, E2, and sometimes E3) that are usually glycosylated, and a fourth capsid (C) protein. The molecular weights (mw) of alphavirus E1 and E2 structural proteins are 45–58 kilodaltons (kDa); that of E3, when present, is 10 kDa, and C is 30–33 kDa (119). Togaviruses replicate in the cytoplasm, and assembly involves budding of nucleocapsids through host-cell plasma membranes. Some togaviruses exhibit pH-dependent hemagglutinating activity.

Togaviridae comprise two genera, *Alphavirus* and *Rubivirus*, but only the *Alphavirus* genus contains arboviruses (119). The alphaviruses formerly were known as the arbovirus A group; the genus includes 29 viruses, the best known being EEE virus, WEE virus, Venezuelan equine encephalitis (VEE) virus, and HJ virus. Based on serologic cross-reactivity (59, 119), alphaviruses have been subdivided into eight antigenic groups named for prototype viruses: EEE virus, WEE virus, VEE virus, Semliki Forest virus, Ndumu virus, Trocara virus, Middleburg virus and Barmah Forest virus. Individual viruses are placed within these antigenic groups based on demonstration of antigenic relatedness to a prototype virus.

Flaviviridae
Flaviviruses formerly were known as the group B arboviruses and until recently were classified in the family Togaviridae. They

now are recognized as a distinct virus family based on differences in virion structure, gene sequences, morphogenesis and replication strategy (110). Flaviviruses resemble togaviruses, with the exception that they are somewhat smaller: approximately 50 nm in diameter. They replicate in the cytoplasm and acquire a lipid envelope by budding into cytoplasmic vesicles. The genome consists of a single molecule of positive-sense, single-stranded RNA of approximately 11 kb. Virions are composed of three structural proteins (64, 110): an envelope (E) glycoprotein with a molecular weight of 51–59 kDa, a core (C) protein of 13–16 kDa, and a membrane-like (prM or M) protein of 7–9 kDa. Flaviviruses exhibit pH-dependent hemagglutinating activity.

The Flaviviridae comprise three genera, *Flavivirus*, *Pestivirus* and *Hepacivirus*, but only the *Flavivirus* genus contains arboviruses (110). The *Flavivirus* genus contains about 70 virus members grouped antigenically into eight antigenic complexes (19, 71). The Japanese encephalitis virus antigenic complex includes WN virus, Japanese encephalitis virus, St. Louis encephalitis virus, and Usutu virus (36, 120). IT virus has been assigned to the Ntaya antigenic complex.

Laboratory Host Systems

Day-old chickens, newborn and baby mice are highly susceptible to arboviruses when inoculated by the intracerebral (IC) route and some are susceptible following inoculation by peripheral routes (88, 101). Intracerebral inoculation of newborn mice, 1 to 4 days of age, is the preferred method for isolation of these viruses. Arboviruses also may be propagated in embryonated chicken eggs and in a variety of vertebrate and arthropod cell cultures. Vero cells, BHK-21 cells, and primary cultures of chicken and duck cells are frequently used for virus propagation. Cytopathic effects are readily produced by arboviruses in vertebrate cell cultures; they are not always produced in arthropod cell cultures.

Arbovirus Diseases of Birds

Five arboviruses have been identified as causes of disease in domestic poultry and farm-reared game birds: eastern equine encephalitis (EEE) virus, western equine encephalitis (WEE) virus, Highlands J (HJ) virus, Israel turkey meningoencephalitis (IT) virus and West Nile (WN) virus.

Eastern Equine Encephalitis

History

Eastern equine encephalitis virus was first isolated in 1933 from the brain of a horse with encephalitis (109). In 1938, the virus was identified by Tyzzer *et al.* (113) as the cause of an epornitic disease of penned pheasants. It was subsequently identified as a cause of disease in pigeons in 1938 (33), chukar partridges (83) and Pekin ducks (28) in 1960, and turkeys in 1961 (103).

Pathogenesis and Epiemiology

Incidence and Distribution
Eastern equine encephalitis is most commonly seen as a disease of horses. Many outbreaks of EEE in farm-raised ring-neck

pheasants and chukar partridges have been identified, but it occurs only sporadically in other species of poultry and game birds. The disease occurs primarily in the eastern parts of North America, throughout Central America and the Caribbean, and in eastern parts of South America. In the United States, EEE has been identified in most states east of the Mississippi River, as well as Louisiana and Texas; it occurs most often in Atlantic seaboard states and Gulf Coast states. Reported isolations of EEE virus in Europe and Asia have not been confirmed.

Outbreaks generally occur in late summer and fall as a consequence of increasing numbers of mosquito vectors. Wallis *et al.* (118) demonstrated that increased population densities of mosquitoes coincided with the appearance of outbreaks. Hayes and Hess (44) studied weather patterns associated with EEE outbreaks in Massachusetts and New Jersey and noted that excessive rainfall during the preceding autumn months influenced the occurrence of the disease.

Natural and Experimental Hosts
Outbreaks of EEE in avian species have been reported primarily in pheasants (58, 113); however, outbreaks in pigeons (33), chukar partridges (83, 93), turkeys (32, 103, 115), and ducks (28) also have been reported. Episodes of clinical disease in chickens and quail have not been reported, but both species are highly susceptible to experimental infection (112, 113).

Transmission, Carriers, Vectors

Culiseta melanura, an ornithophilic mosquito, has been determined to be the principal enzootic vector of EEE virus in North America (20, 51). The virus also has been identified in a variety of other mosquitoes including *Aedes sollicitans, Coquilletia perturbans, Culex (Cx.) pancossa, Cx. dunni,* and *Cx. sacchettae,* as well as mites, lice, simuliid flies, and culicoides (24, 116, 117). *C. melanura* is the likely vector responsible for transmission to poultry and game birds; transmission to mammalian species most likely occurs by other mosquitoes such as *Aedes* spp. and *Coquillettia* spp., which feed on birds but also have a propensity to bite mammals (82).

Wild birds, primarily the smaller species of Passeriformes, are the principal vertebrate hosts of EEE virus (66, 82, 122). These birds rarely become ill but serve as maintenance and amplifying hosts for the virus in the transmission cycle. In experimental studies, a variety of wild birds were shown to develop viremia lasting up to 4 days; small passeriform birds were shown to develop viremias with maximal lethal-dose—50% (LD_{50}) titers greater than 10^6/mL (66).

Although EEE virus is transmitted principally by mosquitoes, direct transmission has been shown to occur among pheasants as a result of feather picking and cannibalism (50). In addition, pheasants have been experimentally infected by oral inoculation of the virus (97). Epornitics of EEE virus infection in pheasants are believed to be initiated by mosquito-borne infection of one or more birds in a flock, with subsequent spread within the flock occurring as a result of feather picking and cannibalism.

Transmission of EEE virus by semen also has been demon-

strated (41); virus was shed in the semen of experimentally infected tom turkeys on days 1 to 5 postinfection (PI). Semen collected from infected tom turkeys at 1–2 days PI resulted in transmission to breeder hens after artificial insemination.

Clinical Signs and Pathology
Clinical disease produced by EEE virus in poultry and game birds usually is attributed to central nervous system (CNS) infection with or without involvement of viscera. However, EEE virus also may produce visceral infections with little or no involvement of CNS tissues.

Pheasants
Naturally infected pheasants develop signs of neurologic dysfunction consisting of depression, leg paralysis, torticollis, and tremors (8, 113). Clinical signs occurred in 40–100% of experimentally infected pheasants with mortality of 25–100% (43, 65, 97). Mortality rates up to 80% have been described for naturally occurring outbreaks.

Tyzzer *et al.* (113) and Jungherr *et al.* (58) described the pathology of EEE in pheasants. Gross lesions were not observed; however, histopathologic changes in the CNS consisted of vasculitis, patchy necrosis, neuronal degeneration, and meningeal inflammation.

Turkeys
Outbreaks of EEE in turkeys in Wisconsin were characterized by drowsiness, incoordination, progressive weakness, and paralysis of legs and wings (103). Mortality in affected flocks was low, generally less than 5%. Infected turkeys had neurologic lesions consisting primarily of calcification of blood vessel walls in the cerebral cortex, the cerebellar folia, and the basal part of the medulla. Central nervous system lesions in intracerebrally inoculated birds included lymphocytic perivascular infiltration, neuronal degeneration, and endothelial cell swelling. Calcification of blood vessel walls was not observed in intracerebrally inoculated birds that died before 6 days PI.

Ficken *et al.* (32) serologically identified EEE virus as the cause of high mortality in young (1- to 4-week-old) turkeys. Subsequent experimental studies demonstrated susceptibility of young turkeys to experimental infection (38). Two-week-old turkeys experimentally infected with EEE virus exhibited depression, somnolence, and high mortality. Viremia was detected in infected turkeys on days 1 and 2 PI, with peak viremia of $10^{5.5}$ plaque-forming units per ml (PFU/ml) detected on day 1 PI. Pathologic changes consisted of multifocal necrosis in the heart (Fig. 14.6A), kidney, and pancreas, and lymphoid necrosis and depletion in the thymus (Fig. 14.6B), spleen and bursa of Fabricius (Fig. 14.6C). No lesions were detected in brains.

Acute drops in egg production in turkey breeder hens due to EEE virus infection were reported by Wages *et al.* in 1993 (115). Decreased egg production in affected flocks was characterized by sudden onset of production of white, thin-shelled and shell-less eggs. No increase in mortality was observed, and acute ovarian regression was the only gross lesion observed. Experimental infection of turkey hens with EEE virus reproduced the disease observed in naturally affected flocks (40). Eastern equine encephalitis virus-infected turkey hens exhibited mild depression and inappetence, but only on day 1 PI. A precipitous decline in egg production began on day 2 PI, and production remained depressed for 15 days; no mortality was observed. Viremia of short duration (1–2 days), peaking at $10^{5.8}$ PFU/ml on day 1 PI, was detected in EEE-virus-infected hens.

Chukar Partridges
Chukar partridges infected with EEE virus exhibited clinical signs of depression, somnolence, and high mortality (30–80%) (93). Pale, focal areas were present in hearts of affected birds, and spleens were mottled and enlarged. Microscopic lesions consisted of gliosis, satellitosis, and perivascular lymphocytic infiltration in brains, and myocardial necrosis with lymphocytic infiltration.

Ducks
White Pekin ducklings infected with EEE virus developed a paralytic disease characterized by sudden onset, posterior paresis, and paralysis (28). Mortality rates in EEE virus-affected flocks were 2–60%. Histopathologic lesions consisted of edema of spinal cord white matter, lymphocytic meningitis, and microgliosis.

Chickens
Newly hatched chickens are highly susceptible to EEE virus and succumb rapidly to the infection, often without showing signs of CNS involvement. Byrne and Robbins (16) demonstrated that susceptibility of chickens to lethal EEE virus infection declined rapidly with age; in their study, chickens became refractory to lethal infection by 14 days of age. In contrast to their findings, susceptibility to lethal infection was demonstrated by Tyzzer and Sellards (112) in 3- to 13-day-old chickens and by Guy *et al.* (39) in 14-day-old chickens. The different findings from these studies have not been explained, but differences in age-dependent resistance may be due to differences in host genetics and/or differences in virulence of the EEE viruses used in these studies.

Experimental infection of young chickens, 1–14 days of age, caused depression, somnolence, and high mortality; paralysis was infrequently observed (39, 112). The principal lesion, and the presumed cause of death, was myocarditis. Microscopic heart lesions consisted of multifocal necrosis with fragmentation of myocardial fibers, and infiltration with lymphocytes, plasma cells, and macrophages (Fig. 14.6E). Central nervous system lesions in infected chickens were inconsistently observed (39, 112). In brains, microscopic lesions consisted of occasional small foci of necrosis and mild perivascular cuffing (Fig. 14.6D). Multifocal necrosis of the liver (Fig. 14.6F) and lymphoid depletion and necrosis in the thymus, spleen, and bursa of Fabricius also were observed in EEE virus-infected chickens (39). Ascites and right ventricular dilatation of the heart were observed in chickens that survived the acute effects of EEE virus infection; these effects likely occur due to myocardial damage (39).

Diagnosis

Isolation and Identification of Causative Agent

Diagnosis of eastern equine encephalitis may be accomplished by isolation and identification of the virus, detection of viral antigens using antigen-capture enzyme-linked immunosorbent assays (ELISAs) (48, 49, 98, 99), or immunohistochemistry (123), detection of viral RNA using reverse transcriptase, polymerase chain reaction (RT-PCR) procedures (114), and serologic testing (101). The virus can be isolated by inoculation of blood or tissue homogenates (brain, spleen, liver, heart) into newborn mice by the intracerebral route, day-old chickens by subcutaneous or intramuscular routes, and 5- to 7-day-old embryonated chicken eggs by the yolk sac route (88, 101). In addition, a variety of cell cultures may be utilized for isolation of the virus; Vero, BHK-21, and chicken or duck embryo cells are highly susceptible. Newborn mice and 1-day-old chickens generally die of encephalitis in 2–5 days. Chicken embryos generally die within 18–72 hr and have a hemorrhagic appearance. Cell cultures develop cytopathic effects (CPE) within 24–48 hr, and plaques develop under agar within 36–48 hr. Identification of EEE virus in inoculated animals, embryonated eggs, or cell cultures generally is accomplished by virus-neutralization (VN) tests or complement fixation (CF) tests.

Antigen-capture ELISA procedures for detection of EEE virus antigens have been described (14, 48, 49, 98, 99). These procedures have been shown to be highly sensitive, detecting EEE virus in experimentally infected birds as early as 12 hr PI and in pools of insects in which only 1% of the insects were infected (14, 48, 49, 98, 99). Commercially available antigen-capture ELISA tests recently have become available for detecting EEE virus in mosquitoes; these also are available for detection of WEE virus and WN virus (85).

An immunohistochemical procedure (123) and a RT-PCR (114) were described for detection of EEE virus antigens and viral RNA, respectively, in tissues of infected birds. These procedures were shown to be rapid, sensitive and specific methods for detection of EEE virus in tissues. Additionally, these diagnostic procedures, along with ELISA, minimize the human health risks inherent with virus isolation and identification procedures.

Serology

Serological diagnosis of EEE virus may be accomplished using VN, hemagglutination-inhibition (HI), ELISA, and CF. Of these, VN and HI tests are most commonly utilized. The HI test is rapid and relatively simple; it requires either goose or 1-day-old chicken erythrocytes, and antigen prepared from infected suckling mouse brains by the sucrose-acetone extraction method (21, 101). Avian serum contains nonspecific inhibitors of hemagglutination and these must be removed by kaolin adsorption before use in HI tests. A presumptive serologic diagnosis may be obtained by detection of EEE virus antibodies in serum collected from recovered birds. A definitive diagnosis is achieved by demonstrating a rising antibody titer in serum samples collected soon after onset of clinical signs and 1–2 wk later.

Guy *et al.* (40) demonstrated the value of serology for diagnosis of EEE virus-induced episodes of decreased egg production in turkey breeder hens. Serology was shown to be particularly important because the virus was found to be present in most tissues of experimentally infected turkey breeder hens for only a very brief period (on days 1–2 PI) following experimental inoculation, yet marked drops in egg production became apparent only after day 2 PI.

Differential Diagnosis

Eastern equine encephalitis must be distinguished from other causes of neurologic disease in poultry and game birds such as HJ virus, Newcastle disease virus, avian encephalomyelitis virus, botulism, and listeriosis. In cases of egg-production drops in turkeys, EEE virus, WEE virus, HJ virus, Newcastle disease virus, avian influenza virus, avian encephalomyelitis virus, paramyxovirus type 3, turkey coronavirus, and turkey rhinotracheitis virus must be considered. These diseases generally are distinguished based on isolation and identification of the causative agent or by serologic analyses.

Intervention Strategies

Eastern equine encephalitis is best prevented and controlled by measures aimed at reducing vector populations. Such measures include reduction of vector habitats by modifications of the environment or by chemical spraying. If feasible, farms that raise susceptible avian species should be located away from swamps and other areas that provide habitat for vectors.

Formalin-inactivated EEE vaccines, prepared for use in horses, have been used to protect pheasants against EEE epornitics (105), although their efficacy has been questioned (29).

Western Equine Encephalitis

Western equine encephalitis virus has many characteristics in common with EEE virus. The virus is rarely associated with disease in avian species; however, a few cases have been reported (23, 31, 93, 124). In 1957, WEE virus was identified by Woodring (124) as the cause of encephalitis and high mortality in turkeys in Wisconsin based on serologic studies; affected turkeys exhibited somnolence, tremors, and leg paralysis. Faddoul and Fellows (31) reported the isolation of WEE virus from the brain of a pheasant in Massachusetts, and Ranck *et al.* (93) identified the virus as the cause of high mortality in chukar partridges in Florida. However, the association of WEE virus with disease in these species, particularly pheasants (31) and chukar partridges (93), is tenuous. It is now generally accepted that WEE virus does not occur in the eastern United States, and that all WEE-related alphaviruses isolated in the eastern United States are actually strains of HJ virus (see below) (17, 111).

Recently, WEE was associated as a cause of decreased egg production in turkey breeder hens in California (22). Decreased egg production in affected flocks was characterized by sudden onset with production of small, white-shelled and shell-less eggs. No increase in mortality and no clinical signs were observed in affected flocks. A WEE virus isolated from affected breeder hens

was evaluated for pathogenicity in 2-week-old turkeys (23). The isolate failed to produce clinically apparent disease in inoculated turkeys, but infection resulted in mild to moderate lymphoid necrosis in the bursa of Fabricius and thymus.

Western equine encephalitis is identified mainly in western parts of the United States and Canada, in Central America, and in South America. It is transmitted principally by *Culiseta tarsalis,* a mosquito vector that is relatively common in the United States west of the Mississippi River (20). Laboratory diagnosis of WEE is accomplished using the same procedures that are used for EEE.

Highlands J Virus Infection

Highlands J virus initially was isolated in 1960 from blue jays in Florida (47). Since that time, the virus has been identified as a cause of disease in chukar partridges (30, 93) and turkeys (32, 38, 40, 115).

Ranck *et al.* (93) reported that WEE virus was the cause of mortality in chukar partridges in Florida in 1964; however, this virus most likely was HJ virus. Antigenically, HJ virus is closely related to WEE virus and for many years was considered to be a variant of that virus (45, 47, 62). However, serologic and oligonu-cleotide mapping studies clearly differentiate these viruses and have identified HJ virus as a distinct virus in the WEE antigenic group of alphaviruses (17, 18, 59, 111). All viruses belonging to the WEE antigenic group that have been isolated in the eastern United States have been determined to be HJ virus (17).

Ranck *et al.* (93) experimentally reproduced the disease by subcutaneous inoculation of young chukars. Experimentally infected chukars exhibited somnolence, ruffled feathers, and recumbency prior to death; lesions primarily consisted of encephalitis and myocardial necrosis. Eleazer and Hill (30) described a more recent outbreak of HJ virus infection in chukar partridges in South Carolina. Chukars exhibited similar clinical signs and high mortality (35%); myocarditis was consistently observed in affected birds, but lesions in the brain were uncommon.

Wages *et al.* (115) found HJ virus to be the cause of acute drops in egg production in turkey breeder hens. In addition, these viruses were serologically associated with mortality in young turkeys (32). Experimental infection of turkeys with HJ virus produced precipitous egg production drops in turkey hens (40), but was only mildly pathogenic for young turkeys (38). The clinical and pathologic characteristics of HJ virus infection in turkeys closely resemble those of EEE virus infection (see above).

Laboratory diagnosis of HJ virus infection is accomplished using the same procedures used for EEE virus and WEE virus. These include virus isolation, serology, antigen-capture ELISA, and RT-PCR procedures (32, 40, 121). Highlands J virus is readily distinguished from WEE virus isolates by a variety of serologic procedures using polyclonal and monoclonal antibodies (63).

Israel Turkey Meningoencephalitis

History
Israel turkey meningoencephalitis (IT) was first described in Israel by Komarov and Kalmar in 1960 (70). In 1961, Porterfield

(91) identified the etiologic agent as a new virus belonging to the Flaviviridae. Based on its serological properties IT virus was assigned to the Ntaya serogroup (19). The disease was identified in South Africa in 1978 (7).

Incidence and Distribution
Israel turkey meningoencephalitis has been reported only in Israel and South Africa. Outbreaks of the disease occur seasonally in all regions of Israel, corresponding with the activity of arthropod vectors; outbreaks generally begin in late summer, peak in October, and disappear in early winter (52).

Pathogenesis and Epidemiology
Natural and Experimental Hosts
Israel turkey meningoencephalitis has been reported only in turkeys. Field cases of IT are rarely observed in turkeys less than 10 wk of age, but younger birds are equally susceptible (95). Experimental infection of turkeys less than 10 wk of age results in disease with an incubation period of 5 to 8 days (52). A viremia is detectable within 24 hr PI in experimentally infected turkeys and persists for 5–8 days (55).

Newly hatched poults (53), Japanese quail (*Coturnix coturnix japonica*) (56) and suckling mice (53) are highly susceptible to IT virus inoculated by the intracerebral and intramuscular routes. Chickens, ducks, geese, and pigeons are refractory to infection (70).

Transmission, Carriers, Vectors
The seasonal incidence and sporadic occurrence in flocks on the same farms strongly suggest that IT virus is transmitted by insect vectors. The virus has been isolated from unsorted pools of mosquitoes (*Aedes* spp. and *Culex pipiens*) and culicoides trapped near affected turkey flocks (12). Experimentally, IT virus has been shown to infect *Aedes aegypti* and *Culex molestus* mosquitoes (87). Field observations and experimental studies indicate that virus transmission does not occur by direct contact between infected and uninfected birds (55, 57).

Clinical Signs and Pathology
In field outbreaks, IT occurs with greatest incidence in turkeys 10 to 12 weeks of age. Affected turkeys exhibit neurologic dysfunction characterized by progressive paresis and paralysis, with variable mortality. Morbidity and mortality rates generally average 15–30% but may be as high as 80% (52). Affected birds initially exhibit an uncoordinated gait and walk with one or both wings drooping. As the disease progresses, birds become reluctant or unable to walk, and rest on their breasts with legs extended forward and wings spread laterally. Turkey breeder hens exhibit a severe drop in egg production, but egg quality, fertility, and hatchability are unaffected. Egg production returns to normal levels after recovery from infection.

Gross lesions include splenomegaly or atrophy of the spleen, catarrhal enteritis, and myocarditis (6, 54, 70). Ovarian regression, ruptured ovarian follicles, and peritonitis are observed in affected breeder hens (6). The principal microscopic lesions are

nonpurulent meningoencephalitis characterized by submeningeal and perivascular lymphocytic infiltration, and focal myocardial necrosis (54, 70).

Diagnosis

Brain, spleen, liver, serum, and ovary are the preferred materials for virus isolation (53, 55). Homogenates of tissue or undiluted serum are inoculated into 6- to 8-day-old embryonated chicken eggs by the yolk sac route, or onto monolayers of chicken embryo fibroblasts (CEF). One or more passages in embryonated chicken eggs may be required before embryo mortality is observed; embryos die 3 to 6 days PI and show a distinct cherry-red discoloration. Suckling mice inoculated by the intracerebral or intramuscular routes also may be used for virus isolation (53). A specific RT-PCR assay for IT virus recently has been described (25).

A readily recognizable CPE is produced in infected CEF cells by 3 days PI (54, 55); however, CEF cells are less sensitive than embryonated chicken eggs or suckling mice for isolation of IT virus. Identification of isolates usually is accomplished by VN tests.

Serological diagnosis can be accomplished using HI or VN tests in CEF or BHK-21 cells (7, 54, 55, 89). The HI test requires either goose or day-old chicken erythrocytes and antigen prepared from infected suckling mouse brains by the sucrose-acetone extraction method (53).

Differential Diagnosis

Israel turkey meningoencephalitis must be differentiated from other causes of neurological disease in turkeys, particularly Newcastle disease virus, highly pathogenic avian influenza virus, EEE virus, and HJ virus. The known geographic distribution of these viruses and the greater severity of paralysis that is observed with IT as compared with EEE and HJ are helpful in distinguishing these agents. Nervous signs may be observed with Newcastle disease, but paralysis generally does not occur. Nervous signs also may be caused by *Riemerella anatipestifer* infection and ionophore toxicity.

Control

Israel turkey meningoencephalitis is controlled by vaccination. Live attenuated vaccines have been prepared by serial passage of IT virus in embryonated chicken eggs (54), Japanese quail kidney cells (57), and BHK-21 cells (7). The Japanese quail kidney cell-attenuated virus has been shown to be highly efficacious and is commercially available. Reduction of insect vector populations in the vicinity of turkey farms also may be useful in controlling the disease. IT virus does not cause disease in humans.

West Nile Virus

History

West Nile (WN) virus was first isolated from the blood of a febrile Ugandan woman in 1937 (102). The virus was first described as the cause of a WN fever epidemic in humans in Israel in 1951 (9, 35), and in a later outbreak, severe meningoen-

cephalitis was seen in elderly patients. The role of mosquitoes in viral transmission was clearly delineated in a series of field studies in Egypt in the 1950s (108); the involvement of various wild birds as reservoirs of the virus also was described during this period (125). Cases of WN fever in horses were reported in Egypt and France several years later. West Nile virus was first identified as a significant cause of disease in domestic avian species in 1997, when the virus was identified as a cause of neurological disease in young geese (75). In August 1999, the disease was detected for the first time in the Western Hemisphere in wild birds, zoo birds, horses and human beings in the United States (104).

Pathogenesis and Epidemiology

Incidence and Distribution

WN virus is now considered to be endemic in many countries of Africa, Asia, southern Europe, North America and Central America (46, 104). Epidemics appear in the human population at infrequent intervals in some of these countries and there is evidence for viral transmission bidirectionally between Africa and Europe by migrating birds (76). Epidemics occurred for the first time in Romania in 1996 and Russia in 1999, in which several hundred people were affected and the case fatality rates reached 10% or more. In 1998 and 2000, outbreaks affecting horses were seen in Italy and southern France respectively. In Israel, outbreaks affecting geese reappeared in 1998, 1999, and 2000; an epidemic affecting 500 people with 29 deaths occurred in 2000.

West Nile viruses isolated from different parts of the world were shown to segregate into two distinct lineages based on complete genomic sequences (72) and sequence analyses of the E protein gene (10). Lineage I contained WN viruses isolated in Europe and Africa; lineage II contained viruses isolated in Africa, Madagascar, and most recently in Central Europe (4).

Natural and Experimental Hosts

Outbreaks of WN in poultry have been reported primarily in geese (3, 5, 34, 75, 79). Episodes of clinical disease in chickens and turkeys have not been reported, but both species are susceptible to experimental infection (100, 106). Experimental infection of young Muscovy ducks resulted in mortality.

A wide variety of feral and captive birds are known to be susceptible to WN virus infection (68). In a study examining the role of various feral birds as reservoirs of WN virus in the transmission cycle, 25 species were infected experimentally with a New York 1999 strain of the virus (69). Based on the levels of viremia, the five most competent species were passerines: blue jay (*Cyanocitta cristata*), common grackle (*Quiscalus quiscula*), house finch (*Carpodacus mexicanus*), American crow (*Corvus brachyrhynchos*), and house sparrow (*Passer domesticus*).

Transmission, Carriers, Vectors

The principal route of transmission is by the bite of a *Culex* mosquito. In the USA during 1999 and 2000, most of the viral isolates were made from *Cx. pipiens* and *Cx. restans* (37). In Africa and the Middle East, the usual vector is *Cx. univittatus* and in

Europe, *Cx. pipiens* and *Cx. modestus*. WNV has been isolated from at least 10 tick species belonging to *Amblyomma*, *Dermacentor*, *Hyalomma*, *Rhipicephalus*, *Argas*, and *Ornothodorus* genera (84). West Nile virus was found in hibernating *Cx. pipiens* found in New York City and in male *Cx. univittatus* in Kenya indicating that transovarian transmission occurs in nature (80).

Most outbreaks begin in mid-July and end in October when cold nights reduce mosquito vector activity, notably *Culex* species. Outbreaks of WN in goose flocks have also been reported in Canada (3), Hungary (34), and the USA (79).

Until recently, wild birds were considered to be only sporadic victims of WN virus infection and evidence for their role as carriers was gained primarily from serological surveys. The isolation of virus during the 2000 epizootic from white storks, gulls, feral pigeons and a wide range of American birds including crow, jay, dove and hawk indicates that wild species actively become infected and also transmit the virus over considerable distances as they migrate. Viral titers in crow blood, for example, exceeded 10^{10} plaque-forming units/ml (2). Based on experimental data, direct transmission between crows is suspected to occur in communal roosts resulting in widespread dispersion of the virus in nature (78).

Incubation Period

Mortality was observed in geese experimentally infected by the intracerebral route beginning on day 5 PI, and on day 8 PI after experimental infection by the intramuscular route. In naturally infected flocks, mortality rates of 10% to 60% have been reported (4, 34); these high rates may be due in part to horizontal spread of the virus. In another experiment, an in-contact goose was found to be viremic on day 10 PI having been infected by cage mates inoculated with a crow isolate of WN virus (107).

Clinical Signs and Pathology

Geese

West Nile virus-infected geese show various degrees of neurological involvement ranging from recumbency to leg and wing paralysis (Fig. 14.17) (34, 107). Affected birds are either reluctant or unable to move when disturbed. Signs of incoordination are pronounced; some birds may fall while attempting to stand. Torticollis and opisthotonus may be observed.

In 3–4 wk old geese experimentally infected by the subcutaneous or intramuscular route, viremia was detected in some birds as early as day 1 PI. Peak viremias of 10^4–10^6 tissue culture doses/ml occurred on days 2–4 PI; viral titers declined or disappeared coincident with the appearance of neutralizing antibodies. Some geese had detectable VN antibodies by day 4 PI. In subcutaneously infected 2-wk-old goslings, WN virus was recovered from the plasma of one in-contact bird on day 10 PI and VN antibody was detected on day 14 and on day 21 PI in this gosling (107). Viral excretion from inoculated geese in this experiment was determined to be from the oropharynx and not from feces. The high viremic levels in infected geese are sufficient to transmit virus to engorging mosquitoes; geese thereby act as reservoirs for further circulation.

During a recent epizootic, losses due to WN virus infection in

14.7. Six-week-old geese infected with West Nile virus. The bird on the left is unable to stand, and the bird on the right has spread its wings in attempt to retain its balance (Weisman).

young goose flocks were estimated to be far greater than expected if mosquito-borne transmission was the principal route of infection. Contact transmission was investigated experimentally as an alternative explanation (5). A group of 3-week-old geese were inoculated subcutaneously and placed in an insect-proof room with 20 geese of the same age. All geese in the inoculated group produced antibodies, eight became viremic and five died between 7 and 10 days after infection. Virus was shed from the cloaca and oral cavity by three geese. Two of the in-contact birds died on days 10 and 17 after infection, and WNV was recovered from another three birds. These findings strongly suggest that horizontal transmission of WN virus can occur in commercial flocks and may be aggravated if cannibalism and feather-picking of sick geese occur.

Pathological changes in WN virus-infected geese include pallor of the myocardium and occasionally the kidneys, splenomegaly and hepatomegaly; engorgement of meningeal blood may be observed. Microscopic lesions were found mainly in the brain and consisted of lymphocytic perivascular infiltration and neuronal degeneration (Fig. 14.8). Small necrotic foci were present in the heart muscle but lymphocytic infiltration was minimal.

Chickens

Day-old chickens develop neurological signs including tremors and paralysis following inoculation by a variety of routes. These signs appeared between 5–10 days PI (94). Chickens aged 1–11 days developed viremia of 10^4–$10^{6.3}$ mouse infectious doses/ml following infection by mosquito bite and were capable in turn of infecting mosquitoes (108). In endemic areas chickens became naturally infected and a serological prevalence rate approaching 20% has been recorded. Sentinel chickens also play an important role in serological surveillance programs and have been used extensively in the USA (67) and England (15).

Experimentally infected 7-week-old chickens developed viremia of 10^5 tissue culture doses/ml on day 5 PI that persisted
14.8.   Microscopic lesions in the brain of West Nile virus-infected goose. A. Perivascular cuffing by mononuclear cells (H&E stain) (Perl). B. Immunohistochemistry. Three intensely stained neurons with viral antigen in the cytoplasm; the nuclei remain unstained. Stained granules are dispersed in the neurophil. Counter-staining with hematoxylin (Perl). Monoclonal antibody supplied by Dr. Vincent Deubel, Pasteur Institute, Paris.

until day 7 PI. Some chickens shed virus in their feces on days 4 and 5 PI (100). Nevertheless, neither clinical signs nor mortality were seen in birds infected subcutaneously with an American crow isolate (100). This level of viremia is enough to infect engorging mosquitoes. Birds sacrificed on days 5 and 10 PI showed myocardial necrosis, nephritis and peritonitis, while at termination of the experiment on day 21 PI non-suppurative encephalitis was found. No viral transmission to in-contact chickens was detected; they remained antibody and viremia negative for 21 days. In the light of these observations, young chickens should be viewed as potential amplifying or reservoir hosts.

Turkeys
No morbidity or mortality has been reported in commercial turkey flocks. When 3-wk-old poults were experimentally infected subcutaneously with an American crow isolate none became clinically affected, however, most of them became viremic for up to 10 days PI (106). Virus was re-isolated from feces on days 4–7 PI but in-contact poults were not infected.

Immunity
Geese rapidly develop high titers of circulating antibodies to WN virus; however, these are not reliable indicators of protection. Cell mediated immunity has not been studied in geese; however, geese vaccinated with a live, attenuated IT vaccine were resistant to intracerebral challenge with a field isolate of WN virus, but failed to develop detectable VN antibodies (77). In a mouse model, B cells and antibody were shown to play critical roles in defense against disseminated infection (27).

Maternal antibodies have been detected in sera collected from 1–2 wk old goslings hatched from commercial geese flocks, but these did not interfere with an active response to inactivated WN virus vaccine. Based on field observations, susceptibility of geese to natural infection appears to decline with increasing age; geese older than 12 weeks of age appear to be resistant to disease.

Diagnosis
Isolation and Identification of WNV
Tissues of choice for isolating WN virus from birds are the brain, spleen and kidneys. Tissue homogenates are inoculated into newborn mice by the intracerebral route, into embryonated eggs by the yolk sac route, or onto monolayers of Vero cell cultures or mosquito cell cultures. Mice develop ataxia within 4–7 days; chick embryos die within 2–6 days PI and have an injected appearance. Cell cultures develop a cytopathic effect within 48–72 hrs. Virus may be identified in cell cultures by indirect immunofluorescence; monoclonal antibodies may be used for this procedure and are available commercially, and from reference laboratories.

Reverse transcriptase-polymerase chain reaction procedures recently have been described (10, 73). These procedures allow rapid detection of WN virus in avian tissues, cell cultures, and field-collected mosquitoes. Immunohistochemistry and *in situ* hybridization have been described for detecting WN virus antigens and viral RNA, respectively, in tissues of infected birds (104). These diagnostic procedures minimize the human health risks inherent with virus isolation and identification procedures.

Serology
Serological diagnosis can be accomplished using HI or ELISA tests. A group-specific flavivirus antigen, acetone-extracted from infected mouse brain, forms the basis of the HI test (see EEE section). Several forms of ELISA have been developed for flaviviruses; one variation is to employ a cross-reactive flavivirus monoclonal antibody to block avian sera (42). An indirect ELISA may be utilized in which flavivirus antigen of cell culture-origin is used to coat the plate. In addition, a blocking ELISA has been developed for working with sera from multiple avian species (11). Flavivirus antibodies were detected by ELISA in chicken sera by day 6–10 PI (13).

Differential Diagnosis

Nervous signs in young geese may be caused by a variety of bacteria including *Riemerella anatipestifer*, *Streptococcus gallolyticus*, *Erysipelothrix spp.*, *Listeria spp.* and *Salmonella spp.* Neurotropic viruses include Newcastle disease, which is rare in geese, and highly pathogenic avian influenza virus. Nervous signs also may be caused by *Aspergillus spp.* and ionophore intoxication.

Intervention Strategies

Management Procedures

Mosquito control is a mandatory component of any WN control program. Unfortunately this is very difficult to implement because of the distances that mosquitoes can fly, or can be carried by prevailing winds. Nevertheless, standing water and similar insect breeding sites in the vicinity of densely populated avian farms should be treated with larvicides. Poultry houses should be constructed to be insect-free. Because WN is a significant public health threat, much can be achieved by cooperation with public health agencies.

Vaccination

Control of WN virus infections in geese is primarily confined to vaccinating young flocks at risk, especially those raised during July through November when *Culex spp.* are most numerous. Because of age susceptibility, goslings should be immunized as young as possible and preferably at 3 weeks of age. WN vaccines are now commercially available, and several types recently have been developed for use in birds and horses (81, 86, 96).

Field trials have been performed extensively with a formaldehyde-inactivated mouse brain-derived product (77, 96). The production protocol is based on that described for Japanese encephalitis virus vaccine (1). Over 75% of geese vaccinated with a single dose of vaccine at 3 weeks of age were protected and 94% protection was achieved with two doses spaced two weeks apart. The duration of immunity was estimated to be approximately 12 weeks. Inactivated vaccines prepared from chick embryos or Vero cells are less protective because of their low antigenic mass.

WN virus has been attenuated by serial passage in mosquito cell cultures (74). A single dose of mosquito cell-passaged virus induced immunity to intracerebral challenge in young geese. Mosquito feeding experiments and back passage/reversion to virulence studies have not been completed.

The use of IT virus vaccine has been investigated in commercial flocks (77). A single injection given at 3 weeks of age produced protection in geese challenged two weeks later. This is an example of cross-protection that is known to exist within the flavivirus family (92). However, some birds vaccinated with IT virus vaccine developed a post-vaccination paralytic reaction causing losses of up to 10% in some flocks.

A DNA vaccine based on a recombinant plasmid that expresses the preM and E proteins has recently been developed (26). In initial experiments mice and horses were protected against infection and lethal challenge.

Turkey Viral Hepatitis

James S. Guy

Introduction

Turkey viral hepatitis (TVH) is a highly contagious, generally subclinical disease of turkeys. It is characterized by multifocal hepatic necrosis with or without accompanying pancreatic necrosis.

The economic significance of TVH is not known. There is no evidence to suggest that TVH virus is transmissible to human beings or other mammalian species.

History

Turkey viral hepatitis initially was described in 1959. It was described simultaneously by Mongeau *et al.* (6) in Canada, and Snoeyenbos *et al.* (9) in the United States.

Etiology

The etiologic agent of TVH has not been characterized. It was suggested in 1959 by both Mongeau *et al.* (6) and Snoeyenbos *et al.* (9) to be a virus based on filtration experiments. The agent was demonstrated by Mongeau *et al.* (6) and by Tzianabos and Snoeyenbos (11) to pass a 100 nm filter.

Based on morphology, site of replication and antigenic analyses, TVH virus likely is a picornavirus (2, 3, 5, 12). In 1982 MacDonald *et al.* (3) identified aggregates of 24 nm, picornavirus-like particles in the cytoplasm of degenerating hepatocytes in livers from turkeys with hepatitis and pancreatitis. In 1991 Klein *et al.* (2) isolated a picornavirus-like virus, 26–28 nm in diameter, with icosahedral morphology from liver and pancreas tissues collected from TVH-affected turkeys. Turkey viral hepatitis was experimentally reproduced by inoculation of young turkeys with this virus. Antigenic analyses based on agar-gel precipitin tests indicated a one-way antigenic relationship between TVH virus and duck hepatitis virus, a picornavirus (12). Antisera produced in rabbits against TVH virus produced confluent precipitin bands with TVH virus and duck hepatitis virus; rabbit antiserum prepared against duck hepatitis virus did not react with TVH virus. While these studies suggest a picornavirus etiology for TVH, additional studies are needed to definitively classify the virus, particularly biochemical and nucleotide sequence analyses of the viral nucleic acid.

Susceptibility to Chemical and Physical Agents

The virus is resistant to ether, chloroform, phenol, and creoline, but not formalin. In yolk it survives 6 hr at 60°C, 14 hr at 56°C, and 4 wk at 37°C. It survived for 1 hr at pH 2 but not at pH 12 (11).

Laboratory Host Systems

Turkey viral hepatitis virus can be propagated and assayed in embryonated chicken eggs, embryonated turkey eggs, and turkey poults. The virus has not been propagated in cell culture (12).

Propagation of the virus may be accomplished by yolk sac inoculation of 5- to 7-day-old embryonated chicken eggs (6, 8, 9). Attempts to propagate TVH virus in embryonated chicken eggs using older embryos or different routes of inoculation generally have been unsuccessful. Virus was demonstrated in inoculated embryonated chicken eggs at 66 hrs postinoculation and peak virus titers of approximately $10^{3.5}$ EID_{50}/ml were detected at 90 hrs postinoculation (10). The virus also may be propagated by yolk sac inoculation of embryonated turkey eggs up to 10 days of incubation; however, embryonated chicken eggs have been shown to be a superior host system, possibly due to the presence of maternal antibody in turkey eggs (4).

Turkey poults are susceptible to infection by intraperitoneal, intravenous and intramuscular routes of exposure. Clinical signs seldom develop in experimentally infected poults, but infection may be demonstrated 5–10 days PI by necropsy and detection of characteristic lesions (7).

Pathobiology and Epidemiology

Incidence and Distribution

Turkey viral hepatitis has been described in Canada, the United States, Italy and Great Britian (3, 4, 6, 9). The disease is believed to be widely distributed in North America, but the true incidence and distribution is not known owing to the frequent subclinical nature of the disease, and the absence of serologic diagnostic tests.

Natural and Experimental Hosts

Turkey viral hepatitis has been recognized only in turkeys. Chickens, pheasants, ducks, quails, mice and rabbits have been shown to be refractory to infection (12).

Transmission, Carriers, Vectors

Transmission of TVH virus occurs readily by both direct and indirect contact. Feces from infected turkeys is believed to be the principal source for virus transmission; the virus could be consistently isolated from liver and feces of experimentally infected birds during the first 28 days PI, and less frequently from bile, blood and kidney during this period. The virus could not be detected in tissues and feces after 28 days PI (10, 12). Vertical transmission via the egg has been suggested by field observations and by the isolation of virus from an ovarian follicle of an experimentally infected hen (8).

Incubation Period

The incubation period in poults, as determined by the appearance of lesions, varied between 2–7 days in both intraperitoneally inoculated and in-contact poults (8, 10).

Clinical Signs

Turkey viral hepatitis is usually a subclinical infection of turkeys (3, 7). It is believed that the disease becomes apparent as a result
14.9.   Multiple, pale tan to gray foci in the liver of a poult with turkey viral hepatitis. Lesions vary from 1 to several mm. They are randomly scattered throughout the liver, and roughly circular, oval, or elliptical. Lesions often have an irregular, "frayed" border, and some have a darker, slightly depressed central area. (Barnes)

14.10.   Poult with turkey viral hepatitis showing prominent pancreatic foci. (Barnes)

of undefined factors such as concurrent infection and/or environmental stresses. Clinical signs in TVH-affected birds are not well defined. Variable degrees of depression may be observed in affected flocks, but more commonly field cases are characterized by sudden death of apparently normal birds. Turkey viral hepatitis virus has been suggested as a cause of decreased egg production, decreased fertility, and decreased hatchability in turkey breeder hen flocks but an etiologic role for TVH virus has not been conclusively determined (7).

Morbidity and Mortality

Morbidity and mortality vary considerably among affected flocks. Usually morbidity and mortality are very low with mortality occurring during a 7- to 10-day period (7). However, morbidity rates of up to 100% have occurred in some flocks, and a 25% mortality was reported in one flock (7). It is believed that severity of morbidity and mortality are influenced by other factors such as concurrent infection. Mortality in turkeys over 6 weeks of age has not been reported.

Pathology

Gross
Gross lesions attributable to TVH have been detected only in the liver and pancreas. Livers generally are enlarged. Hepatic lesions consist of focal, gray, sometimes depressed areas up to several millimeters in diameter (Fig. 14.9). Lesion distribution is variable; birds that die usually exhibit very extensive lesions, which often coalesce and may be partially masked by vascular congestion and focal hemorrhage. Pancreatic lesions are less consistently observed

than hepatic lesions. Lesions in the pancreas generally are roughly circular, gray-pink, and may extend across a lobe (Fig. 14.10).

Microscopic
Vacuolation of hepatocytes occurs early in the course of infection with dense infiltration by mononuclear leukocytes, and proliferation of bile ductules. Lesions progress to overt focal necrosis with pooling of blood around the focus; necrotic cells are scattered among infiltrating lymphocytes (Fig. 14.11). Late in the course of infection lesions are composed of proliferating reticuloendothelial cells which frequently form giant cells (Fig. 14.11).

Pancreatic lesions exhibit the same general histopathologic changes as those observed in livers. Acinar cell degeneration and necrosis are observed with infiltration of macrophages and lymphocytes.

Immunity

Immunologic aspects of TVH have received little attention. Tzianabos and Snoeyenbos were unable to detect neutralizing antibodies in sera from recovered turkeys, or hyperimmunized chickens, turkeys and rabbits (12). However, immunity to rein-
14.11. Microscopic lesions of turkey viral hepatitis. (Barnes). A. Early lesions consist of multiple foci of vacuolar degeneration and coagulative necrosis. Cellular response primarily consists of lymphocytes and macrophages; heterophils are occasionally present but are not numerous. Pancreatic lesions are similar. In the liver, biliary hyperplasia generally is present, but the degree is highly variable among infected turkeys. B. As lesions mature, they advance along sinusoids, often investing islands of liver cells, creating an irregular margin.

fection was observed in previously infected turkeys; reexposure of recovered birds after an interval of 21 days resulted in less frequent and less extensive lesions than in infected controls (9). Recovery from TVH results in resistance to reinfection but the duration of immunity has not been determined.

Diagnosis

Diagnosis of TVH may be based on histopathology or virus isolation; serological procedures currently are not available. Histopathology may be utilized to presumptively diagnose TVH, as the presence of lesions in both the liver and pancreas of turkeys is highly suggestive of the disease. However, similar lesions may be produced in the liver by a variety of bacterial, viral and protozoal agents. These include *Salmonella spp., Pasteurella multocida*, group I and group II avian adenoviruses (1, 14), reovirus (13) and *Histomonas meleagridis* (7, 8).

Isolation and Identification of Causative Agent

Virus isolation may be accomplished using a variety of tissues including liver, pancreas, spleen, kidney or feces, but liver is the preferred sample. Tissues or feces should be homogenized in an appropriate diluent such as minimal essential medium, and clarified by centrifugation; clarified fecal suspensions should be filtered through a 0.45-μm membrane filter. Homogenates of tissue or fecal suspensions are inoculated into 5- to 7-day-old embryonated chicken eggs by the yolk sac route. In TVH-positive cases, embryo mortality generally occurs 4–11 days PI (9). Embryo mortality is delayed if low virus titers are present and in some cases a second passage using yolk harvest may be required. Embryos exhibit cutaneous congestion and edema; dwarfing is observed in those embryos in which mortality is delayed and less cutaneous congestion is observed in these embryos (9). Liver lesions containing necrotic foci are sometimes observed in embryos that survive to 11 days PI. Embryonic fluids do not hemag-
14.11. (continued) C. Frequently, liver cells within or adjacent to lesions fuse together to form syncytial cells. D. Nuclear changes as seen here in hepatocytes adjacent to a lesion develop an appearance suggestive of inclusion bodies. Their nature is currently uncertain, but they are not believed to be of viral origin.

glutinate erythrocytes. Isolates may be further characterized by yolk sac or intraperitoneal inoculation of poults with yolk harvested from infected embryonated eggs; poults are examined for lesions 5–10 days PI.

Intervention Strategies

No specific therapeutic or prophylactic measures are available. Prevention of stress and other infections may be helpful in preventing normally subclinical disease from developing into TVH.

Avian Encephalomyelitis
Bruce W. Calnek

Introduction

Avian encephalomyelitis (AE) is an infectious viral disease affecting young chickens, pheasants, quail, and turkeys. It is characterized by ataxia and rapid tremors, especially of the head and neck; because of the latter, it was often called "epidemic tremor."

No public health significance has been attached to this disease. The disease was of great economic importance to the commercial poultry industries prior to the widespread use of vaccines in the early 1960s.

History

Jones (47, 48) first encountered AE in 1930 in two-week-old commercial Rhode Island red chicks showing tremors. In 1931, two additional outbreaks were observed in one- and four-week-old chicks raised on different farms but originating from the same breeding flock. During the next two years, additional outbreaks were observed in Connecticut, Maine, Massachusetts, and New Hampshire, which led to AE being tagged "New England disease."

In 1934, Jones (48) reproduced the disease in susceptible chicks by intracerebral (IC) inoculation with filtrates of brain material from spontaneous cases. It was not until the mid-1950s, however, that Schaaf reported the first successful control of the disease by immunization (83). The epizootiology of AE was clarified by Calnek et al. in 1960 (21), and the development of an orally administered vaccine (22) soon followed. Historical accounts of the control of AE and other details were provided by Calnek (17), Tannock and Shafren (102), and van der Heide (107).

Etiology

Classification

Avian encephalomyelitis virus (AEV) is a member of the Picornaviridae family (53, 105) based on molecular characterization of the virus genome. Previous studies (13) suggested that AEV belongs to the *Enterovirus* genus, but based on the recent discovery that it has high levels of protein homologies with the hepatitis A virus (66, 105), it has been tentatively placed in the genus *Hepatovirus* (46).

Morphology

Ultrastructure, Size, and Density

In purified preparations of AEV, Gosting et al. (33) observed virions with hexagonal profiles lacking envelopes. The virus was first shown to be filterable by Jones (48). Based on filtration studies, its size was found to range from 20–30 nm, or 16–25 nm, by Olitsky and Bauer (79) and Butterfield et al. (13), respectively. By electron microscopic (EM) examination of purified AEV, Gosting et al. (33) found the virions to be 24–32 nm in diameter; later EM studies by Tannock and Shafren (101) determined the mean diameter to be 26.1 ± 0.4 nm. Intracytoplasmic crystalline arrays observed in Purkinje cells from the brains of infected chickens had particles with diameters estimated to be 22 nm (23) or 25 nm (35).

The virus has a buoyant density of 1.31–1.33 g/mL (13, 33, 101) and a sedimentation coefficient of 148 S (33).

Symmetry

Gosting et al. (33) detected a fivefold symmetry with 32 or 42 capsomeres, in contrast to an earlier report by Krauss and Ueberschaer (55), who proposed an icosahedral symmetry with only 12 capsomeres.

Chemical Composition

Evidence that AEV is an RNA virus came from studies showing that viral replication *in vitro* was unaffected by DNase (8) or by a DNA inhibitor, 5-bromo-2N-deoxyuridine (93). Tannock and Shafren (102) initially detected four virus-specific proteins (VP 1–4) with molecular weights of 43,000, 35,000, 33,000, and 14,000, respectively. They noted in a later report (92), however, that one of the proteins actually was contaminating ovalbumin and that the other three VPs (1–3) were similar in size to those of poliovirus. They also reported that there were no differences between a field isolate and the embryo-adapted Van Roekel (VR) strain of virus when they were compared using a radioimmunoprecipitation assay, in keeping with earlier comparisons of physical, chemical, and serologic properties of the two types of viruses by Butterfield et al. (13).

Todd et al. (105) studied AEV RNA by reverse transcription-polymerase chain reaction and described the AEV genome as polyadenylated, single-stranded RNA, approximately 7.5 kb in size. Further definition of the virus composition came from Marvil et al. (66) who cloned and sequenced the complete RNA genome. They determined that it comprises 7032 nucleotides. Based on the projected product of a 6405-nucleotide open read-

ing frame starting at nucleotide 495, a close relationship (39% overall amino acid identity) with hepatitis A virus was established. One of the nonstructural proteins (2A) associated with AEV was found by Hughes and Stanway (38) to possess conserved motifs shared with two other picornaviruses, human parechoviruses, and Aichi virus. The authors noted that these motifs are characteristic of a family of cellular proteins, two of which are involved in the control of cell growth.

Susceptibility to Chemical and Physical Agents

AEV is resistant to chloroform, acid, trypsin, pepsin, and DNase and is protected against effects of heat by divalent magnesium ions (8, 13). The virus was found susceptible to a single exposure to formaldehyde fumigation (39). Beta-propriolactone inactivates the virus (12, 20).

Strain Classification and Pathogenicity

Although all isolates of AEV are serologically similar, there are two distinct pathotypes of virus. One, represented by natural field strains, is enterotropic. These strains infect chickens readily via the oral route and are shed in the feces. They are relatively nonpathogenic except in susceptible chicks infected by vertical transmission or by early horizontal transmission, in which case they cause neurologic signs. Neurologic disease also occurs following experimental infection by intracerebral inoculation of susceptible chickens.

Embryo-adapted strains constitute the other pathotype. These viruses are highly neurotropic and cause severe neurologic signs following intracerebral inoculation (invariable incidence) or parenteral routes such as intramuscular or subcutaneous inoculation (variable incidence). They do not infect via the oral route except with very high doses, and they do not spread horizontally (19, 44, 45, 70, 92, 113). Adaptation may occur after multiple passages in antibody-free chicken embryos (22, 69, 117), probably the result of selection of laboratory mutants (69). The most commonly used adapted strain is the VR strain, which had been passaged repeatedly by intracerebral inoculation of chickens (108). The VR strain already had the phenotype of adapted strains when first inoculated into embryos after 150 chicken passages (18, 98).

Both pathotypes can replicate in embryos derived from a susceptible flock, but natural strains do not cause obvious signs or gross lesions. However, adapted strains are pathogenic for embryos, causing muscular dystrophy (Fig. 14.12) and immobilization of skeletal muscles (18, 50). The virus was detected in brains of inoculated embryos 3–4 days postinoculation (PI), and peak titers were found 6–9 days PI (10, 18). Histopathologic changes in embryos infected with egg-adapted virus have been described as uniform in character but variable in intensity and location and consisting of encephalomalacia and muscular dystrophy (50). Muscular changes consisted primarily of eosinophilic swelling and necrosis, fragmentation and loss of striations of affected fibers with rare sarcolemmal proliferation and heterophil infiltration. Neural lesions were characterized by severe local edema, gliosis, vascular proliferation, and pyknosis.

14.12.   Chicken embryos on the right were inoculated via the yolk sac with the Van Roekel strain of avian encephalomyelitis virus on the 6th incubation day. Control embryos are on the left. The affected embryos, examined on the 18th incubation day, show extreme muscular dystrophy (most evident in the embryo with the skin removed) and rigidity of the legs.

Laboratory Host Systems

Virus may be propagated in the baby chick, chicken embryos from susceptible flocks, and a variety of cell culture systems. Chicks and embryos must be from a susceptible flock except in the case of intracerebral inoculation of chicks. Several routes of inoculation in embryos have been used (50, 98, 117), but inoculation via the yolk sac at 5–7 days of embryonation generally is considered the method of choice. Gross lesions (see previous section) are observed only with adapted strains. Tannock and Shafren (102) reviewed numerous reports on cell-culture propagation of AEV, beginning with the first successful replication of the VR strain of AEV in chicken embryo brain cultures in 1967 by Mancini and Yates (63). Subsequently, fibroblasts, kidney cells, and neuroglial cells from chicken embryos and pancreatic cells from young chicks were used to cultivate both adapted and field strains of virus (3, 51, 54, 64, 65, 76, 86). Titers, particularly with natural strains, were generally low (rarely exceeding $10^{3.5}$ EID$_{50}$/mL), and cytopathic effects have not been described. Replication in cell cultures is detected by inoculation of embryos (adapted strains only) or by tests for antigen using immunofluorescence or enzyme-linked immunosorbent assays (ELISA). Nicholas *et al.* (75) suggested that chicken embryo neuroglial cells may provide an excellent substrate for production of AEV antigen suitable for serologic tests, such as immunodiffusion and ELISA, and they recommended that cell cultures be adopted as the method of choice for titration of AE vaccine (75). Shafren and Tannock (92) compared the VR strain, a field isolate, and a vaccine strain for the ability to grow in chicken embryo brain cultures; titers with the VR strain, after a 2-day eclipse, were 8–10 times higher than those with the other strains, and virus was largely cell associated. Abe (1) failed to demonstrate replication of AEV in a variety of established mammalian cell lines.

Pathobiology and Epidemiology

Incidence and Distribution

Avian encephalomyelitis occurs virtually worldwide (102, 107). Nearly all chicken flocks eventually become infected with the virus, but the incidence of clinical disease is very low unless a breeder flock is not vaccinated and becomes infected after the commencement of egg production. Turkey flocks apparently also experience high rates of natural infection based on serological surveys (25, 26). The rate of infection in pheasants and quail is not known.

Natural and Experimental Hosts

Avian encephalomyelitis virus has a limited host range. Chickens, pheasants, coturnix quail, pigeons and turkeys have all succumbed to naturally occurring infection (106, also see reviews 11, 107). Experimental infection of young quail chicks (34) caused clinical signs, and the infection spread to breeding quail in the same room. Infection of the adults resulted in reduced egg production and hatchability, and clinical AE developed in chicks hatched from eggs laid during the outbreak. The naturally occurring disease in turkeys is essentially the same as that in chickens (37). Ducklings, poults, young pigeons, and guinea fowl also have been infected experimentally. Mice, guinea pigs, rabbits, and monkeys were refractory to virus introduced intracerebrally (67, 74, 80, 109, 110). Van Steenis (112) found naturally occurring AEV antibodies in serums from partridge, pheasant, and turkeys but not in serums from finches, sparrows, starlings, pigeons, jackdaws, rooks, doves, or ducks. The latter four species also failed to develop antibodies after oral exposure to AEV. AEV antibodies were reported to be present in sera from ostriches (14), waved albatrosses (81) and penguins (52). Bodin et al. (4) compared adult pheasants and red and gray partridges for sensitivity to intramuscular or oral-nasal inoculation with the VR strain of virus. All became infected, but the severity of disease based on signs and lesions was greatest in gray partridges and least in pheasants. Embryonated eggs from the three species were also susceptible to infection.

Transmission

The IC route of inoculation has given the most consistent results in reproducing AE in chickens. Other routes by which infection has been experimentally established are intraperitoneal, subcutaneous, intradermal, intravenous, intramuscular, intrasciatic, intraconjunctival sac, oral, and intranasal inoculation (13, 21, 27, 49, 78, 89, 109).

Under natural conditions, AE is essentially an enteric infection (21). Ingestion is the usual portal of entry (21, 36); exposure via the respiratory tract may be unimportant other than through the coincident exposure of the alimentary tract (21). Virus is shed in the feces for a period of several days, and because it is quite resistant to environmental conditions, it remains infectious for long periods of time. The period during which virus is excreted in feces is dependent in part on the age of the bird when infected. Very young chicks may excrete virus for more than two weeks, whereas those infected after three weeks of age may shed virus for only about five days (116). Shafren and Tannock (91) found virus in

feces from 4–10 days after exposure to a field strain of AEV. Infected litter is a source of virus easily transmitted horizontally by tracking or fomites. Infection spreads rapidly from bird to bird within a pen or house once introduced and from pen to pen on farms where no special precautions are taken to prevent spread. Birds in isolated flocks of a single age group were found to be less likely to have encountered infection than chickens on farms with multiple-age groups. Virus spread was found to be less rapid among birds in cages than in those on the floor (21, 28, 90).

Vertical transmission is a very important means of virus dissemination, based on both field evidence and experimental results (21, 49, 89, 104, 111). Taylor and Schelling (103) reported that 57% of breeder flocks tested in North America had been exposed to the virus by 5 months of age; however, 96% were serologically positive by 13 months. Although the source of infection for susceptible flocks is unknown, it is likely that it is carried from infected farms by people or fomites. When susceptible flocks are exposed after sexual maturity, the hens infect a variable proportion of their eggs. Calnek et al. (21) showed that infected embryos and chicks came from eggs laid during the period 5–13 days after experimental infection of susceptible breeders. Jungherr and Minard (49) reported that hatchability of eggs from an infected flock was not affected. Conversely, Taylor et al. (104) observed a high embryo death pattern during the last three days of incubation. The percentage of embryos that hatched declined from a 78.6% preinfection level to 59.6% during the clinical stage and increased to 75.4% postinfection. Eggs produced just prior to and during the period of depressed egg production showed decreased hatchability and increased embryo mortality during the last three days of incubation. Furthermore, only chicks from the group with depressed hatchability showed signs of AE; chicks hatched prior to and after the affected hatch appeared normal. Similar observations have been reported by other workers (21, 84).

Calnek et al. (21) demonstrated that virus transmission can occur in the incubator. Chicks hatched from eggs inoculated at six days' incubation manifested signs on the first day of age; by the sixth day, 49 of 52 showed clinical evidence of AE. Chicks from uninoculated eggs hatched with the infected birds first manifested signs on the tenth day, and 15 of 18 chicks developed clinical signs. An isolated control group of 19 chicks remained negative.

The possibility of a carrier status is unknown. Richey (84) incriminated a ready-to-lay pullet flock housed in the same building, but in a separate pen, as the source of infection for outbreaks that occurred in several susceptible breeding flocks at 45 weeks of age. The pullet flock had experienced an acute outbreak of AE at 3 weeks of age; it was suggested that a carrier existed in the flock. Although certain aspects of transmission have been well established, other phases remain unknown.

Incubation Period

Studies conducted by Calnek et al. (21) demonstrated that the incubation period in chicks infected by embryo transmission was 1–7 days, whereas chicks infected by contact transmission or oral administration had a minimum incubation period of 11 days.

Clinical Signs

Avian encephalomyelitis presents an interesting syndrome. In naturally occurring outbreaks, it usually makes its appearance when chicks are 1–2 weeks of age, although affected chicks have been observed at the time of hatching. Affected chicks first show a slightly dull expression of the eyes, followed by a progressive ataxia from incoordination of the muscles, which may be detected readily by exercising the chicks. As the ataxia grows more pronounced, chicks show an inclination to sit on their hocks. When disturbed, they may move about, exhibiting little control over speed and gait; finally, they come to rest or fall on their sides. Some may refuse to move or may walk on their hocks and shanks. The dull expression becomes more pronounced and is accompanied by a weakened cry. Fine tremors of the head and neck may become evident, the frequency and magnitude of which may vary. Exciting or disturbing the chicks may bring on the tremor, which may continue for variable periods and recur at irregular intervals. Ataxic signs usually, but not always, appear before the tremor. In some cases, only tremor has been observed. Ataxia usually progresses until the chick is incapable of moving about, and this stage is followed by inanition, prostration, and finally death. Chicks with marked ataxia and prostration are frequently trampled by their penmates. Some chicks with definite signs of AE may survive and grow to maturity, and in some instances signs may disappear completely. Survivors may later develop blindness from an opacity giving a bluish discoloration to the lens (7, 82).

There is a marked age resistance to clinical signs in birds exposed after they are 2–3 weeks of age (see "Pathogenesis of the Infectious Process"). Mature birds may experience a temporary drop in egg production (5–10%) but do not develop neurologic signs.

Morbidity and Mortality

Morbidity from the naturally occurring disease has been observed only in young stock. The usual morbidity rate is 40–60% if all the chicks come from the infected flock. Mortality averages 25% and may exceed 50%. These rates are considerably lower if many of the chicks comprising the flock originate from breeder flocks of immune birds.

Pathology

Gross

The only gross lesions associated with AE in chicks are whitish areas (due to masses of infiltrating lymphocytes) in the muscularis of the ventriculus. These are subtle changes and require favorable conditions to be discerned. No changes have been described for infected adult birds, other than the lens opacities described in "Signs."

Microscopic

The principal changes are in the CNS and some viscera. The peripheral nervous system is not involved—a point of importance in differential diagnosis.

In the CNS, the lesions are those of a disseminated, nonpurulent encephalomyelitis and a ganglionitis of the dorsal root ganglia. The most frequently encountered addition is a striking
14.13.   Spinal cord at lumbar level of chick. Large glial nodule and several perivascular infiltrates of lymphocytes are in gray matter. Central canal is at top. H & E, ×75.

perivascular infiltrate seeming to occur in all portions of the brain and spinal cord (Figs. 14.13 and 14.14), except the cerebellum, where it is confined to the nucleus (n.) cerebellaris. Infiltrating small lymphocytes may pile up several layers to form an impressive perivascular cuff.

Microgliosis occurs as diffuse and nodular aggregates. The glial lesion is seen chiefly in the cerebellar molecular layer, where it tends to be compact (Fig. 14.15). A loose gliosis usually is found in the n. cerebellaris, brain stem, midbrain, and optic lobes and less often in the corpus straita. In the midbrain, two nuclei, Cn. rotundus and n. ovoidalis, are invariably affected with a loose microgliosis that can be considered pathognomonic. Another lesion of pathognomonic significance is central chromatolysis (axonal reaction) of the neurons in the nuclei of the brain stem, particularly those of the medulla oblongata (Fig. 14.16). If several sagittal sections are made, one can almost always find this alteration. The dying neuron is surrounded by satellite oligodendroglia, and, later, microglia phagocytize the remains; the central chromatolysis is never seen without an attending cellular reaction.

Hishida *et al.* (35) examined brain and spinal cord lesions from experimentally infected chicks on a sequential basis using light- and electron-microscopy and immunofluorescence techniques. They considered the most characteristic changes to be degeneration of Purkinje neurons in the cerebellum and motor neurons in the medulla oblongata and spinal cord. The central chromatolysis

observed in the motor neurons was thought to be reversible, whereas affected Purkinje neurons always became necrotic. Purkinje neurons contained abundant viral antigen and cystalline arrays of virus particles in the cytoplasm, confirming the observations of Cheville (23). Degenerated neuronal cells showed dilatation of rough-surfaced endoplasmic reticulum, a reduction in ribosomes, and mitochondrial degeneration (23, 35, 119). Liu *et al.* (56, 57, 58), in a series of studies on the nonstructural virus protein 3A, have shed some light on the subject of cell death due to AEV infection. They showed that this membrane-interacting protein can result in membrane permeability and is capable of inducing apoptosis by activating the cytochrome c/capase-9 pathway.

The dorsal root ganglia often contain rather tight aggregates of small lymphocytes amid the neurons. The lesion is always confined to the ganglion and never enters the nerves (Fig. 14.17).

In general, signs cannot be correlated with severity of lesions or distribution in the CNS.

Visceral lesions appear to be hyperplasia of the lymphocytic aggregates scattered in a random fashion throughout the bird. In the proventriculus, aggregates of a few small lymphocytes normally are within the muscular wall; in AE, these are obvious dense nodules that are certainly pathognomonic (Fig. 14.18). Similar lesions occur in the ventriculus muscle, but unfortunately, they also occur in Marek's disease. In the pancreas, circumscribed lymphocytic follicles are normal (59), but in AE the number increases several times (Fig. 14.19). In the myocardium and particularly the atrium, aggregates of lymphocytes are con-

sidered to be the result of AE (97). Lymphocytes in the myocardium of young chicks are not unusual; however, one may consider them a lesion only if they are widespread and accompanied by previously noted alterations.

There appears to be an excellent correlation between clinical signs and histologic lesions in the nervous system. In one study, 11% had signs but no lesions, and 8% had lesions but no signs (49). Later, Jungherr believed that all birds with clinical signs had histologic lesions. This was based on more intensive research that, in turn, was based on multiple sections of brain and viscera. Experimentally inoculated chicks killed in sequential fashion invariably yield lesions 1–2 days before clinical signs. Recovered birds free from signs have CNS lesions for at least one week and probably much longer.

Pathogenesis of the Infectious Process
Significant differences exist between embryo-adapted AEV and field strains of the virus in terms of pathogenesis. This is largely because the adapted strains generally lose the enterotropic properties that characterize the natural strains. Consequently, adapted strains are relatively noninfectious by the oral route of exposure, do not replicate in the intestine, and are not excreted in the feces following infection by parenteral inoculation (19, 21; *see also* 102).

Localization of viral antigen using virus isolation, immunodiffusion, immunofluorescence, and ELISA techniques has been reported by van der Heide (107), Braune and Gentry (6), Ikeda and coworkers (40, 42, 45), Miyamae and coworkers (68, 70, 71, 72, 73), and Shafren and Tannock (91, 92). In young chicks exposed

orally to field strains of AEV, primary infection of the alimentary tract, especially in the duodenum, is rapidly followed by a viremia and subsequent infection of the pancreas and other visceral organs (liver, heart, kidney, spleen) and skeletal muscle, and finally the central nervous system (CNS). Alimentary tract infections involve muscular layers, and pancreatic infections are found in both the acinar and islet cells, persisting more in the latter. Viral antigen is relatively abundant in the CNS where Purkinje neurons and the molecular layer of the cerebellum are apparently favored sites of virus replication. Neuroglial cells are probably also infected given the report of their susceptibility to AEV *in vitro* (75). Chicks with clinical signs at 10–30 days of age tend to have viral antigen mostly in the CNS and pancreas; lesser amounts of antigen have been seen in heart and kidney; and only very small amounts have been seen in liver and spleen. Persistence of the virus infection is common in the CNS, alimentary tract, and pancreas. Interestingly, the CNS and the pancreas are the only sites uniformly infected by embryo-adapted strains of AEV, although small amounts of virus may be found transiently in other tissues including the liver, heart, and spleen.

Van der Heide (107) was unable to find viral antigen when tissues from experimentally infected mature birds were examined. However, Miyamae (71) did detect viral antigen in viscera and intestinal tract of two-year-old hens infected orally with field strains of AEV. In the intestinal tract, viral antigen was found in the epithelial tunica mucosa, circular muscle layer, and/or muscularis mucosa and in the tunica propria mucosa, but the detection rate was lower than has been reported for young chicks. No viral antigen was found in the CNS; presumably this lack of infection correlates with the absence of clinical disease in infected adults. As in young chicks, infection of older birds with embryo-adapted AEV has a more limited tissue distribution and/or lower titers of AEV in tissues other than those of the CNS, when compared with infection with field strains (42, 43).

Cheville (23) and Westbury and Sinkovic (113, 114, 115, 116) did much to clarify certain aspects of the pathogenesis of the naturally occurring or experimental disease. Age at exposure was especially important; Cheville noted that birds infected at 1 day of age generally died, whereas those infected at 8 days developed paresis but usually recovered, and infection at 28 days caused no clinical signs. Bursectomy but not thymectomy abrogated the age resistance. Westbury and Sinkovic (113) also noted disease when infection was initiated at 14 or fewer days of age, but not when it occurred at 20 or more days. They confirmed Cheville's (23) conclusion that humoral immunity was the basis of age resistance. In their studies, they correlated young age (thus, immunologic incompetence) with extended viremia, persistence of virus in the brain, and development of clinical disease. Presumably, the immune response of an immunologically competent bird would stop the spread of infection before it reached the CNS. Age resistance was not expressed when experimental infection was induced by IC inoculation of virus. Interestingly, Calnek *et al.* (21) found clinical signs in contact-exposed young chicks to have a minimum incubation period of 10–11 days, the same time that virus-neutralizing (VN) antibodies can be detected in adult birds.

Immunity

Birds recovered from naturally occurring and experimental infection develop circulating antibodies capable of neutralizing the virus (see reviews 11, 16, 15, 102).

Cheville (23), and later Westbury and Sinkovic (114), clearly showed that humoral, but not cellular, immunity was important in curtailing infection. If the response is rapid, as is usual in birds greater than 21 days of age, the CNS infection apparently does not progress to the point where clinical signs may develop.

Active

When chickens are immunologically competent, the serologic response can be relatively rapid. Data from Calnek *et al.* (21) suggested that chicks from eggs laid as early as 11 days after exposure already carried passively acquired antibodies, because they were resistant to contact exposure after hatching. Also, positive VN tests (i.e., those with a neutralization index (NI) of 1.1 or greater) (18), can be found after 11–14 days PI (22, 115), and positive immunodiffusion (ID) tests as early as 4–10 days PI (41).

Flocks of chickens with positive serology rarely if ever have recurrent outbreaks of AE.

Passive

Antibodies are transferred to progeny from the dam via the embryo and can be demonstrated in egg yolk (99). Birds from immune dams were not fully susceptible to oral inoculation until 8–10 weeks of age, and antibodies were demonstrated in the serum until 4–6 weeks of age (22). Passively acquired antibodies can prevent development of disease (116) and prevent or reduce the period of virus excretion in feces (21, 116). They also render embryonating eggs resistant to virus inoculated via the yolk sac, forming the basis for the embryo-susceptibility test (see "Diagnosis").

Diagnosis

Isolation and Identification of Causative Agents

The brain is an excellent source of virus for isolation, although other tissues and organs induce the disease when injected into chicks (48, 108). Miyamae (72) found that in addition to the brain, the pancreas and duodenum were especially reliable sources of virus.

The need to titrate vaccine virus makes a sensitive method for virus detection very important. One system for assay of virus is to inoculate embryos (obtained from a susceptible flock) via the yolk sac when 5–7 days of age, allow these to hatch, and observe chicks for signs of disease during the first 10 days (9, 36). When clinical signs appear, brain, proventriculus, and pancreas should be examined for lesions as described in "Pathology." Additionally or alternatively, brain, pancreas, and duodenum from affected chicks can be examined for specific viral antigen by immunofluorescence (5, 6, 68, 70, 107) or ID (40) tests. A newly described monoclonal antibody (74), which recognizes a common epitope among AEV strains, may be a useful addition to the reagents available for virus detection in vaccine titrations or for other assays.

Berger (3) infected chicken embryo brain cell cultures and then used an indirect fluorescent antibody (FA) test to detect viral antigen. He found it to be more sensitive than the embryo inoculation method. Nicholas *et al.* (76) compared several methods for detection of AEV. Inoculation of brain cell cultures followed by indirect FA test was found to be convenient, but inoculation of two-week-old susceptible chicks followed by serologic tests such as ELISA or ID was slightly more sensitive. Xie *et al.* (118) developed a reverse transcriptase-polymerase chain reaction to detect AEV and found it to be both specific and sensitive to as little as 10 picograms of AEV RNA.

Serology

Chickens exposed to AEV develop antibodies that can be measured with the standard VN test (18, 99), indirect FA test (24), the ID test (31, 41, 60), ELISA (29, 95, 120 *see also* 96), and passive hemagglutination test (2).

The VR embryo-adapted strain is recommended to determine the neutralizing capacity of the serum or plasma. Six-day-old embryos inoculated via the yolk sac with virus dilutions mixed with serum are examined for characteristic lesions 10–12 days PI. An NI of 1.1 or greater is considered as positive evidence of previous exposure to AEV. Among samples from a recently exposed flock, the NI may vary from 1.5 to 3.0. Antibodies may be detected as early as the second week after exposure and remain at significant levels for at least several months. Calnek and Jehnich (18) reported that in many instances birds having no detectable VN antibodies (NI less than 1.1) would resist IC challenge with as many as 10,000 EID_{50} of virus.

Another method to determine immunity of a flock is the embryo susceptibility (ES) test (99). Fertile eggs from the flock to be tested are incubated, along with control eggs from a known susceptible flock. After six days, each embryo is inoculated via the yolk sac with 100 EID_{50} of egg-adapted virus. Embryos are examined 10–12 days PI for characteristic lesions. If 100% of embryos are affected, the flock is considered susceptible; less than 50% affected indicates immunity. Intermediate figures should be considered nondefinitive and may indicate recent exposure.

Titers in the indirect FA test appear to parallel those of the VN test. Choi and Miura (24) and Dovadola *et al.* (26) found the indirect FA test to be as useful as the ES test for assessing immunity in turkey breeder flocks.

Standard procedures for ID tests were first reported by Ikeda (40, 41), who used concentrated tissue extracts from infected embryos as the antigen. Antibodies could be found as early as 4–10 days post-exposure, and these persisted for at least 28 months. Rare false-positives and false-negatives were reported when the ID test was compared with the VN test. Girshick and Crary (31), who used a similar antigen, confirmed Ikeda's general results but did not find discrepancies between the ID and VN tests.

Ahmed *et al.* (2) described a passive hemagglutination test, which they found to be more sensitive than the ID test and equal to the ES test in sensitivity.

An ELISA test using purified viral antigen compared well with the VN test and was found more suitable than the ID test for evaluation of immunity (29, 62, 85, 100). The use of a negative-antigen-subtraction step may enhance the ability to discriminate between positive and negative sera (91). Smart *et al.* (96) determined ELISA to correlate well with the ES test. They used ELISA to diagnose active infections with AEV by an increase in titer with sequential serum samples. Garrett *et al.* (30) were able to correlate ELISA titers in hens with the resistance of progeny embryos to challenge with AEV.

Differential Diagnosis

In spontaneous cases, a tentative and frequently definite diagnosis of disease can be made when a complete history of the flock and typical specimens are provided for histopathology.

Histopathologic evidence of gliosis, lymphocytic perivascular infiltration, axonal type of neuronal degeneration in the CNS, and hyperplasia of the lymphoid follicles in certain visceral tissues usually can be considered as a basis for a positive diagnosis. Virus isolation or a rise in titer with serologic tests gives a more specific diagnosis.

Avian encephalomyelitis should not be confused with other avian diseases manifesting similar clinical signs, such as Newcastle disease, equine encephalomyelitis infection, nutritional disturbances (rickets, encephalomalacia, riboflavin deficiency), and Marek's disease.

Avian encephalomyelitis is predominantly a disease of one- to three-week-old chicks. Because Newcastle disease may strike at this time, a problem of differential diagnosis can arise. Certain histological lesions are peculiar to AE: central chromatolysis as opposed to peripheral chromatolysis of Newcastle disease, gliosis in the n. rotundus and n. ovoidalis that is not observed in Newcastle disease, lymphocytic foci in the muscular wall of the proventriculus, and circumscribed lymphocytic follicles in the pancreas. Newcastle disease rarely causes an interstitial pancreatitis.

Encephalomalacia generally appears 2–3 weeks later than AE, and from the standpoint of clinical history, the signs should be no problem. Histologically, it causes severe degenerative lesions in no way similar to AE.

Marek's disease, which occurs still later, presents little difficulty. The peripheral nerve involvement and state of lymphomatosis of the viscera are two criteria not seen in AE.

Intervention Strategies

No satisfactory treatment is known for acute outbreaks in young chicks. Removal and segregation of affected chicks may be indicated under certain conditions, but they generally will not develop into profitable stock. After a flock has experienced an outbreak of AE, no further evidence of it is likely to be observed (89).

Vaccination

Control of AE is achieved by vaccination of breeder flocks during the growing period to ensure that they do not become infected after maturity, thereby preventing dissemination of the virus by the egg-borne route. Also, maternal antibodies protect progeny against contact to AEV during the critical first 2–3 weeks. Vaccination may also be used with commercial egg-

laying flocks to prevent a temporary drop in egg production associated with AE. Vaccines used to control AE in chickens have been shown to be efficacious in turkeys as well (25).

The development of AE vaccination strategies has been detailed by Calnek (17). Inactivated vaccines have been developed (12, 20, 61, 88) and may be useful in flocks already in production or where the use of a live virus is contraindicated. Most flocks, however, are vaccinated with a live, embryo-propagated virus, such as strain 1143 (22), which can be administered by naturally occurring routes such as via drinking water or by spraying (9, 22, 28). Live virus vaccines, which can be stored frozen or after lyophilization (8, 83), are similar to field virus in that they spread readily within a flock. This allows for administration per os to a small percentage of the birds in a flock, which then spread infection to others, although this method is generally unsatisfactory for birds in wire cages (28, 90). Shafren *et al.* (94) found that serologic responses to vaccine administered conjunctivally to 10% (but not 5%) of a flock were as good as those following drinking-water administration of virus to the entire flock. Vaccination by wing-web inoculation of AEV is also practiced in many flocks, but this method may carry some risk of clinical signs (32). Generally, vaccination is done after 8 weeks of age and at least 4 weeks before egg production.

It is very important that embryo adaptation of strains used for live virus vaccines does not occur because 1) adapted virus loses its ability to infect via the intestinal tract and is, therefore, no longer efficacious when administered by naturally occurring routes (22); and 2) adapted virus, like field strains, can cause clinical disease when administered by the wing-web route (19). Glisson and Fletcher (32) observed clinical encephalitis in broiler-breeder pullets given embryo-propagated AEV vaccine by the wing-web route and concluded that the most probable explanation was that the vaccine virus was inadvertently adapted during manufacture. Adaptation is detected by careful monitoring of inoculated embryos used in the production of vaccine for characteristic signs (see "Etiology"), and any adapted virus can be eliminated from vaccine seed virus stocks by passage in susceptible chicks inoculated orally.

Avian Hepatitis E Virus Infections
X. J. Meng, H. L. Shivaprasad, and C. Payne

Introduction

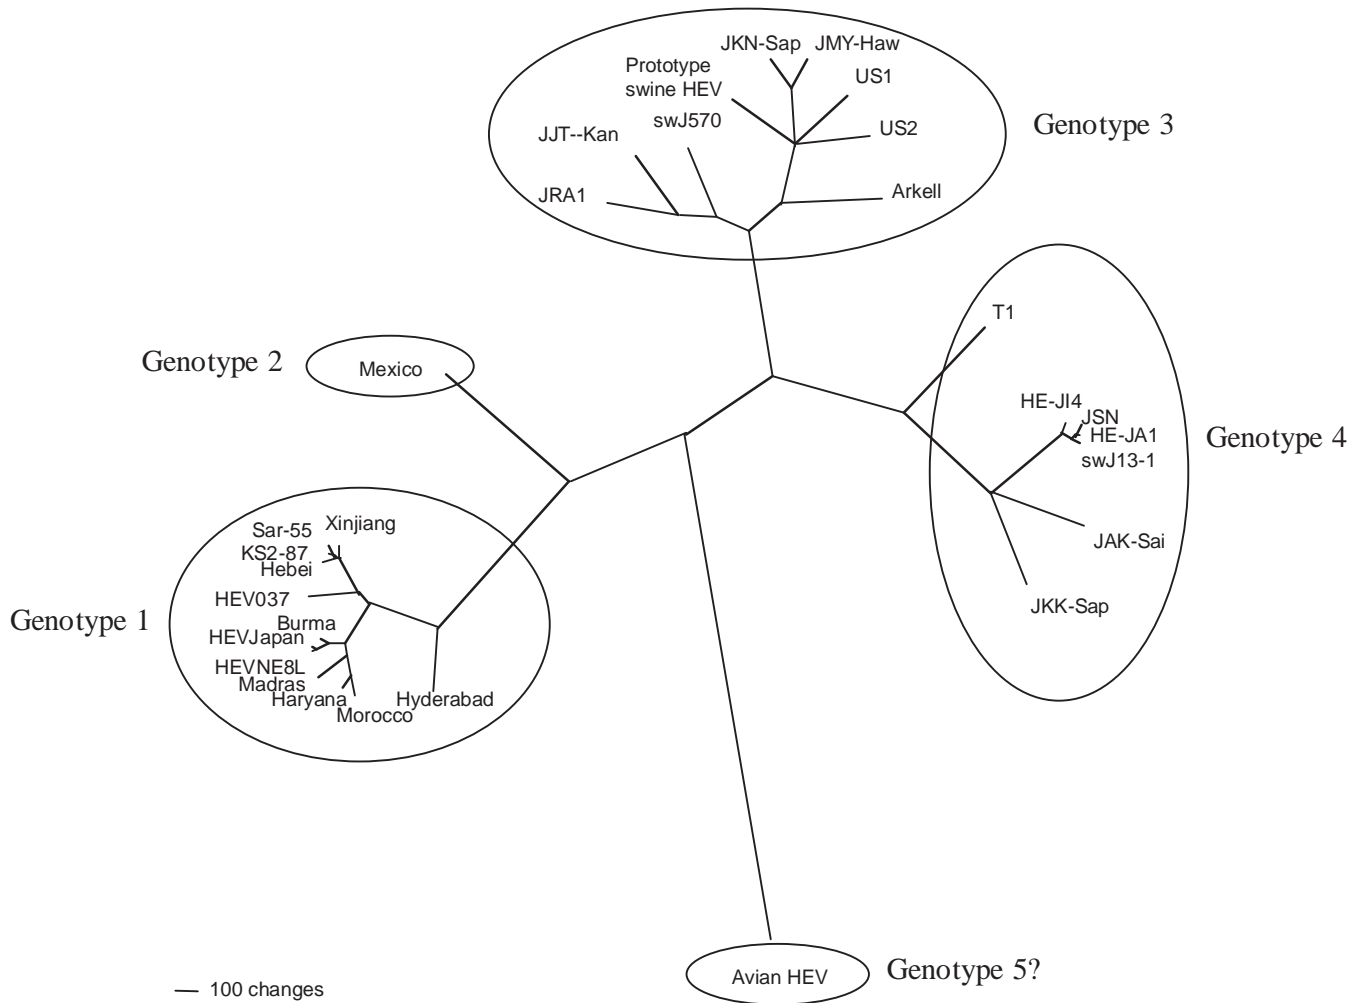
Hepatitis-splenomegaly (HS) syndrome is a disease of layer and broiler breeder chickens characterized by increased mortality and decreased egg production and is primarily caused by avian hepatitis E virus (avian HEV)(19, 40, 42, 51). Dead birds have red fluid or clotted blood in their abdomens, and enlarged livers and spleens. Field veterinarians have recognized this disease since the mid 1980's in some parts of the United States. Although first described as HS syndrome, the disease is also referred to as big-liver-and-spleen (BLS) disease (30, 38–39, 58), necrotic hemorrhage hepatitis-splenomegaly syndrome (45), necrotic hemorrhagic hepatomegalic hepatitis (55), hepatitis-liver hemorrhage syndrome (25), and chronic fulminating cholangiohepatitis (26). Since there are only a few reports of HS syndrome outbreaks in Canada and the United States, the economic impact of this disease is not known. However, in Australia the disease was considered the most economically significant disease of broiler breeders with estimated annual loss at 8 eggs per hen in 50% of broiler breeder flocks for approximately 2.8 million Australian dollars (39–41).

Hepatitis diseases caused by related hepatitis E viruses (HEV) (See Classification below) have been reported in humans (human HEV) and swine (swine HEV) (31, 32, 35, 37, 43). In addition, antibodies to HEV have been detected in numerous animal species including rodents, dogs, cats, sheep, goats, cattle and nonhuman primates, suggesting that these animal species have been infected by HEV of unknown classification (1, 33–36, 43). Unfortunately, the genotype of these infecting HEV and resulting seropositivity in many of these animal species, with the exception of pigs and chickens, could not be identified. Swine HEV from pigs can infect humans (33–37). However, human infections by avian HEV have not been reported.

Etiology

Bacteria could not be routinely isolated from affected livers (24, 45, 47, 49, 51, 55), except in one outbreak in which *Campylobacter spp.* were isolated (26). Attempts to link the cause of HS syndrome to toxins or bacterins were unsuccessful (44, 45, 55). It is now known that the primary causative agent of HS syndrome or BLS is a strain of hepatitis E virus (19, 40).

Classification

On the basis of its superficial similar genomic organization to caliciviruses, HEV was originally classified in the family Caliciviridae (43). However, as additional HEV sequences become available, it is clear that the genomic organization of HEV is quite different from that of the caliciviruses: the 5′ end of the HEV genome contains a cap structure that is absent in calicivirus, and HEV does not share significant sequence homology with caliciviruses (12, 28). Therefore, recently the International Committee on Taxonomy of Viruses officially declassified HEV from the Caliciviridae family and placed it in a new family Hepeviridae (13). All strains of HEV identified thus far, including avian HEV from chickens, belong to a single genus *Hepevirus*. At least 5 genotypes of HEV have been identified worldwide from humans and other animal species (22, 23): genotype 1 (Burmese-like Asian strains of human HEV), genotype 2 (a single Mexican strain of human HEV), genotype 3 (human HEV strains from sporadic cases in industrialized countries and swine HEV from pigs), genotype 4 (variant strains of human HEV from sporadic cases in Asia and swine HEV from pigs), and putative genotype 5 (avian HEV strains from the United States, Canada and Australia) (Figure 14.20).


14.20. A phylogenetic tree based on the complete genomic sequences of avian HEV (genotype 5) and 29 human and swine HEV strains (genotypes 1–4). The tree was constructed with the aid of the PAUP program by using heuristic search with 1,000 replicates. The scale bar, indicating the number of character state changes, is proportional to the genetic distance. Reproduced with permission from The Society for General Microbiology (22).

Morphology

Human HEV is a spherical, non-enveloped, symmetrical virus particle of approximately 32–34 nm in diameter with cup-shaped depressions on the surface, similar to caliciviruses (43). The avian HEV particles revealed by negative staining EM of bile samples from chickens with HS syndrome are similar in size and morphology to human HEV (Fig. 14.21).

Chemical Composition

The complete genome of avian HEV has been sequenced, and shown to be a polyadenylated, single-stranded positive sense RNA molecule of 6,654 bp in length excluding the poly (A) tail, which is approximately 600 bp shorter than that of human and swine HEVs. Similar to mammalian HEV genomes, the avian HEV genome consists of a short 5′ non-coding region (NCR) followed by three partially overlapping open reading frames (ORFs), and a 3′ NCR (Fig. 14.22). ORF1, located at the 5′ end of the genome, is believed to encode the nonstructural proteins.

The predicted polyprotein encoded by ORF1 of avian HEV contained several putative functional domains including methyltransferase, papain-like cysteine protease, helicase, and RNA-dependent RNA polymerase (RdRp) that are also present in mammalian HEVs (Fig. 14.22), thus further supporting the conclusion that avian HEV is a member of the genus *Hepevirus*.

It has been shown that functional motifs typical of the helicase superfamily I and of the putative viral methyltransferase found throughout the alpha-like virus supergroup were conserved between avian HEV and mammalian HEVs (22, 28). ORF2 encodes the immunogenic capsid protein, and a truncated version of the avian HEV capsid protein has been expressed in bacteria and used for serological diagnosis of avian HEV infection (20, 21). ORF3 encodes a small protein with unknown function, although the ORF3 protein of human HEV has been shown to be a cytoskeleton-associated phosphoprotein that may be involved in virus replication (60). Complete genomic sequence analyses revealed that avian HEV shares approximately 50% nucleotide se-
14.21.   Electron micrograph of negatively stained 30–35 nm diameter avian hepatitis E virus particles in bile sample from a chicken with hepatitis-splenomegaly syndrome. Bar = 100 nm. Reproduced with permission from The Society for General Microbiology (19).

quence identity in the complete genome with human and swine HEV strains (22). Phylogenetic analyses revealed that avian HEV represents a putative genotype 5 branch distinct from human and swine HEVs (22, 54) (Fig. 14.20).

Virus Replication

Due to the lack of a sufficient cell culture system for avian HEV or mammalian HEVs, the virus replication strategy is largely unknown. In specific-pathogen-free (SPF) chickens experimentally infected with avian HEV, replicating viruses were detected in livers as well as in several extrahepatic tissues including colon, cecum, jejunum, ileum, duodenum and cecal tonsils (5), indicating that avian HEV replicates not only in the liver but in the gastrointestinal tissues as well. The initial site of avian HEV replication in chickens is still unknown but it is believed that, prior to reaching its target organ liver, the virus first replicates in the gastrointestinal tract following oral ingestion of the virus (7, 59). Like swine and human HEVs, avian HEV is excreted in large amount in feces (4, 53).

Susceptibility to Chemical and Physical Agents

Little is known regarding avian HEV resistance to inactivation by physical, chemical or environmental forces. Most data known thus far are based on human HEV, but avian HEV and human HEV are likely similar in susceptibility to inactivation. Liver suspensions containing avian HEV remained infectious after treatment with chloroform and ether (11, 42) but lost infectivity after incubating at 56°C for 1 hour or 37°C for 6 hour. Avian HEV infectivity in liver suspensions was reduced 1000-fold after treatment with 0.05% Tween-20, 0.1% NP40, and 0.05% formalin (11, 41). Human HEV is sensitive to CsCl gradient centrifugation and low-temperature storage (6, 43). Iodinated disinfectants and autoclaving destroy the virus (3, 48). Human HEV virions are reportedly stable when exposed to trifluorotrichloroethane (56). Like other non-enveloped small RNA viruses, however, avian HEV can survive harsh environments. The fecal-oral route of transmission indicates that avian HEV is resistant to inactivation by acidic and mild alkaline conditions in the intestinal tract. It has recently been shown that human HEV is more heat labile than is hepatitis A virus (HAV), another enterically transmitted hepatitis virus (14). When fecal suspensions of a HAV or a human HEV strain were diluted in PBS buffer and compared in the same test by heating for one hour at 45, 50, 56, 60, 66, or 70°C, HAV was only 50% inactivated at 60°C but was almost totally inactivated at 66°C. In contrast, human HEV was about 50% inactivated at 56°C and almost totally inactivated (96%) at 60°C (14).

Strain Classification

The virus isolated from Australian chickens with BLS is a genetically variant strain of avian HEV (29–30, 40, 58) with approximately 80% nucleotide sequence identity with the avian HEV strains from the United States and Canada (2, 19–21, 54). Recently Sun et al (54) identified apparently avirulent strains of avian HEV from healthy chickens in normal chicken flocks in Virginia, and preliminary characterizations revealed unique genetic differences between the strains from chickens with HS syndrome and from healthy chickens (Billam and Meng, unpublished data). It remains to be studied whether or not the avian HEV strains recovered from healthy chickens in normal flocks are indeed non-pathogenic.

14.22.   Schematic diagram of the genomic organization of avian HEV, which contains a short 5′ NCR, a 3′ NCR and three partially overlapping open reading frames (ORFs): ORF1 encodes non-structural proteins including putative functional domains of methyltransferase (Methyl), helicase (Heli) and RNA dependent RNA polymerase (RdRp); ORF2 encodes putative capsid protein (CP), and ORF3 encodes a small protein with unknown function. The beginning and ending nucleotide (nt) positions of NCRs and ORFs are indicated in parentheses. Reproduced with permission from The Society for General Microbiology (22).

Avian HEV is not only genetically, but also antigenically, related to swine and human HEVs (15, 16, 19, 20, 22). It has been demonstrated that the avian HEV capsid protein reacted with antisera against a genotype 1 human HEV, and genotype 3 human and swine HEVs. Convalescent sera from chickens experimentally infected with avian HEV also reacted with recombinant capsid proteins of genotype 3 swine HEV and genotype 1 human HEV (20).

Laboratory Host Systems

HEV is notoriously difficult to propagate *in vitro*. Avian HEV can be propagated in chicken embryos only when the virus is inoculated intravenously but not by other conventional inoculation methods (8, 38, Haqshenas and Meng, unpublished data). It has been demonstrated that LMH chicken liver cells (ATCC CRL-2117), when transfected with RNA transcripts from infectious cDNA clones of avian HEV, supported avian HEV replication (23). Viral antigens were detected in transfected LMH cells by immunofluorescence assay with avian HEV antiserum, and the fluorescent signals were mainly in the cytoplasm. Approximately 10–15% of the cells were positive for avian HEV antigens, however the virus does not spread from cell to cell (23).

Pathobiology and Epidemiology

Incidence and Distribution

First reported in western Canada in 1991 (47), HS syndrome has now been recognized in eastern Canada (2, 55), California (45), and the midwestern and eastern United States (26, Shivaprasad, unpublished data). BLS has been reported in Australia (8, 9, 10, 18, 38, 40), and serological evidence of avian HEV infection was also reported in the United Kingdom (57). Leghorn hens in cages are typically affected and HS syndrome frequently reoccurs on some farms (45, 47). The disease has also been recognized in broiler breeder hens (24, 49, 50), and may be associated with sporadic mortality in dual-purpose hens and in small flocks kept on litter (25).

In the United States, avian HEV infection is enzootic in chicken flocks. A recent serological survey for the prevalence of avian HEV antibodies included a total of 1,276 chickens of different ages and breeds from 76 different flocks in five states (CA, CO, CT, VA, and WI) (21). It was found that approximately 71% chicken flocks and 30% chickens in the United States were positive for antibodies to avian HEV (21). Approximately 17% of young chickens (less than 18 weeks of age) and about 36% of adult chickens were positive for avian HEV-specific antibodies.

Natural and Experimental Hosts

Under field conditions, chickens are the only known host for avian HEV infections. Under experimental conditions, chickens of all ages are susceptible to avian HEV infection (4, 5, 23, 38, 53). SPF chickens were experimentally infected with avian HEV via both intravenous and oronasal routes of inoculation (4). Embryonic chicken eggs are also susceptible to infections by avian HEV but only via intravenous route of inoculation (38, Haqshenas and Meng, unpublished data). Under laboratory con-

ditions, eight-week-old turkeys intravenously inoculated with an infectious stock of avian HEV also became infected as evidenced by seroconversion to avian HEV antibodies, viremia, and fecal virus shedding (53). However, attempts to experimentally infect rhesus monkeys (22) and mice (Sun and Meng, unpublished data) with avian HEV were unsuccessful.

Transmission, Carriers, Vectors

Transmission within and between flocks appears to occur readily. In a prospective study of natural avian HEV infection in a chicken flock (54), all 14 chickens monitored in the study were seronegative at 12 weeks of age. The first chicken became seroconverted at 13 weeks of age, and by 21 weeks of age all 14 chickens in the flock had seroconverted (54). Like human and swine HEVs, the transmission route for avian HEV is presumably fecal-oral, and experimental avian HEV infection has been successfully reproduced via oronasal route inoculation of SPF chickens (4). Feces from infected chickens are likely the main source of virus for transmission as large amounts of virus are shed in feces in experimentally infected chickens (4, 53). Other routes of transmission cannot be ruled out at this time. Vertical transmission has been suggested during avian HEV infection of hens (9), and experimental aerosol transmission of avian HEV was unsuccessful (10, 11). It has been demonstrated that uninoculated chickens housed in the same room with avian HEV-inoculated chickens became infected through direct contacts with infected ones (53). There is no known carrier or vector implicated in the transmission of avian HEV, although rodents on the chicken farms might serve as a mechanical carrier (Sun and Meng, unpublished data).

Clinical Signs

The incubation period, from the time of infection to virus shedding in feces, ranged from 1 to 3 weeks in oronasally-infected chickens (4). The disease (HS syndrome or BLS) morbidity and mortality in the field are relatively low, although subclinical avian HEV infections are widespread in chicken flocks in the United States and perhaps in other countries as well (21, 54). No clinical sign has been recognized in birds with HS syndrome prior to death (45, 47, 49, 55). In some outbreaks, there has been a drop in egg production of up to 20% (45, 47), but in other outbreaks egg production has not been affected (55). HS syndrome is characterized by above-normal mortality in broiler breeder hens and laying hens of 30–72 week of age, with the highest incidence occurring between 40–50 weeks of age (46, 49). Weekly mortality increases to approximately 0.3% for several weeks during the middle of the production period and may sometimes exceed 1.0% (45, 47, 49, 55). The clinical signs for BLS in Australia also vary from subclinical infection to egg drops that may reach 20% and accompanied by up to 1% mortality per week over a period of 3–4 weeks (9, 18). Diseased birds may have pale combs and wattles, depression, anorexia, and soiled vent feathers or pasty droppings (9, 10, 18, 41, 46). Small eggs with thin and poorly pigmented shells are produced in affected flocks, however the internal quality, fertility and hatchability of the eggs are unaffected (41, 42). Affected flocks in the United States and Europe

appear to have milder or subclinical infections compared to those in Australia (42, 54).

Pathology

Under field conditions, dead chickens usually have regressive ovaries, red fluid in the abdomen, and enlarged liver and spleen (18,46, 47, 49, 55). Prior to death, affected birds are usually in good condition, with pale combs and wattles (55), but sometimes birds in poor condition are also seen (47). Livers are enlarged with hemorrhage and/or clotted blood can be seen in the abdominal cavity (Fig. 14.23).

Livers can often be friable, mottled and stippled with red, yellow, and/or tan foci, and may have subcapsular hematomas and attached blood clots on the surface (45, 49). Presence of clotted blood in the abdominal cavity and hemorrhages in the liver can be confused with hemorrhagic fatty liver syndrome (HFLS), which is a common condition in laying type chickens, but the livers are not fatty in HS syndrome. Spleens from affected birds are mild to severely enlarged (Fig. 14.24), sometimes with white mottling (24, 45,49, 55). Affected birds generally have regressive ovaries (45, 47), but some also have active ovaries (55).

Microscopically, liver lesions vary from multifocal hemorrhage to extensive areas of necrosis and hemorrhage and infiltration of heterophils and mononuclear inflammatory cells around portal triads. There is often segmental infiltration of lymphocytes and a few plasma cells in and around portal veins. Also, accumulation of homogenous eosinophilic material, amyloid in the interstitium of the liver and separation of hepatocytes are common. In severe cases, discrete granulomas and possible thrombosis of portal veins were recognized. Lesions in spleens consist of lymphoid depletion accompanied by an increase in the cells of the mononuclear phagocyte system in later stages. There is accumulation of homogenous eosinophilic material, amyloid in the walls of small arteries and arterioles and in the interstitium. Eosinophilic material in both livers and spleens was identified as amyloid using Congo red stain (45, 49, 50, 51, 55) (Fig. 14.25).

Under experimental conditions, gross lesions were observed primarily in the liver of SPF chickens experimentally infected with avian HEV (4). Subcapsular hemorrhages, and a slightly enlarged right intermediate lobe of the liver (Fig. 14.26) were observed in approximately one-fourth of the infected chickens (4).

Microscopically, lymphocytic periphlebitis and phlebitis foci were observed in liver sections (Fig. 14.27). The severity of liver lesions peaked at 10 days post-inoculation (DPI) in the intravenously inoculated chickens. Other liver lesions such as foci of hepatocellular necrosis, amyloid in the interstitium, and subcapsular hemorrhages were also observed in some chickens (Fig. 14.27). Microscopic lesions were also observed in spleen (mild lymphoid hyperplasia), thymus (mild cortical hypoplasia), kidney (occasional mild lymphocytic interstitial nephritis), and lung (mild lymphocytic and heterophilic parabronchial and interstitial inflammation) of SPF chickens infected with avian HEV (4). Microscopic lesions were generally absent in the tissues collected from gastroenteric tract. There was no significant elevation of serum levels of liver enzymes AST, albumin/globulin (A/G) ratios or bile acids (4). However, LDH levels behaved differently over time ($P = 0.0851$). In intravenously-inoculated chickens, LDH levels peaked at 1 week post-inoculation (wpi) and then returned to baseline levels. The LDH levels in oronasally-inoculated chickens remained elevated from 1 to 4, and 6 wpi prior to returning to baseline values at 7 wpi. The oronasally-inoculated chickens having higher total proteins than intravenously-inoculated and control group chickens ($P<0.0001$) (4).

Pathogenesis of the Infectious Process

The pathogenesis of avian HEV infection in chickens is largely unknown. It is believed that, like mammalian HEVs (43, 59), avian HEV enters the host through the fecal-oral route. However, the primary site of avian HEV replication in chickens is not yet known. In primates and pigs experimentally infected with human HEV or swine HEV, virus replication in the liver has been demonstrated (17, 32). It is believed that, after replication in the liver, HEV is released to the gallbladder from hepatocytes and then is excreted in feces. Williams et al (59) showed that there exist extrahepatic sites of HEV replication in pigs experimentally infected with swine HEV and human HEV. To identify the extrahepatic sites of avian HEV replication in chickens, Billam *et al.* (5) employed a negative-strand-specific RT-PCR that can detect replicating avian HEV RNA in tissues. It was found that, in addition to the liver, replicating avian HEV was also detected in colon tissues at 5, 16, 20 and 35 dpi, in cecum and jejunum tissues at 20 and 35 dpi, in ileum tissues at 7, 10, 20 and 35 dpi, in duodenum tissues at 20 dpi, and in cecal tonsils at 35 and 56 dpi of experimentally infected chickens (5). Therefore, the gastrointestinal tissues appear to be the first site of avian HEV replication following oral inoculation. However, the clinical and pathological significances of these extrahepatic sites of HEV replication remain unknown.

Immunity

The humoral immune response in chickens infected with avian HEV, characterized by the appearance of IgG antibodies, appears at approximately 1 to 4 weeks post-inoculation (4, 53). The cell-mediated immunity in response to avian HEV infection in chickens is unknown. Like mammalian HEVs, the capsid protein of avian HEV is immunogenic and induces protective immunity against avian HEV infection (16). It has been demonstrated that the avian HEV capsid protein shares common antigenic epitopes and cross-reacts with that of swine and human HEVs (15, 16, 20). Avian HEV capsid protein reacted with antisera against human HEV (Sar-55 strain) and with convalescent antisera against swine HEV and the US2 strain of human HEV. Conversely, convalescent sera from chickens experimentally infected with avian HEV also reacted with the recombinant capsid proteins of swine and human HEVs (20). A total of 4 putative antigenic domains (I, II, III, IV) have been identified in the avian HEV capsid protein. Recently Guo *et al.* (15) identified a B-cell epitope at the C-terminus of domain II (possibly between aa 477–492) that is unique for avian HEV, a B-cell epitope in domain I (aa 389–410) that is common to avian, human and swine HEVs, and one or more B-cell epitopes in domain IV (aa

583–600) that are shared between avian and human HEVs. It appears that all HEV strains identified thus far belong to a single serotype.

Diagnosis

A presumptive diagnosis of HS syndrome can be made on the basis of clinical signs and gross and microscopic lesions. However, HS syndrome needs to be differentiated from hemorrhagic fatty liver syndrome (HFLS) due to the presence of clotted blood in the abdominal cavity and hemorrhages in the liver with HS syndrome. The livers in HS syndrome are not fatty as in HFLS. Clotted or unclotted blood in the abdominal cavity or around the liver sometime can also be seen in cases of rodenticide (anticoagulants) toxicities. Trauma to the body or the liver with blood in and around liver in a chicken should also be considered for differential diagnosis. Virus particles of 30–35 nm may be detected in bile of chickens with HS syndrome by negative staining electron microscopy.

Avian HEV does not replicate in cell culture. Although embryonic chicken eggs can be experimentally infected with avian HEV via intravenous inoculation (38, Haqshenas and Meng, unpublished data), virus isolation with chicken embryos is not practical due to the technical difficulty and high mortality associated with the intravenous inoculation procedure. Currently, the diagnosis of avian HEV infection is primarily based on detection of the virus RNA by RT-PCR or detection of antibodies by ELISA (21, 53, 54). However, the sensitivity and specificity of these assays are largely not known. A truncated version of the avian HEV capsid protein has been expressed and used in an ELISA to detect avian HEV antibodies in chickens (4, 20–21, 53–54). An agarose gel immunodiffusion test (AGID) and an ELISA assay using purified antigen extracted from the spleen and liver of affected chickens have been developed to detect avian HEV infection in Australia (11, 40, 57).

Serological assays alone are inadequate in screening for acute avian HEV infection. Viremia and fecal virus shedding occur in infected birds much earlier than the appearance of avian HEV IgG antibodies and thus, seronegative birds could still be infected with avian HEV (4, 53–54). Avian HEV-specific RT-PCR assays have been successfully developed for the detection of avian HEV infections in chickens (4, 21, 27, 53, 54). However, the specificity of the RT-PCR assays in detecting avian HEV strains in chickens from different geographic regions is not known, since avian HEV strains identified from chickens in different geographic regions are genetically heterogenic (21, 54). Therefore, genetic identification and characterization of additional field strains of avian HEV from chickens in different geographic regions will be critical for developing a universal RT-PCR assay that can detect all strains of avian HEV. A heteroduplex mobility assay has recently been developed as a pre-sequencing tool to identify genetically divergent strains of avian HEV (52). The recent identification of antigenic epitopes unique to avian HEV capsid protein (15) will allow future development of differential diagnostic assays to distinguish infections caused by avian HEV, swine HEV or human HEV.

Intervention Strategies

A vaccine against avian HEV or mammalian HEVs is not yet available. Currently there is no treatment for avian HEV infection. Implementation of strict biosecurity in chicken farms may limit the spread of virus.

Chapter 15
Neoplastic Diseases

Introduction
Aly. M. Fadly

Neoplastic diseases of poultry comprise a variety of related and unrelated conditions possessing a single common denominator: neoplastic character. This group of diseases is divided into two main categories, depending on whether the etiologic agent is known. In addition to causing economic loss from tumor mortality as well as poor performance, some of these neoplastic diseases have served as highly suitable models for studying various phenomena of neoplasia. Indeed, medical research has found avian oncology an abundant resource (4). This chapter deals primarily with the three most economically important virus-induced neoplastic diseases of poultry, namely Marek's disease, caused by a herpesvirus, and the avian leukoses and reticuloendotheliosis, caused by retroviruses. Virus-induced tumors are principally of mesodermal origin and are transmissible. These neoplastic diseases or disease complexes are described, each in a separate section because of its etiologic distinctness.

The first section describes Marek's disease (MD), a T-cell lymphoma primarily of chickens caused by a highly cell-associated alphaherpesvirus, although the lymphotropic properties of MD virus are similar to those of gammaherpesviruses. MD lymphoproliferative lesions involve the peripheral nervous system as well as other tissues and visceral organs. MD is and has been controlled since early 1970s by use of conventional vaccines. During the last three decades, research on MD has resulted not only in improved conventional vaccines, but also in improved methods of vaccination, and a better understanding of host genetic resistance to the disease. However, despite widespread use of vaccines and development of new methods of vaccination, economic losses from mortality of layers and breeders and condemnation of broilers continue to occur (12, 18, 23). Further, MD has been diagnosed in commercial turkey flocks in France, Germany, Israel, and Ukraine (6, 7, 15, 16, 23), suggesting that the host range of MDV has apparently expanded to include turkeys. Clearly, in the absence of control measures, MD is capable of causing devastating losses in commercial layer and broiler flocks (24, 25). As a disease occurring worldwide, with reports

of vaccination breaks and probable emergence of more virulent pathotypes, MD poses severe threats to the poultry industry and developing strategies for its control remains one of the great challenges today (18, 23, 24, 25).

A second section describes a group of leukoses, sarcomas, and related neoplasms induced by a number of closely related group of avian retroviruses termed the leukosis/sarcoma (L/S) viruses. The term *leukosis* is used because a leukemic blood picture is not always present during the course of leukemia-like proliferative diseases of the hemopoietic system (11, 18). The various forms of hemopoietic system neoplastic changes induced by the L/S group of avian retroviruses include the lymphopoietic (lymphocytic) system, the erythropoietic (red cell) system, and the myelopoietic (myelocytic) system. Lymphoid leukosis, a lymphoproliferative disease of chickens affecting primarily the bursa of Fabricius and visceral organs, is the most common form of leukosis that arise from infection with a member of the L/S group of viruses known as avian leukosis virus (ALV) (5, 8, 11, 18). Other neoplasms of hematopoietic origin that can also be seen in ALV-infected chickens, albeit infrequently, include erythroblastosis, myeloblastosis, myelocytomatosis, and certain related neoplasms such as nephroblastoma and osteopetrosis. However, with the recognition of subgroup J ALV infection, myelocytomatosis, as a neoplastic condition was frequently diagnosed during the 1990s, particularly in affected breeders of meat-type chickens (17, 18). These conditions, along with sarcomas and other connective tissue tumors, are etiologically related and are discussed as a group.

The third section describes reticuloendotheliosis (RE), a group of disease syndromes caused by an avian retrovirus unrelated to the L/S group of viruses termed RE virus (REV) (20, 21, 26). The most common clinical diseases induced by REV are chronic lymphomas and an immunosuppressive runting disease. Although REV infrequently causes clinical disease, the virus is widespread. REV infects chickens, turkeys, ducks, geese, pheasants, quail, and probably many other avian species. However, the principal economic concerns of REV infection are as contaminants of biologic products produced in chicken embryo cells or tissues or as a barrier to export of breeding stock to certain countries (9, 24, 26).

Table 15.1.   Transmissible neoplasms.

Virus type	Nucleic acid type	Virus classification of etiological agent	Neoplastic diseases
Retrovirus	RNA	Leukosis/sarcoma group	Leukoses 　Lymphoid leukosis Erythroblastosis Myeoloblastosis Sarcomas and other connective tissue tumors 　Fibrosarcoma, fibroma 　Myxosarcoma, myxoma 　Osteogenic sarcoma, osteoma 　Histiocytic sarcoma Related neoplasms 　Hemangioma 　Nephroblastoma 　Hepatocarcinoma 　Osteopetrosis
		Reticuloendotheliosis group	Reticuloendotheliosis Lymphoid leukosis
Herpesvirus	DNA	Marek's disease virus	Marek's disease

The fourth section describes tumors of unknown etiology on the basis of morphologic characteristics. Included are a wide variety of benign and malignant neoplasms derived from muscle, epithelial, and nerve tissues; serous membranes; and pigmented cells.

A neoplastic disease of turkeys known as lymphoproliferative disease (LPD) that had been reported in Europe and Israel is induced by yet another retrovirus distinct from both the L/S and RE viruses (2). The incidence of LPD of turkeys has always been sporadic (10, 24); therefore discussion of this rare neoplastic syndrome of turkeys is not included in this chapter.

Because many of the avian tumor viruses appear to have multipotent characteristics, i.e., they can sometimes induce a variety of neoplasms, classification and nomenclature of these virus-induced neoplasms present a problem. The dilemma is largely due to the fact that certain strains of these viruses induce some pathologic lesions difficult to distinguish from those induced by another unrelated virus. The two prevalent lymphomatotic diseases, namely MD and lymphoid leukosis, are particularly confusing. Although REV-induced lymphoid tumors are observed only infrequently such as in cases of using contaminated vaccines, or only under experimental conditions, they may also add to the confusion. The problem is compounded by the fact that avian tumor viruses are widespread and infection in the absence of tumor formation is common. Recently, Witter *et al.* (27) introduced a practical and useful strategy for the differential diagnosis of viral lymphomas in chickens.

Choice of terminology for this chapter (Table 15.1) is based on that originally adopted by the World Veterinary Poultry Association (3) and includes modifications in current use. The classification system accompanying this nomenclature is especially suited to the mode of presentation that follows, i.e., categorization of diseases or disease complexes by agent type instead of

pathologic manifestation. Subdivision within agent-type diseases by pathologic expression has been employed where it seemed appropriate.

Incidence and importance of neoplasms in poultry can only be generally estimated. Feldman and Olson (13) quoted reports (1915–55) in which the incidence of tumors, except neurolymphomatosis and osteopetrosis, varied from 3 to 19%. More recently, we have had the advantage of data accumulated by the United States Department of Agriculture (USDA) from federally inspected slaughtered poultry. These data showed that incidence of "leukosis" in young chickens (probably nearly all MD) increased dramatically during a 10-yr period beginning in 1961.

There was a gradual rise in leukosis condemnations in young chickens from about 0.1% in 1961 to over 1.5% in 1968–70 (see (19)). After 1970, the trend was reversed and condemnations of young birds returned to 1961 levels, undoubtedly the result of MD vaccination of broilers. During peak years, however, over 40 million young birds (nearly 50% of all condemnations) were condemned for leukosis, and it was conceded that it was one of the most serious problems confronting the poultry industry.

Condemnations due to leukosis in mature birds were fairly consistent and much lower (less than 0.5 million birds, usually less than 10% of all condemnations). Condemnation rates with other tumors, many of which were leiomyomas of the mesosalpinx, were actually much higher (up to five times) than those from leukosis. In some cases, condemnations due to squamous cell carcinoma exceed that of leukosis and can have at least some economic impact (see subchapter on squamous cell carcinoma). Because most losses from leukotic diseases occur during growing and productive periods of layers, presence of gross lesions at slaughter is a poor index of their true incidence and importance.

Annual losses in the United States were placed at more than $150 million in 1967, prior to the introduction of MD vaccines (1). In 1985, Purchase (19) estimated that benefits derived by the poultry industry in the United States as a result of MD vaccine totaled nearly $170 million annually. This included increased egg production and decreased losses from non-MD causes as indirect benefits as well as the direct effect of lowered MD mortality and condemnations. Lymphoid leukosis losses may be significant in some flocks, but mortality probably constitutes only a small portion of the economic loss from that disease. Studies by Gavora *et al.* (14) and Spencer *et al.* (22) have shown that lowered egg production and increased mortality from causes other than lymphoid leukosis are associated with infection by lymphoid leukosis virus, and the total economic impact from these could be extremely significant. However, present and past efforts by the primary breeders to reduce the infection rate or to eradicate infection have markedly lower this impact (24). Generally, the incidence of neoplasms other than lymphoid tumors appears to be low and of questionable economic significance.

Marek's Disease

Karel A. Schat and Venugopal Nair

Introduction

Marek's disease (MD) is a common lymphoproliferative disease of chickens, usually characterized by mononuclear cellular infiltrates in peripheral nerves and various other organs and tissues including iris and skin. The disease is caused by a herpesvirus, is transmissible, and can be distinguished etiologically from other lymphoid neoplasms of birds.

Because the literature on MD has greatly expanded, it is no longer feasible to cite all relevant publications that provide the scientific basis for our current knowledge of the disease. In this chapter, literature is cited selectively, and reviews are often substituted for original papers. Readers are encouraged to look elsewhere for additional details. Useful sources of information on MD are the books *Marek's Disease: Scientific Basis and Methods of Control*, *Marek's Disease*, and *Marek's Disease. An Evolving Problem* edited by respectively, L. N. Payne (481), K. Hirai (263),and F. Davison and V. Nair (183) and the proceedings from 7 international symposia on MD conducted in 1978, 1984, 1988, 1992, 1996, 2000, and 2004.

Definition and Synonyms

The old terminology was confusing because early authors used a variety of names to designate the lymphoproliferative and neurological aspects of the disease. Also, the differentiation between inflammatory and neoplastic aspects originally were confused, probably because the virus strains were less virulent and induced few if any lymphomas. The seminal description by József Marek (408) identified the disease as *polyneuritis*. Other common synonyms included *neuritis*, *neurolymphomatosis gallinarum*, and *range paralysis*. Jungherr and colleagues (323) proposed that the term *lymphomatosis* be subdivided into *visceral*, *neural*, and *ocular* forms. This nomenclature was widely applied for more than 20 years to all lymphoproliferative diseases (also called *leukosis*) of chickens, including MD, but masked the etiological distinctions between MD and lymphoid leukosis (LL). In retrospect, neural and ocular lymphomatosis were probably MD; whereas visceral lymphomatosis included both MD and LL. The term *acute leukosis* or *acute Marek's disease* was used in the 1960s to designate more virulent manifestations of MD characterized by visceral lymphomas. Lymphomatous lesions in the skin, which were common in broilers, were sometimes termed *skin leukosis*. In 1961, Biggs (53, 59) proposed the term *Marek's disease* to distinguish the condition clearly from etiologically different lymphoproliferative diseases. This term is in common use.

MD has also been subdivided into *acute* and *classical* forms, where the latter term designates forms of the disease prevalent prior to the 1950s (54). MD virus can also induce other clinically distinct disease syndromes such as *transient paralysis*, *early mortality syndrome*, *cytolytic infection*, *atherosclerosis*, and *persistent neurological disease*.

Economic Significance

Prior to the use of vaccines, MD constituted a serious economic threat to the poultry industry causing up to 60% mortality in layer flocks and 10% condemnations in broiler flocks. Because vaccines are not 100% effective, sporadic losses still occur, but they are no longer as serious a problem. Purchase (526) estimated that mortality and condemnation losses due to MD totaled about $12 million in the United States in 1984. When combined with economic loss from the costs of vaccine and application and reduced egg production, however, the total was about $169 million in the United States and $943 million worldwide. Morrow and Fehler (432) quoted current worldwide, annual losses in the range of US$ 1 to 2 billion, but they indicated that these figures are impossible to verify. The disease remains a major concern for the poultry industry due to the unpredictability of outbreaks and the possibility that vaccines may ultimately fail as a consequence of the evolution of more virulent strains of MD virus (MDV).

Public Health Significance

Purchase and Witter (530) have reviewed the literature related to MD and human health concerns, particularly human cancer. They cite numerous reports of virologic, pathologic, serologic, and epidemiologic studies that support a conclusion that no etiologic relationship exists between MDV or any of the MD vaccine viruses and human cancer. The public health significance of MD has attracted little attention. A role for MDV in the etiology of multiple sclerosis of humans has been suggested (404, 405, 415) but was later refuted (257). Recently, a similar claim was made for HVT or HVT-like viruses (71) lacking any supportive evidence for this speculation. The presence of DNA sequences of the gD gene of MDV was described in sera from humans with and without exposure to poultry (363, 364), but genes unique to MDV were not analyzed in these studies. However, Hennig *et al.* (256) were unable to detect any MDV sequences in 300 human plasma samples by quantitative real-time PCR. At this time, no compelling evidence suggests that MDV infects humans or adversely affects human health.

Scientific Significance

MD has provided a fertile environment for contributions to veterinary medicine, basic science, and comparative oncology. The disease itself is uncommonly complex, featuring an interplay of neoplasia and inflammation expressed as several distinct clinical syndromes, each modified in important ways by host genetic in-

fluences. MDV, an alphaherpesvirus with lymphotropic properties of gammaherpesviruses, is highly cell-associated but readily transmitted, and its virulence varies and evolves. It has 2 unique sister viruses, both nononcogenic, that naturally infect chickens and turkeys. Infection induces complex immune responses usually resulting in high levels of protection. Vaccination for MD constitutes an outstanding example of successful disease control in veterinary medicine. Moreover, MD vaccines are the first effective vaccines against cancer in any species.

History

The seminal report by József Marek, published in 1907 (408), of paresis in 4 roosters is the first account of the disease that now bears this author's name. Outbreaks were reported as early as 1914 in the United States, and subsequently, the disease was recognized in The Netherlands, Great Britain, and many other countries. The detailed description by Pappenheimer *et al.* (471) clarified the lymphoproliferative nature of the lesions in peripheral nerves and spinal ganglia and established, as part of the syndrome, lymphoid neoplasms in the ovary and other visceral organs.

Many early attempts at transmission were equivocal or unsuccessful due to the lack of susceptible chickens and adequate biocontainment and to the failure to recognize the cell-associated nature of the causative agent. However, experiments initiated by Hutt and Cole in 1935 established the role of genetic resistance in the disease and ultimately provided susceptible chicken lines for transmission studies (282, 283).

The disease gradually increased in severity. Pappenheimer *et al.* (471) reported mortality from fowl paralysis reaching 20% in one pullet flock as early as 1922. A marked increase in mortality in commercial chickens occurred between 1925 and 1937, at least half of which was due to fowl paralysis and other neoplasms (685). Industry concerns prompted the appropriation of federal funds to construct a new laboratory in East Lansing, Michigan, dedicated to this disease. Its initial projects, launched in 1939, were directed toward the genetics and pathology of fowl paralysis in chickens.

An acute form of the disease in broiler chickens, characterized by tumors in multiple viscera, muscle, and skin, was first recognized in the mid-1950s (50). By the early 1960s, it was a major cause of condemnation of broiler carcasses (51). The incidence continued to increase during the 1960s, and by 1970 about 1.5% of all broilers in the United States were discarded at processing with neoplastic lesions. Mortality in pullets and layers reached as high as 30–60%, and the poultry industry was facing an economic crisis. The definitive transmission of MD, established in the early 1960s (64, 593), confirmed the infectious nature of the disease and provided an experimental system for its study. The avid cell association of the agent (65) made identification of the agent elusive. Isolation of a herpesvirus in cell cultures inoculated with cells from diseased chickens was reported in 1967 by 2 independent laboratories (154, 443, 631). This virus was confirmed as the etiological agent through association studies (60, 706) and, ultimately, by transmission with cell-free virus ob-

tained from feather follicles (110). The virus became attenuated upon serial passage in chicken kidney cultures (156), and the attenuated virus, when inoculated into newly hatched chicks, provided protection against subsequent challenge with virulent strains (157). Naturally avirulent, antigenically related strains were found in turkeys (718) and chickens (63, 143) and provided protective immunity. Thus, in the span of a very few highly productive years, the causative agent was identified, and vaccination was established as an effective control strategy.

Meanwhile, Calnek *et al.* (110, 114, 130) found that the virus was shed in a cell-free, fully infectious form from the feather follicle providing an explanation for the highly contagious nature of the disease. The virus was relatively stable in the poultry house environment, and respiratory exposure to dust or dander appeared to be the mechanism of natural transmission (48).

The ensuing years continued the stream of new findings about MD. Important contributions prior to 1985 include the development of lymphoblastoid cell lines from MD tumors (13) characterization of the T-cell nature of the tumor cell (280) identification of cytolytic and immunosuppressive phases of the disease (485), linkage of transient paralysis with MDV infection (343), isolation of the CVI988 (546) and SB-1 (571) strains, which proved to be successful vaccines, and identification of 3 viral serotypes based on antigenic characteristics (370, 676). Genetic resistance was linked to the B-locus or major histocompatibility complex (MHC) (77, 249). The stages of infection from respiratory tract to cytolytic infection of B cells, to activation, latent infection, and ultimately transformation of T cells were elucidated (105, 127, 613). Synergism among vaccine viruses was identified (574, 688) and contributed to the development of bivalent vaccines (123, 722).

These and other important findings that laid the basis for our current understanding of the disease are detailed in several historical reviews (e.g., 58, 59). Advancements of knowledge on MD during the 1960s, leading to effective vaccines, were showcased during the 5th International Symposium on Marek's disease in 1996, and relevant information is available in the proceedings, the videotape "Legacy of the 1960s," and the historical archives of the American Association of Avian Pathologists.

Etiology

Classification

MDV is a cell-associated herpesvirus (citations in 564) with lymphotropic properties similar to those of gammaherpesviruses. However, its molecular structure and genomic organization are similar to alphaherpesviruses (83, 375, 664). McGeoch *et al.* (414) proposed to place all MDV serotypes in a separate subgroup, a3, of the alphaherpesvirinae. As per the recent classsification by the International Committee on Taxonomy of Viruses (ICTV) (http://www.ncbi.nlm.gov/ICTVdb/ICTVdB), all MDV serotypes are grouped together in the genus *Mardivirus* (284) within the subfamily *Alphaherpesvirinae*. Members of the genus *Mardivirus*, described as belonging to the 3 serotypes (see below) are now grouped as the 3 species *viz. Gallid herpesvirus* 2 (serotype 1), *Gallid herpesvirus* 3 (serotype 2) and *Meleagrid*

(441) (Nazerian)
herpesvirus 1 (serotype 3). Serotype 1 MDV is the prototype virus for this group of avian viruses, and except where otherwise indicated, MDV refers to serotype 1 virus. On the basis of their virulence, serotype 1 strains are further divided into pathotypes, which are often referred to as mild (m)MDV, virulent (v)MDV, very virulent (vv)MDV, and very virulent plus (vv+)MDV strains (699, 708).

Two additional groups of nononcogenic herpesviruses isolated from chickens (63, 143) and turkeys (338, 718), respectively, are considered part of the MDV group and are included in this chapter. The serotypic classification for MDV and HVT strains (675, 676), originally based on the recognition of common and distinct antigenic epitopes for each serotype, has recently been justified based on the complete sequence for serotype 2 HPRS-24 and serotype 3 FC126 virus strains (11, 304, 347).

Morphology

The morphology and morphogenesis of MDV have been reviewed by Kato and Hirai (335) and Schat (564). In general, viral particles are typical of those described for other herpesviruses. Scattered virions are commonly seen in the nucleus and more rarely in the cytoplasm or extracellular spaces. Hexagonal nucleocapsids 85–100 nm in diameter and enveloped particles 150–160 nm in diameter may be seen in thin sections of infected cell cultures. Enveloped virus particles appearing as irregular amorphous structures and measuring 273–400 nm can be observed in negatively stained preparations of lysed feather follicle epithelium (FFE) (110). Thin-section preparations of the FFE revealed large numbers of cytoplasmic enveloped herpesvirus particles in keratinizing cells. The morphology of MD virions in cell cultures and FFE is shown in Fig. 15.1A.

The morphology of serotype 2 and 3 strains resembles that of MDV serotype 1. In thin sections, however, nucleocapsids of HVT commonly show a unique crossed appearance (441). The morphology of serotype 2 MDV has not been studied in detail, but typical herpesvirus particles have been visualized (485, 571).

Chemical Composition
Viral DNA
Physical Properties

The complete sequence for the 3 serotypes (11, 304, 347, 375, 664) confirmed that the genomes are very similar consisting of linear, double-stranded DNA molecules of approximately 160–180 kb with a buoyant density in neutral CsCl of 1.706 g/mL for serotype 1 (368, 550). The guanine plus cytosine (G+C)

[D] ND = not determined.

ratio is different for the 3 serotypes and ranges from 43.9–53.6% in serotype 1 and 2, respectively, and 47.6% for HVT (Table 15.2) (304, 621). It is difficult to separate viral DNA from host cell DNA because its density is close to that of chicken DNA. Several methods have been described to obtain viral DNA (550). Pulse-field electrophoresis is probably the best way to obtain pure infectious viral DNA (269, 298, 683). However, the cloning of the complete MDV genome as bacterial artificial chromosomes (BAC) has greatly facilitated the production of MDV DNA (588, 745). Infectious BAC clones of at least 4 different MDV strains—three avirulent and the highly oncogenic RB-1B—have been constructed. This has allowed rapid genetic manipulation of MDV genomes to identify various determinants associated with MD biology (137, 467). Similarly, the rescue of infectious MDV by transfecting overlapping cosmid clones of the Md5 strain of MDV into chicken embryo fibroblasts (CEF) (537) has allowed rapid manipulation of MDV DNA by site-directed mutagenesis and the generation of recombinant viruses to gain insights into gene functions (400, 622).

Structural Organization
The genomic structure of the 3 serotypes is typical for alphaherpesviruses as previously suggested (135) with a unique long (U_L) and a unique short (U_S) sequence. These unique sequences are flanked by sets of inverted repeat sequences: the terminal repeat long (T_{RL}), internal repeat long (I_{RL}), internal repeat short (I_{RS}), and terminal repeat short (T_{RS}), respectively. Alpha (α)-like sequences typical for alphaherpesviruses are located at the termi-

nal ends of the T_{RL} and I_{RL} and between the I_{RL} and I_{RS} regions (11, 304, 348, 664) (Table 15.2), which can be variable in length (539). These a-like sequences are believed to be important for the cleavage and packaging of viral DNA into virions.

The complete genome sequences of four serotype 1 MDV strains are available up to now. These include Md5 (177874 base pairs, GenBank Accession number AF243438), GA (174077 base pairs, GenBank Accession number AF147806), BAC clone of Md11 (178632 base pairs, GenBank Accession number AY510475), and BAC clone of CVI988 (178311 base pairs, GenBank Accession number DQ530348). The genome structure and the sequences of these strains are very similar and the differences in the lengths are mostly caused by the changes in the copy numbers of the direct repeats in the repeat regions of the genome. Comparison between the vMDV GA and vvMDV Md5 strains shows very few structural differences between serotype 1 strains (621). The U_L regions of GA and Md5 are very similar in length and organization, but the U_S sequence of GA is longer than in Md5. The differences in the U_S and the flanking repeats result in the presence of 1 copy of small ORF2 (SORF2) in GA and a second SORF2-like gene in Md5. In addition SORF1 in Md5 is completely located in the repeats, but has a frame shift resulting in a truncated SORF1. The importance of these differences is not clear. Additional minor differences between strains can be expected. CVI988 BAC contains 14 copies of the 132-bp repeat, the expansion of which was once thought to be associated with viral attenuation (619, 622). Kaplan and Schat (333) reported differences in 2 of the 3 promoter regions for ICP4 between the GA,
15.2. Genetic organization of the GA strain of Marek's disease virus. (375) (Proceedings of the National Academy of Sciences) (L. F. Lee)

RB-1B, and CVI988 strains. *In vitro* assays suggest that these differences may influence the level of transcription of ICP4. Comprehensive analysis of the sequence of the T_{RL}/I_{RL} regions in the genomes of 13 strains of varying virulence has identified several single nucleotide polymorphisms (SNPs) which loosely partition between attenuated and nonattenuated strains (634). The physical map of GA is presented in Figure 15.2.

The complete genome sequences of serotype 2 strain HPRS 24 (GenBank Accession number NC_002577) (304) and the serotype 3 HVT strain Fc126 (GenBank Accession numbers AF291866, AF282130) (11, 347) have also been determined. Inspection of the sequences of the 3 serotypes confirms that the genomes are colinear as had been suggested based on cross-hybridization stud-

ies with cloned fragments of the 3 serotypes (285, 465). The three serotypes differ substantially in their restriction endonuclease digestion patterns (225, 264, 554, 618) but share significant homology at the DNA level (11, 304, 347, 375, 664).

DNA Structure in Infected Cells.   The structure of viral DNA in infected cells is dependent on the virus-cell interaction. Linear viral DNA can be found in nuclei of cells undergoing virus replication (135). It is still unknown how viral DNA is maintained in latently infected, nontransformed cells (426, 550). The status of DNA in transformed cells has been difficult to determine in part because a variable percentage of the transformed cells may undergo viral replication at any point in time, in which case linear

DNA can be detected. In addition, most of the studies on the structure of viral DNA have been done using established cell lines, which may have undergone additional selection. Initial reports indicated an absence of integration (652) or a mixture of integrated and episomal DNA (334, 544). The association of viral DNA with chromosomes by density gradient centrifugation and *in situ* hybridization supported the idea that integration may occur. More recently, Delecluse *et al.* (186, 187) showed that viral DNA can be integrated into primary tumor cells and tumor cell lines. Integration into primary lymphoma cells occurred randomly at multiple sites. In cell lines, integration occurred at 2–12 sites, which were characteristic for the individual cell lines. Integration sites were preferentially located at the telomeres of large- and mid-size chromosomes or in minichromosomes. Note that the terminal ends of the MDV genome contain host cell telomere-like sequences (348), which are thought to assist in the preferential integration of the viral DNA near to the telomeres of the host cellular DNA in latently infected cells (186).

Structural Changes by Recombination and/or Mutation. Spontaneous recombination among the 3 MDV serotypes under field conditions is probably a very rare occurrence, despite the fact that chickens vaccinated with all 3 serotypes frequently are superinfected with virulent MDV. Concomitant infections in the same tissue (142) and cells (447) have been reported. Only 1 case of a recombination between 2 serotypes has been reported when a virus was isolated from the MSB1–41C cell line with serotype 1 and 2 sequences. Cloning of the junction fragment showed that this was indeed a recombinant virus (269).

Serotype 1 strains quickly develop altered biologic characteristics upon serial passage *in vitro,* such as loss of oncogenicity (156)**,** reduced expression of the so-called A antigen [glycoprotein C (gC)] (156), and decreased replication *in vivo* (576) indicating that spontaneous mutations may have occurred. The gradual evolution of pathotypes toward greater virulence and the changes in biologic properties of MDV during *in vivo* backpassage (692) further support the mutability of MDVs.

These biological changes are accompanied by several molecular changes, although it is not clear which molecular change correlates with a specific biological change. An expansion was found within the BamHI D and H fragments that are commonly associated with cell culture passage and attenuation in serotype 1 strains (221, 265, 623). This expansion was caused by a tandem amplification of direct 132 bp repeat (278, 406, 555). Other changes have also been described including the deletion of 400 bp in the BamHI A fragment of CVI988 clone C (988C) and 988C/R6 (278) and a deletion of 200 bp in the BamH1 L fragment of the vvMDV strain Md11 (683). Additional changes have been reported for CVI988 in the *meq* gene (378) and the ICP4 promoter/enhancer region of CVI988 (333). It is not clear whether these differences are a consequence of cell culture passage or reflect strain differences.

Serial passage of serotype 2 and serotype 3 strains can also lead to biological and structural changes. The biological changes are often associated with loss of *in vivo* replication and protective immunity (703, 719, 735). Other changes have also been reported

such as the release of large quantities of cell-free HVT (735) or the development of resistance to inhibition by phosphonoacetate (371). Structural DNA changes have been described using restriction endonuclease patterns (267, 618) and total size estimates based on pulsed field electrophoresis experiments (683).

In vitro co-cultivation of MDV or HVT with avian leukosis virus (ALV) or reticuloendotheliosis virus (REV) resulted in spontaneous insertion of long terminal repeats (LTR) of the retroviral provirus in the MDV genome (295, 319), but full-length, infectious provirus occasionally can integrate (297). Integration of endogenous ALV sequences into MDV has also been reported (560). The integration occurs often at the border regions of the repeats and unique sequences of MDV and in the gD gene (80). Davidson and Borenshtain (173, 174, 175) reported the *in vivo* integration of retrovirus sequences into MDV in commercial poultry. The relevance of the integration of retrovirus for the pathogenesis of MD is not clear, although LTR insertions can cause increased transcription of MDV genes (318).

Viral Genes and Proteins

Over the last 20 years, a number of individual genes of MDV-1 have been identified and sequenced, and the proteins have been characterized (558, 720). Comprehensive reviews based on the complete sequences for the 3 serotypes recently have been published including lists of ORFs and their putative products (304, 401, 467, 621). Table 15.3 summarizes the location of the ORFs and indicates the number of ORFs with homologues to HSV, the number of ORFs with homologues shared among the 3 serotypes, and the number of unique genes for each serotype. Many of the genes in the U_L and the U_S regions have homologues with HSV and equine herpesvirus 1 and 4, and the genome organization is similar to these 2 alphaherpesviruses (401). For this chapter, the MDV genes are grouped into 2 general categories: genes with homologues in alphaherpesviruses and genes unique for MDV. Only the genes that are important for the pathogenesis and immune responses will be reviewed briefly. The reader is referred to the contemporary literature for additional information.

Genes with Homologues in Alphaherpesviruses

This broad category of genes can be divided into immediate early (IE), early, and late genes, which are with few exceptions important for virus replication.

IE and Early Genes with Homology to HSV. The IE genes are important transcriptional regulators. Four IE genes have been identified: intracellular protein (ICP)4, ICP0, ICP22, and ICP27. Anderson *et al*. (17) identified ICP4 as a 4245 bp ORF, but sequence data indicated the presence of an open reading frame (ORF) of 6969 bp. This is in agreement with the finding that 2 functional promoter/enhancer regions are located upstream of the larger ORF and that the putative promoter/enhancer region for the short ORF was nonfunctional in *in vitro* assays (333). Proof that ICP4 protein is a transactivator was provided by transfection of the MD cell line (MDCC) MSB-1 with the short form of ICP4, showing increased transcription of the pp38 and pp24 genes (520) and the endogenous ICP4 gene (206, 520). The ICP4 pro-

tein can also transactivate the LTR of Rous sarcoma virus at low levels (41). Transcription of ICP4 may require the presence of VP16, a late protein coded for by UL48 and present in the tegument of MDV particles (72). However, Kaplan and Schat (333) were unable to confirm this observation, and the requirement for VP16 in a cell-associated virus may not be absolute.

The role of ICP22 (=US1) protein (81) in MDV replication is poorly understood. Deletion mutants lacking ICP22 replicate *in vitro* but to a lower degree than wild-type virus. ICP22 is not essential for *in vivo* infection, oncogenesis, and reisolation of virus (472, 473). The MDV ICP27 phosphoprotein (540) localizes in the nucleus, can transactivate pp38 and pp14 independently of ICP4, and represses the early thymidine kinase gene (541). Although the precise functions of the MDV ICP27 have not been demonstrated, recent reports on the role of HSV ICP27 in the mRNA export pathway (352) and NFκβ activation (250) suggest important roles for this protein in MD biology. ICP0 (R-LORF1) has been identified as an ORF in the TRL and IRL, and a recent study using proteomic approaches has demonstrated that the ICP0 gene product is expressed in MDV-infected CEF (393). However, it is currently unknown if the protein has similar functions as ICP0 in HSV.

The early genes with homology to HSV-1 have been identified. The functions of these genes are expected to be similar to those in other alphaherpesviruses (401) and will not be further discussed in this chapter. The MDV genes MDV008 and MDV073 encoding the related phosphoproteins pp24 and pp38, respectively, (664) with early expression kinetics are discussed separately.

Late Genes. The late gene products include the nucleocapsid proteins, the tegument proteins, including VP16, and the glycoproteins (reviewed in 401). The glycoproteins (gB, gC, gD, gH, gI, gK, gL, and gM) will be discussed briefly because these are presumed to be important for infection of cells, transfer of virus from cell to cell, and immune responses. Churchill *et al.* (156) identified 2 glycoproteins by AGP tests: the soluble A antigen and the cell-bound B antigen, which are now known as gC and gB, respectively.

gB, encoded by UL27, consists of a complex of 3 glycoproteins with molecular weights of 100, 60, and 49 kD (gp100, gp60, and gp49) (138, 292, 299, 449, 620). gB is important for cell attachment and/or penetration based on the production of gB-specific virus-neutralizing (VN) antibodies (292, 299, 442, 463, 552). Deletion of gB from MDV prevented the cell to cell spread demonstrating the essential nature of this protein for MDV replication (588), as is the case with all other herpesviruses (500).

The UL44 gene encodes gC, a 57–65 kD glycoprotein identified in some early references as gA, which is extensively synthesized in productively infected cells and is expressed on the cell surface and cytoplasm. In addition, gC is actively secreted by infected cells (165, 290, 296, 300) and is one of the major antigens to which the chicken immune system mounts a substantial serological response. The function of gC has not been elucidated; the production of gC in cell culture decreases with attenuation (156, 291) probably due to reduced transcription of UL44 (684). Recent data suggest that the reduction of MDV replication due to overexpression of gC in cultured cells is possibly caused by the

secreted forms of gC (659). A gC deletion mutant had an attenuated phenotype with a decrease in infectivity, horizontal transmission, and oncogenicity. However, a revertant virus needs to be generated to confirm that the attenuation was caused by deletion of gC (422). Recent *in vivo* studies using a gC-negative mutant of RB-1B showed that although the viral load in the peripheral blood was not affected, it was compromised in establishing latency and inducing tumors suggesting a major role for gC in MD pathogenesis (468).

The importance of gD, coded by US6, is poorly understood. It is expressed poorly (464) or not at all (651) *in vitro* probably as a consequence of no or limited transcription. Limited expression of gD compared to pp38 and gB has been described in FFE (450), suggesting that specific transcription factors in the FFE may be needed for the production of gD. A gD deletion mutant constructed in the oncogenic RB-1B strain was fully oncogenic and capable of horizontal transmission indicating that gD is nonessential (18). Recently SNP analysis in the gD gene was used in a retrospective molecular epidemiological study to determine the variation among MDV strains (364).

The functions of the other glycoproteins have not been studied in detail. The gI and gE proteins interact with each other based on immunoprecipitation assays (651). It is not clear whether the gE/gI complex functions as Fc receptors as described for other alphaherpesviruses. Mutants constructed in a BAC clone carrying deletions in the gM, gI, or gE gene indicate that the encoded glycoproteins are essential for virus replication, because the deletion mutants are unable to transfer infectivity from infected to uninfected cells (589, 660).

Genes Unique for MDV
Several genes have been identified that are unique for MDV strains (Table 15.3). Some of these genes are present only in serotype 1, and others may have homologues in MDV serotype 2 and/or HVT.

Latency Associated Transcripts (LATs). The LATs are a group of transcripts antisense to ICP4 and recently have been reviewed in detail (426). These include a large 10 kb transcript as well as several spliced transcripts referred to as MSR (MDV small RNA) or SAR (small antisense RNA) (132, 133, 387, 388, 417). The importance of LATs for latency or transformation is unclear. LATs are expressed in both lytically infected and transformed cells. One of the small LATs, identified as SAR, was expressed consistently in the CD4[+], AV37[+] fractions of primary lymphomas (557). LATs have also been described in the MDV-positive QT35 cell line (736). A deletion mutant of RB-1B with an insertion of LacZ, which disrupts the 5′ end of the MSR has been generated. Chickens inoculated with the mutant virus were able to induce robust lytic infection but failed to induce tumors. The importance of this finding is not clear until a rescued virus has been generated from this mutant (426).

Meq (Marek's EcoQ). The molecular biology of Meq (R-LORF7) has been reviewed (360, 426, 435). The Meq protein of 339 amino acids contains a basic leucine zipper (bZIP) domain at the N terminal closely resembling the *jun/fos* oncogene family. The proline-rich repeat region at the C terminal resembles the WT-1 tumor suppressor gene (320). The Meq protein is expressed consistently in the nucleus of lymphoma cells and tumor cell lines (396, 532, 557) and can be expressed during the S-phase (394). Meq has a domain for dimerization with itself or the cellular oncoprotein Jun; the complex can bind to two distinct sequences, MERE I and MERE II. MERE I is located in the promoter/enhancer region of *meq*, and a MERE II site has been located in the putative MDV origin of replication (531, 532). Several lines of evidence suggest that Meq is important for transformation. The expression of *meq* antisense RNA in MSB-1 cells reduced colony formation in soft agar (732). Overexpression of Meq in transfected rat cells resulted in morphological transformation, inhibition of apoptosis (396), and interactions with the cell cycle regulator CDK2 (397). Interestingly, CVI988 has a 178 bp insert resulting in a frame-shift encoding for the proline-rich domain (378), although the frame-shift in the protein sequence could not be confirmed in a subsequent study (502). Forms of large Meq (L-Meq) containing the insertion have a suppressive effect on the Meq expression on the basis of reporter assays (136). Variations in the sequence of the proline-rich domains also showed association with virulence (594).

Meq shows differential binding to different promoters depending on its dimerization status. As heterodimers with leucine zipper proteins, e.g., c-Jun, Meq can transactivate promoters containing AP-1 sites (385) resulting in the upregulation of a number of genes including interleukin (IL)-2 and CD30, a member of the tumor necrosis factor receptor II (TNFR-II) family (93). It is suggested that Meq transforms chicken cells through the activation of genes such as JTAP-1, JAC, and HB-EGF, all of which are associated with the v-Jun transforming pathway (384). These data together with the upregulation of anti-apoptotic factors such as Bcl-2 and c-*Ski*, the cellular homologue of the retrovirus-transduced oncogene v-*Ski*, strongly indicate a converging pathway for transformation by oncogenic retroviruses and herpesviruses. Further evidence for a direct role for Meq has come from a recent study in which a Meq-deletion mutant of the vvMDV strain Md5 failed to induce tumors. However, this may also be caused by a significant reduction in the replication of the virus. Specific interaction between Meq and the transcriptional co-repressor protein CtBP was shown to be critical for MD oncogenicity, since specific mutations abolishing the interaction resulted in the total loss of oncogenicity of the virus (78).

Two spliced products from the Meq region have also been identified, one of which has been named vIL-8, and the second one lacks the transactivator domain. Examining the dynamic cellular properties and distribution of Meq and Meq/vIL8 proteins Anobile *et al*. (22) indicated that these two forms may have fundamentally different functions in MDV-infected cells. In addition to Meq, two transcripts of 852 and 1168 bp antisense to *meq* have been described. The 1168 bp ORF codes for a 23 kd nuclear protein that has been detected in lytically infected and transformed cells (495).

v-IL8. Recently, a homologue of the avian chemokine IL-8 has been identified in MDV (395, 475). The vIL-8 gene (R-LORF2)

is located in the long repeat region and originally was identified by Peng and Shirazi (494) as a spliced *meq* variant. The gene consists of 3 exons and is expressed late during cytolytic infection. IL-8 attracts T cells, especially after IL-8 receptors are upregulated by interferon-γ (IFN-γ) leading Schat and Xing (584) to hypothesize that vIL-8 may be important for the switch of infection from B to T lymphocytes (see "Pathogenesis").

Viral Lipase. The 3 serotypes of MDV code for a viral lipase gene (v-LIP) (11, 304, 347, 375, 664). v-LIP, a soluble, glycosylated protein, is encoded by the R-LORF-2 gene consisting of 2 exons. The first exon codes for the signal peptide, and the second exon codes for the lipase activity. v-LIP is probably an IE or early protein (328). The glycosylated protein is required for the efficient lytic replication in birds (329).

pp38/pp24. The MDV phosphorylated protein complex, often referred to as pp38/pp24, is coded by 2 genes located at opposite ends of the U_L region (749). The pp24 gene (R-LORF14) is located partly in the TR_L and the U_L region, and the pp38 gene (R-LORF14a) is located in the IR_L and the U_L region. Homologues for pp24 and pp38 have been identified in serotype 2 strains (304, 466). The TR_L and IR_L of HVT contain a gene with homology to pp38, but the functional relationship to serotype 1 pp38 is unknown (11, 626). The presence of these homologues was expected because HVT and SB-1 induce cell-mediated immune response to pp38 (460, 521).

The function of the pp24/pp38 complex has not been elucidated. Originally, it had been linked to oncogenicity because pp38 is expressed in the cytoplasm of a variable proportion of MDV-transformed, latently infected lymphocytes (169, 288, 437, 438). Expression of pp24/pp38 can be enhanced by treatment with IUdR (289) or transfection with the ICP4 gene (520). Interestingly, infection of QT35 cells, which are latently infected with serotype 1 MDV, with HVT activates pp38 expression (736). These data suggest that pp38 may play a role during reactivation and subsequent virus replication rather than with oncogenicity. The fact that pp38 is also expressed in productively infected cells including the FFE (169, 288, 437, 438) supports this hypothesis. Ross (558) suggested that pp38 may be responsible for the induction of apoptosis. A recent study examining the pp38 expression in QT35 cells identified two new splice variants that enhanced the metabolic activity suggesting additional roles for this phosoprotein in MDV latency and transformation (389). Recently it has been shown that pp38 is essential for cytolytic infection of B cells and maintenance of transformed state (536). However, pp38 deletion did not affect the ability of the virus to spread horizontally (229). Minor differences in amino acid sequences among strains have been noted for pp38. Originally, it was believed that pp38 was not expressed in CVI988 (725). However, it subsequently was shown that the gene is present in CVI988 but that amino acid 107 in an epitope defined by monoclonal antibody (MAb) H19 was changed from glutamine to arginine (170, 171). The biological relevance of this difference is not clear. The demonstration that vvMDV5 strain expressing the pp38 protein from CVI988 remains oncogenic indicates that the attenuation of CVI988 is not associated with pp38 (367).

The promoter/enhancer regions of pp38 and pp24 are part of a bidirectional promoter complex regulating the transcription of pp38/pp24, and the 1.8 kb gene family. This region also contains the origin of replication (423). Several transcription factors are located in this region including binding sites for Meq. Interestingly, serotype 2 has also a binding site for Meq (MERE II) in this region (614), although a homologue for the *meq* gene has not been identified in HPRS-24 (304). Differential transcription for pp38/pp24 and the 1.8 kb gene family has been reported (614).

The 1.8 kb Gene Family. Several immediate early transcripts originate from the 1.8 kb gene family containing 3 exons (73, 354, reviewed in 426). These transcripts are truncated in attenuated strains due to an expansion of a tandem 132 bp direct repeat (132 bp DR) (74, 555). Usually, nonattenuated serotype 1 strains including low passage CVI988 have few copies, and attenuated strains have multiple copies of the 132 bp DR (278, 331, 556), a distinction that forms the basis of differentiation by polymerase chain reaction (PCR) assays (49, 616, 750). However, the 132 bp region *per se* appears not to be directly associated with oncogenicity since the deletion of the region did not appear to affect the pattern or the frequency of tumors (622). Furthermore, it was shown that viruses lacking the 132 bp repeats can still be attenuated by repeated cell culture passages (619).

So far, a 7KDa (493) and a 14 KDa (277) protein have been associated with these transcripts. Both proteins can be detected in lytically infected and transformed cells, but the 7 KDa protein was not found after infection with attenuated virus. The function of these proteins has not been elucidated, although expression of 1.69 kb and 1.5 kb cDNAs derived from the 1.8 kb gene family in transfected CEF prolonged proliferation and reduced serum dependence, suggesting that one of the functions may involve the control of the cell cycle (492). In addition, expression of oligonucleotides antisense to the 132 bp DR transcripts inhibited proliferation of lymphoblastoid cell lines (339), further suggesting that the 1.8 kb gene family may be important for transformation.

Telomerase RNA (vTR). The existence of a unique gene encoding the RNA telomerase subunit (vTR) was identified in the IR_L/TR_L region of the MDV genome (217). MDV vTR showed nearly 88% sequence identity to the chicken telomerase RNA (ChTR) indicating its transduction from the host genome. vTR can constitute telomerase activity by interacting with chicken telomerase reverse transcriptase (ChTERT) more efficiently than ChR (218). The direct association between MDV oncogenicity and vTR was recently demonstrated using RB-1B virus lacking either one or both copies of vTR (662). vTR-negative mutants were significantly impaired in their ability to induce lymphomas with smaller less-disseminated tumors.

MDV-encoded microRNAs. MicroRNAs (miRNAs) are a distinct class of small regulatory molecules of approximately 22 nt affecting the gene expression in various cell types. These have been identified in a large range of organisms including several herpesviruses (436). Recently, several novel MDV encoded miRNAs flanking the Meq gene and the LAT region of the genome were

identified in MDV-infected CEF (95). The precise functions of these novel miRNAs in MD biology are not yet known. However, as these molecules are expressed at very high levels in MD lymphomas and MDV-transformed cell lines, they may play major roles in oncogenesis.

Other Unique Genes. Proteins have not been identified for several unique ORFs that are transcribed in tumor cells. Most of these have not been further studied with a few exceptions. RLORF5a [ORF-L1 (456)] is expressed in tumor cell lines, QT35 latently infected with MDV, and in a REV cell line latently infected with MDV (456, 496, 736). The function of RLORF5a remains unknown. Expression is not essential for reactivation from latency and virus replication (580) or tumor formation (313).

Jarosinski *et al.* (312) found that RLORF4 was expressed in MD tumor cell lines and that this ORF was deleted in a series of attenuated MDV strains. Deletion of both copies of RLORF4, but not one copy, in RB-1B resulted in an attenuated phenotype *in vitro* and resulted in a major reduction in tumor development, but early viral replication was not affected by the deletion (313).

Viral Vectors

Several nonessential sites in the 3 serotypes of MDV can be used for the insertion and expression of foreign and specific MDV genes (reviewed in 268). The anticipated advantages of MDV-vectored vaccines are that these vaccines will protect simultaneously against MD and other pathogens, and reactivation from latency will reinforce immune responses against MD and the other pathogens. So far, most of the MDV-vectored vaccines have shown protection in specific-pathogen-free (SPF) chickens [e.g., against Newcastle disease (424) and very virulent infectious bursal disease (IBD) (663)]. The disadvantage is that the MDV-vectored vaccines need to be given *in ovo* or at hatch. The presence of maternal antibodies against the expressed foreign protein may impede the development of active immunity against the inserted gene and perhaps also MDV, especially if the inserted gene is under the control of a strong promoter. For example, when the F protein of Newcastle disease virus (NDV) was expressed in a CVI988 MDV-vectored vaccine under control of the SV40 late promoter, protection against NDV challenge was suboptimal in maternal antibody-positive chickens. However, expression under control of the MDV gB promoter induced protection (633).

Virus Replication

Replication of the 3 serotypes is typical of other cell-associated herpesviruses and has been reviewed extensively (58, 335, 467, 550, 564). For initial infection of cultures or chickens by cell-free virus, enveloped virions bind to cellular receptors probably by gB perhaps in combination with other glycoproteins. Heparan sulfate, a member of the glycosaminoglycans, has been identified as one of the cellular receptor molecules (377). In cell cultures, viral penetration occurs within 1 hour after attachment, which is enhanced for serotype 1 by chelators such as ethylenediaminetetraacetic acid (EDTA) (8). Subsequent spread of infection to other cells occurs by direct contact with infected cells, and virus transfer probably is accomplished through formation of intracel-

lular bridges (327). This is presumed to be the principal mode of virus spread after initial infection *in vitro* and *in vivo*. Recent data demonstrate the role of the U_S3-encoded kinase in the morphogenesis as well as cell-to-cell spread of virions through the effect of stress on fiber breakdown and polymerization of actin (590). The glycoproteins gE, gI, and gM play a role in the transfer of virus from infected to uninfected cells (589, 660). Replication rates vary with serotype, passage level of the virus strain, cell type, and temperature of incubation.

The spread of virus *in vivo* from cell to cell will require intimate contact between infected and uninfected cells, which are most often lymphocytes, although epithelial cells also can be involved in this process. The precise interaction between these cells remains one of the important unsolved issues.

Virus-cell Interactions

Three general types of virus-cell interactions are recognized: productive, latent, and transforming.

Productive Infection. During productive infection, replication of viral DNA occurs; proteins are synthesized; and in some cases, virus particles are produced. The number of genome copies per cell can increase 100-fold and exceed 1200 in the case of HVT (334). Two types of productive infection exist. Fully productive infection in the FFE of chickens results in development of large numbers of enveloped, fully infectious virions (110). In productive-restrictive infection, most of the virions are nonenveloped and noninfectious. A variable number of the virions in cultured cells may be enveloped, however, and these can be recovered as cell-free, infectious virus by disruption of cells. The use of an appropriate stabilizer such as SPA (116) will improve the yield of cell-free virus. A variant strain of HVT that releases large quantities of cell-free virus into the medium of infected cell cultures has been described. This strain is replication-defective in chickens (735). In all susceptible cells, productive infection leads to intranuclear inclusion body formation and lysis of the cell. A gene for the viral host shut-off protein has been identified, UL41 (401), that is probably responsible for the initiation of the lytic process. Lytic infection *in vivo* can cause frank necrobiotic lesion formation. Because of this, productive infection has been termed cytolytic, and the terms are used synonymously (105).

In productively infected fibroblasts, most of the MDV genome is transcribed (407, 570, 625). Differences in transcripts between productive infection with virulent and attenuated serotype 1 strains have been described (73, 555) and are mostly associated with transcripts in the repeat regions flanking U_L. Recent study employing a mass spectrometry-based proteomic approach has further confirmed the expression of the majority of MDV-encoded proteins during cytolytic infection in CEF (393).

Productive infection in cell cultures is influenced by several factors. Inhibitors of viral DNA polymerase and thymidine kinase will inhibit virus replication in productively infected cell cultures but do not influence the growth of lymphoblastoid cell lines (550, 564). The presence of nitric oxide (NO) in cell cultures reduces virus replication in a dose-dependent manner (188, 734). *In vitro* infection can change transcriptional regulation of

cellular genes in infected and in neighboring cells. Microarrays have been used to determine which genes may be up- or down-regulated by infection with MDV (425). For example, MHC class I and II genes and two IFN-response elements were upregulated. The importance of these results needs to be further examined. Hunt *et al.* (281) reported that productive-restrictive MDV replication downregulated expression of MHC class I expression in OU2 cells and in lymphoblastoid cell lines. Upregulation of MHC genes actually occurs in noninfected cells (340) probably through IFN (383). This is certainly compatible with the upregulation of IFN-response genes. IFN, probably IFN-α, may be produced at least by some MDV and HVT strains (276, 326).

Latent Infection. Latent herpesvirus infections have been defined as the presence of viral DNA in the absence of viral transcripts and proteins, although LATs have been described for many herpesviruses. This definition is appropriate for the non-transforming serotype 2 and 3 strains. For serotype 1 strains, the distinction between latency and transformation is often problematic. In both cases, the viral genome is present, but no information is available on differences in transcriptional regulation between latently infected and transformed cells, because it is impossible to separate latently infected, nontransformed cells from noninfected cells. As a consequence, studies on latency have often been done in MD transformed cell lines.

MDV latency mostly is associated with CD4$^+$ T cells, although CD8$^+$ T cells and B cells can also be latently infected (125, 376). Fewer than 5 copies of the viral genome are present in latently infected cells (550). *In vitro* latent infections have been described in REV-transformed (522), OU2 (6) and QT35 cell lines (736). The MDV genome can be reactivated from latently infected cells and tumor cells by inoculation of susceptible chickens, cocultivation with permissive cells, and *in vitro* cultivation of latently infected lymphocytes. The latter approach can be used to estimate the number of latently infected cells by enumeration of antigen-positive cells at 0 hours and 48 hours in culture (127). The presence of latent MD infections can also be detected by PCR assays (see "Diagnosis"). However, the PCR assay needs to be combined with RT-PCR, demonstrating the absence of early and late transcripts to ensure that the amplified DNA is obtained from latently and not from the few productive-restrictive infected cells that commonly occur in populations of latently infected lymphocytes. Upregulation of ICP4 transcripts and downregulation of LATs have been associated with reactivation of early and late genes in latently infected cells (6, 736).

At least 2 cytokines produced by concanavalin A-stimulated spleen cell cultures can help maintain latency in cultured lymphocytes (96). Subsequently, 2 recombinant chicken (rCh) cytokines, rChIFN-α (671) and rChIFN-γ (332), have been shown to suppress production of IE, early, and late viral antigens in latently infected lymphocytes. Curiously, IFN-α was more effective in the suppression of viral genes in later stages of latency than during early stages (671). *In vivo* selective reactivation of latently infected cells can be induced by treatment with cyclosporin or betamethazone (97), but not by infection with immunosuppressive viruses, such as IBD virus (IBDV) or REV. Chicken in-

fectious anemia virus (CIAV) may influence latency in MD based on its influence on cytokine production and cytotoxic T lymphoctes (CTL) (567).

Transforming Infection. Transforming infections occur only in cells infected with serotype 1 MDV. Selection of transformed cells from the background of immunologically committed and noncommitted cells (490) would facilitate comparative studies on transformed cells in tumors and tumor cell lines. The search for specific surface markers associated with tumors has yielded 2 potential antigens. An MD tumor-associated surface antigen (MATSA) was detected on cells from MD lymphomas and lymphoblastoid cell lines but not on the surface of productively infected cells (511, 731). MATSA was also detected on lymphocytes from chickens vaccinated with HVT or serotype 2 strains of MDV (349, 512, 572), and subsequent studies revealed MATSA to be present on activated T cells from uninfected chickens (412). Recently, a second antigen, CD30, detected by MAb AV37, has been associated with MD-transformed CD4$^+$ T cells and MDV-infected cells during the cytolytic phase. However, this antigen can also be detected on B cells and REV-transformed cells (92, 557). Recent studies confirm that CD30^{hi} expression is characteristic of MD lymphomas suggesting that CD30 is a component of a critical intracellular signaling pathway perturbed in neoplastic transformation (93). Both MATSA and CD30 can be used to enrich for transformed cells in tumor cell suspensions. Ross *et al.* (557) purified cells from lymphomas using CD4 and AV37 MAbs and found that *meq* and SAR transcripts were abundant in these populations. In contrast, pp38 and VP16 transcripts were not detected. Most other studies have used lymphoblastoid cell lines to identify transcripts, which have been detailed in a previous section. Antigens normally are not detected in lymphomas or lymphoblastoid cell lines by FA tests with convalescent serum, except for occasional cells that probably have converted to a productive infection (12, 119) and, by definition, are no longer transformed. Some transformed lymphocytes can be induced to produce viral antigens by treatment with IUdR (128, 195, 366) or by culture at suboptimal temperatures (23, 128).

Replication of Other Serotypes
In most reports, replication of MDV serotype 2 and HVT are similar to serotype 1. Because HVT and serotype 2 MDV are nononcogenic (571, 718) no cell lines have been developed equivalent to those derived from MD lymphomas, and transforming infections have not been recognized.

Latent infections have been demonstrated in chickens infected with serotype 2 and 3 viruses (613). The phenotype(s) of cells latently infected with serotype 2 and 3 strains have not been elucidated. The observation of latent infection of SB-1 in ALV-transformed B cell lines suggests that B cells are likely target cells for latent infection with serotype 2 strains (223). Occasionally, HVT can be present in MDV-transformed T cell lines, probably representing a latent infection (119, 266).

Holland *et al.* (274) reported the presence of HVT transcripts encoded in the TR$_L$ and IR$_L$ in the thymus and spleen, but not the bursa of Fabricius, in the absence of gB expression. Interestingly,

these transcripts were also detected in peripheral nerves and feather-associated tissues.

Virus Stock Production and Stability

Productively infected cell cultures are a common source of cell-associated virus stocks for all 3 viral serotypes and for cell-free HVT stocks. Techniques for the production and cryopreservation of cell-free and cell-associated virus stocks have been described (reviewed in 153). Cell-associated stocks of MDV or HVT are routinely stored at –196°C. The infectivity of such stocks, however, is directly related to viability of the cells contained in these preparations and depends also on optimal freezing and thawing techniques. Under ideal conditions, the half-life of diluted, cell-associated virus stocks or vaccines should be at least 2–6 hours (656).

Cell-free serotypes 1 and 2 virus stocks are best obtained from FFE (low-passage virus) or infected cell cultures (high-passage virus). Small quantities of low-passage virus can be obtained from infected cell cultures by lysing cells in SPA (116). The production of cell-free HVT is best achieved by lysing heavily infected cell cultures. Cell-free MDV and HVT can be stored at –70°C or lyophilized (116). Potency of both cell-associated and cell-free vaccines can be affected adversely by storage temperature, reconstitution technique, choice of diluent, and holding time and temperature after reconstitution (245, 478).

Susceptibility to Chemical and Physical Agents

The stability of cell-associated MDV serotype 1 and 2 strains is completely dependent on the viability of the cells. Any treatment affecting cell viability will impact directly the infectivity of virus stocks.

Cell-free MDV obtained from the skin of infected chickens was inactivated when treated for 10 minutes at pH 3 or 11 and stored for 2 weeks at 4°C, 4 days at 25°C, 18 hours at 37°C, 30 minutes at 56°C, or 10 minutes at 60°C (109). Dander, litter, and feathers from infected chickens are infectious and presumably contain cell-free virus from the FFE bound to cellular debris. The infectivity of such materials was retained for 4–8 months at room temperature (271, 705) and for at least 10 years at 4°C (102). Virus infectivity was inactivated by a variety of common chemical disinfectants within a 10-minute treatment period (115, 270). Survival of virus in litter may be affected adversely by increased humidity (705).

Strain Classification

Serotypes

Von Bülow and Biggs (675, 676) classified the MDV herpesvirus group into 3 distinct virus groups that correlated with biologic properties. Type-specific monoclonal antibodies (286, 370) usually are used to determine virus serotype.

Although distinguishable by serologic tests, the 3 serotypes also share many common antigens. Thus, sera against a serotype usually will react with antigens of other serotypes, although somewhat less vigorously than with homologous antigens (675).

A number of biological characteristics are associated with

viral serotypes (63, 564). Low-passage serotype 1 viruses grow best in duck embryo fibroblast (DEF) or chicken kidney cell (CKC) cultures, grow slowly, and produce small plaques. Serotype 2 viruses grow best in chicken embryo fibroblasts (CEF), grow slowly, and produce medium plaques with some large syncytia. HVT grows best in CEF, grows rapidly, and produces large plaques. More infectious virus can be extracted from HVT-infected cells than from cells infected with serotype 1 or 2 viruses.

Pathotypes

Virulence or oncogenicity is associated with only serotype 1 MDVs. Within this group, however, a wide variation in pathogenic potential is recognized and undoubtedly represents a continuum from nearly avirulent to maximally virulent. Pathotypic classification schemes have evolved over the last 30 years with the continued increase in virulence. Current classification schemes recognize 4 groups of viruses. These groups are designated as mMDV, vMDV, vvMDV, and vv+MDV (699, 708). Pathotyping of virus isolates involves comparative pathogenicity tests in vaccinated and unvaccinated maternal antibody positive chickens with prototype viruses as controls (693, 708). No *in vitro* methods have yet been developed. Prototype viruses are the CVI988 (546) and CU2 (627) strains of mMDV; the JM (593), GA (197), and HPRS-16 (527) strains of vMDV, the Md5 (721) and RB-1B (574) strains of vvMDVs; and the RK-1 (113), also identified as 625 by Witter (699), and the 648A (699) strains of vv+MDV. The evolution in the virulence of MDV strains is recognized, but the molecular basis for this evolution has not been elucidated. For many years, MD was the classic disease with paralysis as the main lesion induced by viruses of the mMDV pathotype. A more virulent form of MD was first noted in the late 1940s (50), associated with viruses of the vMDV pathotype, which became the dominant pathotype during the 1960s. The vvMDV pathotype virus strains were first noted in the late l970s (196), mainly in HVT-vaccinated flocks with excessive MD losses, which led to introduction of bivalent vaccines in the early 1980s. During the early 1990s, the vv+ strains appeared and together with the vv strains are the dominant types.

Certain biologic characteristics are associated with pathotypes of serotype 1 MDVs but are most pronounced between low-passage and high-passage (attenuated) strains. Serial passage *in vitro* (30–70 passages usually are required) results in attenuation of virulent isolates (156, 546, 576, 688). Attenuated strains grow more readily *in vitro* but produce lower viremia titers *in vivo* (712), which may be associated with a marked decrease in their ability to infect and/or replicate in lymphocytes (576). The production of gC (A antigen) is reduced or absent (156). Attenuated strains do not spread well among chickens by contact (184, 692). Some strains are incompletely attenuated and induce minor lesions in highly susceptible chickens (505, 674). Overattenuated strains do not replicate in or protect chickens (353, 719). The *in vivo* growth potential of attenuated serotype 1 isolates can be increased by backpassage in chickens (185, 692), although in one case virulence was also increased (185). The incidence of tumors induced by low-virulence strains of serotype 1 MDV is increased

by infection at 7 days of embryonation or by immunosuppression (112, 121). Viruses of serotype 2 (SB-1 strain) and 3 remained nononcogenic following similar treatments (121, 571).

Laboratory Host Systems

MDV usually is propagated and assayed in tissue cultures, newly hatched chicks, and embryonated eggs. Lymphoblastoid cell lines from MD lymphomas are also an important laboratory host system.

Cell Cultures

The propagation of MDV serotypes *in vitro* has been reviewed in (58, 564). Cultured DEF or CKC prepared from 1- to 2-week-old chicks are suitable for isolation and propagation of low-passage MDV isolates (154, 631). Isolation of low-passage MDV in CEF or embryonal CKC cultures is far less efficient than in CKC or DEF (569). Propagation in CEF leads to accelerated attenuation compared to CKC or DEF (576). In embryonal CKC, replication of serotype 1 MDV (but not HVT) is abortive, leading to loss of infectivity within 2 to 3 passages. Attenuated MDV and serotype 2 and 3 viruses can be isolated readily and propagated in CEF (63, 571). Infected cultures usually develop discrete focal lesions, called foci or plaques, which consist of clusters of rounded, refractile degenerating cells when mature (Fig. 15.3). Plaques are usually less than 1 mm in diameter and of variable cell density, although plaque size varies with viral strain, time, and other factors. Polykaryocytosis is seen in cultured fibroblasts and is a major component of the viral plaques or foci frequently used as a marker in virus assays. Affected cells may contain 2 to several hundred nuclei, and type A intranuclear inclusion bodies are commonly seen. Despite release of rounded cells into the medium as plaques mature, large areas of cell lysis are not seen.

Serotype 1 plaques develop in 5–14 days on primary isolation and in 3–7 days after adaptation to culture and usually are enumerated by microscopic examination, but different staining techniques have been developed, allowing enumeration at a later time. Differences in development and morphology of serotype 1 plaques in chick and duck cells and in plaques induced by the 3 viral serotypes (564) have been described. Other cell culture systems such as chick embryo skin (518), tracheal explants (535), and embryo fibroblasts from several avian species including Japanese quail (528) also have been used.

A few avian cell lines have been used for the propagation of MDV strains. The OU2 cell line can be used to propagate the three serotypes. Plaques develop after the monolayers become stationary, but virus remains latent when the cultures are subconfluent (5, 7). The DF-1 cell line can also be used for the propagation of all three serotypes of MDV. Recently developed quail cell lines free of MDV can be used to propagate serotype 1 MDV and HVT, but SB-1 did not replicate efficiently (390).

Serotype 1, but not serotype 2, MDVs can also be grown in chicken splenic lymphocytes *in vitro* (126). Passages are made by the addition of fresh spleen cells to the suspension cell cultures every 2 days, and infection is monitored by immunofluorescence. HVT may be similarly grown in turkey spleen cell cultures, but viral antigen is rarely seen, if at all.

Mammalian cell lines and primary cultures are, in general, considered to be refractory to infection (reviewed in 530, 564). However, a recent report suggests that Vero (African green monkey kidney) cells can replicate MDV and HVT, but the possible survival of inoculum-derived CEF or chicken-Vero cell hybrids has not been excluded (308).

Chickens

Newly hatched chicks inoculated with virulent, serotype 1 MDV develop gross lesions or lesions that can be detected histologically in ganglia, nerves, and certain viscera after 2–4 weeks. Response is greatly dependent on genetic susceptibility of the chicken and virulence of the MDV isolate. Presence of virus or antibody, which can be detected by *in vitro* tests, or the presence of virus-associated antigen detected by FA tests on tissues, are also specific host responses of inoculated chickens to MD infection. All these responses are markedly enhanced in chicks lacking maternal antibodies against MDV (100). The induction of virus-specific lesions in the wing web (118) or the feather pulp (427) constitutes alternate approaches that provide direct access to the site of lesion development.

Embryos

Virus pocks develop on the chorioallantoic membrane (CAM) of chicken embryos following yolk sac inoculation with cellular MDV preparations (62, 673). Embryos have also been used for MD vaccine evaluation, because *in ovo* vaccination is becoming increasingly common in the field (See "Pathogenesis of *in ovo* Infection"). Embryos may also be used to isolate MDV viruses that cannot be isolated directly in cell culture for unknown reasons. Yamaguchi *et al.* (736) reported the isolation of MDV from the QT35 cell line by using kidney cell cultures prepared from 4- to 7-day-old chicks that had been inoculated at ED 8 with QT35 cells.

Lymphoblastoid Cell Lines

Lymphoblastoid cell lines developed from MD lymphomas (see 106) grow continuously in cell culture without attachment to the culture vessel. Success rates for establishing cell lines from MD lymphomas have improved because of better methodology (128, 486) but *in vitro* immortalization of lymphocytes has not been achieved with 2 exceptions (120, 287). Many cell lines are now available including several from MD lymphomas in turkeys (439). The majority of the chicken cell lines established from lymphomas are $CD4^+/CD8^-$ T cells expressing MHC class II and T cell receptor (TCR) 2 or 3 (474, 577). Lymphoblastoid cell lines can also be established from lymphocytes harvested from early [4–6 days postinfection (PI)] lesions induced in the wing web or pectoral muscle by injection of a mixture of MDV and allogeneic kidney cells. The cell lines from early lesions may be $CD4^+/CD8^-$, $CD4^-/CD8^+$, or $CD4^-/CD8^-$ (577, 579). Cells of the MDCC-RP1 line are illustrated in Fig. 15.4.

Some transformed cells contain about 5–15 copies of viral genome, although the mean number may be considerably higher in different cell lines, perhaps in relation to the proportion of productively infected cells in the population (426, 550). Viral DNA
15.3. Focal lesions in cultured cells infected with various Marek's disease virus (MDV) serotypes. A. Low-passage serotype 1 MDV in chicken kidney cells cultured from an infected chicken, 9 days. B. Low-passage serotype 1 MDV in duck embryo fibroblasts (DEF), 5 days. C. High-passage, attenuated serotype 1 MDV in chick embryo fibroblasts (CEF), 5 days. D. Low-passage serotype 2 MDV in CEF, 8 days. E. Low-passage HVT (serotype 3) in CEF, 4 days. F. Low-passage turkey herpesviruses (HVT) in DEF, 12 days. All photos unstained, about ×40. (Witter)

can be highly methylated in cell lines in contrast to viral DNA in productively infected cells (330). However, methylation is not essential for maintaining the transformed state (474).

Most cell lines can be termed "producer" lines, because a small proportion (1–2%) of the cells enter into productive infec-

tion (128, 511). Virus can be recovered readily from most cell lines, although several nonproducer cell lines have been developed in which evidence of genome expression is limited or lacking (444, 486, 652). Prolonged culture can result in reduced expression of the MDV genome (411). Most, but not all, MD cell

lines established from lymphomas were found to display a chromosomal aberration in which an amplification of DNA resulted in an extra G-band and interband in the short arm of chromosome 1 (70, 421). The aberration was found only infrequently in MD lines established from local MD lesions (420), and it remains to be determined whether any relationship exists between this change and neoplastic transformation.

MD cell lines have been used to analyze the potential interaction with tumor suppressor genes and cellular oncogenes. Meq protein induces the transcription of the proto-oncogene *bcl-2* in Rat-2 cells (396), and the gene product can delay apoptosis. However, Ohashi *et al.* (455) were unable to detect the transcription of *bcl-2* in 2 cell lines and in T cells 3 weeks after infection *in vivo*. The transcript for *bcl-xL*, another gene involved in the prevention of apoptosis, was expressed, suggesting the *bcl-xL* rather than the *bcl-2* gene product may be important for transformation. Several mutations of p53, a tumor suppressor gene, have also been reported, but these mutations are not located in the traditional hot-spots associated with loss of function of p53 (647, 649). However, several kinds of truncated p53 transcripts with truncations ranging from 101–765 bp, thought to be generated by alternate splicing, were identified in MD-derived tumor cell lines (648). Further studies examining the expression of p53 protein identified two forms—a 40kDa large form and a 30kDa small form—of the p53 protein in MD-transformed cell lines (650). The levels of the short form of the protein showed increase during apoptosis suggesting that this form could play a role in the initiation of apoptosis.

Recently, a fibroblast cell line has been established that was apparently transformed by MDV. This cell line produces pp38, Meq, and the late gene product gB, but virus particles were not demonstrated (88). It is unknown whether complete viral DNA is present in these cells.

Pathobiology and Epidemiology

Multiple Syndromes

It is now apparent that MD consists of several distinct pathologic syndromes (107). Also, differences are apparent among the types of MDV-induced syndromes typically seen in layer/breeder flocks, broiler flocks, and those induced in the laboratory. Of the various syndromes, lymphoproliferative syndromes are most frequently associated with MD and have the most practical importance (see Table 15.4A). Of these, MD lymphoma is probably the most common. However, fowl paralysis, persistent neurological disease, skin leukosis, and ocular lesions are additional clinical manifestations that have lymphoproliferative components. Some of the lymphoproliferative syndromes may also have degenerative components. Several additional clinical syndromes characterized solely by degenerative and inflammatory lesions, often with accompanying immunosuppression, are induced by MDV infection in the laboratory (see Table 15.4B). Nonneoplastic brain pathology, mainly vasogenic edema, is responsible for transient paralysis (231). Vascular lesions are manifested as atherosclerosis. Under laboratory conditions, young chicks inoculated with tumor cells may develop localized or diffuse transplantable tumors (641, 655). Inoculation of MDV-infected, allogeneic CKC in the wing web may induce what Calnek *et al.* (118) termed local lesions. Some of the syndromes induced under laboratory conditions are rare or nonexistent in the field, probably because

Table 15.4A Clinical and pathologic syndromes associated with Marek's disease virus (part A).

Situation in which syndrome observed	Lymphoproliferative syndromes[A][B] (Marek's disease)			
	Lymphomas and nerve lesions	Fowl paralysis (nerve lesions)	Skin leukosis (integument)	Blindness and ocular lesions
Experimental chickens (laboratory)

most commercial chickens are hatched with passive MD antibodies and receive MD vaccines at or before hatch.

Subclinical disease syndromes may also occur but are more difficult to define. Purchase *et al.* (529) found that vaccinated flocks produced more eggs than nonvaccinated flocks, indicating that MDV may depress productivity in otherwise normal-appearing, nonvaccinated chickens.

Incidence and Distribution

MD exists in poultry-producing countries throughout the world. Probably every flock of chickens raised in areas where poultry is prevalent becomes infected, and many experience some loss. Reporting systems vary, however, and it is difficult to determine the true incidence. The incidence of infection is surely much higher than the incidence of disease. Even in susceptible chickens, infection does not always induce clinical disease and, in genetically resistant or vaccinated chickens, infection may rarely cause overt disease.

In the United States, the incidence of MD losses can be illustrated through the use of broiler condemnation data, collected since 1961 at the processing plant. A biphasic pattern is noted consistently with maximum frequencies around April and minimum frequencies around August (Fig. 15.5A), perhaps reflecting the effects of temperature stress and limited ventilation during winter months (526). Regional differences are striking. Analysis of the devastating 1960s outbreak showed that the initial losses occurred in the Delmarva and northeastern states, but the disease spread quickly to other regions (698). Historically and to the present time, condemnations in Delaware have been consistently higher and condemnations in Georgia have been consistently lower than mean values for the United States (Fig. 15.5B). Long- and short-term trends due to the introduction of vaccines can also be evaluated through condemnation data. Since 1971, when HVT vaccine was introduced, through 2000, yearly condemnations have decreased by 79-fold, 169-fold, and 958-fold in Delaware, the United States, and Georgia, respectively (Fig. 15.5B). Upturns in the early 1980s and the early 1990s were both successfully resolved by the introduction of more effective vaccines (see "Vaccination"). However, during the early part of 2005 outbreaks occurred in the Delmarva region with condemnations of almost 10% in broilers vaccinated with bivalent and trivalent vaccines (561). Layer and breeder flocks have experienced similar trends.

Sporadic outbreaks of MD occur on individual farms or regions. Several reports lend credence to the implication of exceptionally virulent MDV isolates in vaccine failures (196, 510, 574, 721). It is usually difficult to associate increased virulence of MDV isolates with regional fluctuations in MD frequency, but layer outbreaks in northwestern Ohio in 1995 (399) yielded several isolates of unusual virulence (113, 699).

Natural and Experimental Hosts

Chickens are by far the most important natural host for MD, but quail, turkeys, and pheasants are also susceptible to virus infection and disease. Virtually all chickens including game fowl (344), native breeds (235, 559) and jungle fowl (145, 681) are susceptible to MDV infection and tumor development. Most

(Data from National Agricultural Statistics Service.) (Witter)

other avian species including ducks, sparrows, partridge, pigeons, and peafowl (46, 234, 342, 513) are probably refractory, although MDV-inoculated ducks developed antibodies (46). Mammals, including several species of primates, are also refractory to experimental inoculation (155, 272, 546, 609, 611). Mice inoculated with tumor cells from chickens from field cases of MD developed a high rate of neoplasms (16), but the etiological role of MDV in these tumors is unsubstantiated.

Quail

In Japanese quail, natural outbreaks of MD in commercial flocks are relatively common (350). Affected birds develop lymphomas in various visceral organs, but peripheral nerves are rarely affected (350, 497, 516). Mortality can reach 10–20%, but deaths occur relatively late. MDV antigens can be demonstrated in the FFE, and MDV occasionally can be isolated from blood, although titers can be low (279, 293) or detected by PCR assays (497). Transmission of MDV from chickens to quail and from quail to chickens has been reported (294). MD can be induced in quail by experimental inoculation or contact exposure to MDV strains of both chicken and quail origin (293, 345). The experi-

mental disease appears similar to that of natural outbreaks. Many commercial quail flocks are vaccinated with HVT, and Kobayashi *et al.* (350) considered vaccination to be protective. However, Kaul and Pradhan (337) reported that quail were poorly protected by HVT against challenge at 10 days of age with an MDV strain of quail origin. Bobwhite quail are also susceptible, but perhaps less so than Japanese quail (513).

Turkeys

In turkeys, MD-like tumors have been occasionally reported (21, 679), but causal associations with MDV usually have been lacking, and natural outbreaks have been rare, at least until recently. However, turkeys are susceptible to experimental infection with MDV with mortality around 22–70% at 8–19 weeks (179, 479, 730). Enlarged peripheral nerves were rare or absent in these studies. Characteristics of the viral infection were similar to those in chickens but generally are more subdued. Virus could be reisolated from peripheral blood lymphocytes and antigen detected in lymphoid tissues and lungs of inoculated turkeys but less frequently and at lower concentrations than in chickens (201). Immunosuppression was also noted in turkeys that developed tumors (201). Interestingly, vaccination with HVT provided no protection against MDV challenge (202). Both B-cell (440) and T cell (509) lines have been developed from turkey lymphomas induced by MDV inoculation, suggesting that both cell types are susceptible to transformation.

Severe clinical outbreaks of MD in commercial turkey flocks were reported in France (164), Israel (179), Germany (670), and Scotland (498). Mortality from tumors reached 40–80% between 8–17 weeks of age. In some of these cases, the affected turkey flocks were raised in proximity to broilers. The lesions were similar to those produced experimentally, although paralysis was noted in some birds, and peripheral nerves were occasionally infiltrated with lymphocytes (164). Serotype 1 MDV was detected by virus isolation or PCR (176). Transmission between turkeys and between chickens and turkeys was established (164). Vaccination of turkeys with CVI988 appears to offer protection (164). The disease has not yet shown the ability to become endemic within commercial turkey populations.

Other Species

Pheasants and related species like the Black Francolin may also be susceptible as indicated by occasional reports of typical lymphomas and nerve lesions (251, 322, 503). Challenge of the common pheasant (*Phasianus colchicus*) with virulent MDV induced paralysis, visceral lymphomas, and precipitating antibodies within 75–85 days PI (380). Unlike quail and turkeys, pheasants appear to be more susceptible to neurological lesions of MD. However, the disease has not been well characterized in this species. MD was reported in white-fronted geese (*Anser albifrons*) in Japan (661). Subsequent analysis showed high prevalence of MDV genome in the feather tips of this species (433).

Transmission, Carriers, Vectors

MDV is transmitted readily by direct or indirect contact between chickens, apparently by the airborne route (citations in 57).

Epithelial cells in the keratinizing layer of the feather follicle replicate fully infectious virus (110), and these cells serve as a source of contamination to the environment and to other chickens. Virus associated with feathers and dander is infectious (48, 130), and contaminated poultry house dust remains infectious for at least several months at 20–25°C and for years at 4°C (citations in 105). Under commercial field conditions, young chickens are most commonly exposed to MDV by contact with residual dust and dander in the growing house or by the introduction of these materials by aerosols (from adjacent chicken houses), fomites, or personnel. After the virus is introduced into a chicken flock, regardless of vaccination status, infection spreads quickly from bird to bird. Virus excretion begins about 2 weeks after inoculation or exposure (341), with maximal shedding occurring between the third and fifth week (686). Once infected, chickens appear to shed virus indefinitely (729). Quantitative (q)PCR assays have recently been established to measure virus load in FFE and dust for MDV serotype 1 including the vaccine strain CVI988 (2, 34, 39, 301), serotype 2 (543) and serotype 3 (301). Preliminary data confirm the earlier observations that maximal shedding occurs early after the presence of virus in the FFE.

Darkling beetles (*Alphitobius diaperinus*) were shown to passively carry the virus, but free-living litter mites, mosquitoes, and coccidial oocysts could not be associated with transmission (47, 75, 198). Vertical transmission of MDV does not occur (546, 630, 632). Transmission from dam to progeny as the result of external egg contamination is also unlikely because of poor virus survival at temperature and humidity levels used during incubation (115).

Experimental transmission is accomplished by inoculation of day-old, genetically susceptible chicks with blood, tumor suspensions, or cell-free virus by virtually any parenteral route. Exposure by direct or indirect contact with infected chickens is also effective. The virus can be transmitted by intratracheal instillation or inhalation exposure using cell-free virus preparations. Cellular inocula contain few, if any, infectious virions and are unlikely to cause infection except by parenteral inoculation.

Incubation Period

The incubation period for experimentally induced MD is well established (see reviews 32, 107). Mononuclear infiltrations may be found in nerves and other organs after about 2 weeks (488). Clinical signs and gross lesions, however, generally do not appear until between the third and fourth weeks (484).

The incubation periods can be short for several nonlymphomatous syndromes associated with MDV infection. Cytolytic infections occur at 3–6 days PI and are followed by degenerative lesions (atrophy) of the thymus and bursa of Fabricius within 6–8 days PI (107). The early mortality syndrome is characterized by deaths at 8–14 days PI (721). The clinical expression of both acute and classical forms of transient paralysis usually occurs from 8–18 days PI (343, 710). Field cases of transient paralysis are seen mainly between 6–12 weeks of age, probably reflecting MDV exposure 8–10 days prior to the onset of symptoms. Development of atherosclerosis requires 3–7 months (209). Induction of tumors within 10–14 days after inoculation of cellular material is suggestive of a transplantation response (641).

Local lesions in the wing web are visible 3–4 days PI with allogeneic MDV-infected CKC (118).

Under field conditions, MD outbreaks sometimes occur in unvaccinated layer chickens as young as 3–4 weeks. Most of the serious cases begin after 8–9 weeks but also sometimes commence well after the onset of egg production (358). MD outbreaks in commercial, vaccinated chickens have been termed as "early" and "late" breaks, referring to the apparent failure of vaccines to provide protection (703). The late breaks are especially troublesome and have been known to occur late in the laying cycle (446), or even after chickens have been induced to molt and the second laying cycle has commenced. It is uncertain whether late onset of disease is caused by early (old) or late (recent) infection. Witter and Gimeno (709) infected birds between 18 and 102 weeks of age and found that nonvaccinated birds developed MD within 68 days PI when challenged with highly virulent strains. In contrast, vaccinated birds of similar ages did not develop MD after challenge. The authors suggested that late breaks were not likely the result of recent infections alone and that additional factors are needed to cause the late breaks.

Clinical Signs

Signs associated with MD vary according to the specific syndrome (Tables 15.4A and 15.4B). Chickens with MD lymphoma or fowl paralysis syndromes may exhibit signs, but few are specific to MD (55). In general, signs related to peripheral nerve dysfunction are those associated with asymmetric progressive paresis and, later, complete spastic paralysis of one or more of the extremities. Involvement of the vagus nerve can result in paralysis and dilation of the crop and/or gasping. Because locomotory disturbances are easily recognized, incoordination or stilted gait may be the first observed sign. A particularly characteristic clinical presentation is a bird with one leg stretched forward and the other back as a result of unilateral paresis or paralysis of the leg (Fig. 15.6). However, chickens with MD lymphomas may exhibit few signs and, instead, become depressed and comatose prior to death. Other chickens may appear clinically normal and still have extensive neoplastic involvement when euthanized. Nonspecific signs such as weight loss, paleness, anorexia, and diarrhea may be observed, especially in birds in which the course is prolonged. Under commercial conditions, death often results from starvation and dehydration because of the inability to reach food and water or, in many cases, from trampling by penmates. Some birds develop nervous tics or torticollis 18–26 days after virus exposure, often after recovery from classical transient paralysis. This syndrome has been termed persistent neurological disease (231) and can be induced by partially attenuated MDVs that no longer induce transient paralysis (230). However, the central nervous system (CNS) signs are difficult to distinguish from those associated with MD nerve lesions.

Birds with ocular involvement may show evidence of blindness (214), which can be unilateral or bilateral, although recognition of clinical blindness requires careful observation. Affected eyes gradually lose their ability to accommodate to light intensity.

Early mortality syndrome results in high mortality 8–16 days

15.6. Fowl paralysis. Spastic paralysis of limbs associated with peripheral nerve involvement in Marek's disease. (Witter)

PI of young chickens with virulent MDV strains (667, 721). Chickens become depressed and comatose prior to death, which occurs within 48 hours of the onset of signs. Some affected chickens may also exhibit flaccid neck paralysis prior to death (710). Chickens undergoing acute cytolytic infection at 3–6 days PI may be depressed but rarely die during this period, although some may die later from early mortality syndrome. Immunosuppressed chickens may succumb to ancillary infections, but some chickens die 20–40 days PI with few signs.

A transient paralysis syndrome has been described in field flocks (741) and is associated with MDV infection (343). However, it has been observed infrequently in the field since vaccination for MD has become widespread. Two forms exist, classical and acute. In the classical form, affected chickens display varying degrees of ataxia and flaccid paralysis of the neck or limbs beginning 8–12 days after exposure to the virus by inoculation or contact (Fig. 15.7). Signs typically last 1–2 days followed by a rapid and complete recovery, although recovered chickens may succumb a few weeks later with MD lymphomas. The acute (fatal) form results in death within 24–72 hours following the onset of paralytic signs (710).

Morbidity and Mortality

The incidence of MD is quite variable in commercial flocks. Although a few birds that develop signs apparently recover from the clinical disease (65, 89), the recovery is rarely permanent; chickens that develop clinical disease usually die. Prior to the use of vaccines, losses in affected flocks were estimated to range from a few birds to 25 or 30% and occasionally as high as 60%. In broilers, MD condemnations averaged 1.0% in 1970 and could reach 10% or higher in individual flocks. Presently, nearly all commercial egg-type chickens are vaccinated against MD, and this has reduced losses to less than 5% in most countries (526). Broiler flocks, which are vaccinated in some but not all countries, may experience mortality of 0.1–0.5% and condemnations of 0.2% or more (526). The average condemnation rate for MD in the United States has decreased dramatically (Fig. 15.5B), falling to less than 0.001% in most regions in 2002 (432). However, spikes in condemnations can occur as was noted in Delmarva in 2005 (561).

Some flocks experience significant disease outbreaks despite

15.7. Transient paralysis. Flaccid paralysis of neck of young chicken 9 days after inoculation with Marek's disease virus. (Courtesy of *Avian Diseases*) (Witter)

vaccination. After the disease appears, mortality builds gradually and generally persists for 4–10 weeks. Outbreaks occur in isolated flocks or occasionally in several flocks in a region or in succeeding flocks on a farm. An interesting, albeit fortunate, tendency has developed for regional outbreaks to abate spontaneously. The reasons for the occurrence and cessation of regional outbreaks are poorly understood.

Response rates or mortality approaching 100% for lymphomas, early mortality syndrome, acute cytolytic infection, or transient paralysis can be achieved following inoculation or exposure of unvaccinated, susceptible chickens to MDV. Because the response frequency is influenced by many factors (see below), laboratory experiments can be designed to produce a wide range of specific clinical and pathologic responses.

Factors That Influence Mortality and Lesions
Virus Strain
The virulence of MDV strains varies widely and appears to have increased over time (699). Compared to the milder forms of the disease, which caused mainly peripheral nerve lesions, the more virulent MDV pathotypes more frequently induce higher mortality and more visceral lymphomas, and have the tendency to more frequently break through genetic host resistance or immunity induced by vaccination (66, 721). In some outbreaks, a high incidence of blindness and ocular lesions appeared to be related to only certain virus strains (214, 638). However, in other trials, many contemporary MDV strains appeared to induce ocular lesions (699). The extent of disease induced by a given strain depends in part on the genetic constitution of the host (575).

Virus Dose and Route
Dosage may influence disease frequency under natural conditions, although the MD response in genetically susceptible birds given virulent virus was found to be maximal even when a limiting dilution of virus was inoculated (628). Route of exposure probably functions in the same manner because less efficient routes may effectively decrease the dose to the bird.

Host Gender
Biggs (56) cited several studies in which it was observed that females died earlier and experienced higher losses than males. The difference was apparently not due to sex hormones, varied with the genetic strain, was most pronounced with susceptible strains of chickens, and was most apparent with viruses of higher virulence. In practice, the influence of gender appears variable and is probably less important than other factors.

Maternal Antibody
Maternal antibody reduces and delays MD mortality (151) and virtually all other manifestations of the disease, probably by limiting the spread of virus in tissues during the first few days post exposure (99, 488). Transient paralysis can be reproduced consistently only in chickens lacking maternal antibodies (343). The early mortality syndrome is reduced markedly in chickens with maternal antibodies (721). Breeder stocks are vaccinated uniformly and exposed to virulent MDV, and, therefore, virtually all chickens are hatched with maternal antibodies (normally against multiple viral serotypes). SPF flocks are a source of antibody-free chicks for laboratory studies. Thus, unlike some other virus infections, passive antibodies do not provide a sterilizing immunity, and antibody-positive chickens can be infected successfully and vaccinated, albeit with reduced responses.

Host Genetics and Age at Exposure
Genetic factors and age at initial exposure are important determinants of MD susceptibility (see reviews 25, 86). Genetic resistance correlated with the development of virus-neutralizing antibody (99, 607) and retention of cell-mediated immune functions (372, 582). This resulted from a sparing of immune competence in the case of resistant birds, rather than from an inherent difference between strains (259, 260, 627).

Newly hatched chicks and older chickens are both susceptible to infection and cytolytic infection (107), but in older chickens, cytolytic infections are resolved more rapidly (97) and virus load is somewhat lower (181). The frequency of lymphomas is variable and often markedly reduced in older chickens compared to newly hatched chicks, especially in genetically resistant lines (19, 101, 668, 724). However, nonvaccinated, SPF, older chickens may develop high rates of lymphomas and transient paralysis following challenge with vv and vv+ strains (548, 709). Age-related resistance can be abrogated by neonatal thymectomy (610) suggesting that other immunosuppressive stress factors may increase the susceptibility of older chickens to disease, at least under some conditions. Lesion regression has been identified as the basis for age-related resistance (608).

Prior Infection
Before the use of vaccines, naturally occurring infections with serotype 2 MDV often provided some protection against later exposure to oncogenic strains (307). Mild strains of serotype 1 MDV also can induce protective immune responses (628). However, the influence of natural infections with avirulent serotype 1 MDVs on disease response in vaccinated chickens probably is

minimal and, at present, such infections are not likely to have much clinical importance.

Environmental Factors and Stress

Various environmental factors and intercurrent infections appear to affect the incidence of MD, probably through interference with host immune responses. Gross (237) observed increased incidence among chickens selected for high concentrations of plasma corticosterone or subjected to a high degree of social stress. The administration of corticosteroids to latently infected chickens precipitated the appearance of clinical MD (507) and the feeding of corticosteroid inhibitors tended to increase resistance to the disease (160). Restricted feed intake delayed and reduced incidence of MD (247) whereas high-protein diets (524) or the selection of chickens for fast growth rate were associated with increased susceptibility to the disease (246).

Effects of intercurrent infections with other avian pathogens on MD have been extensively studied. Because MDV infection may depress host immune responses in its own right, concurrent infections are often exacerbated. Examples include coccidiosis (61) and cryptosporidiosis (1, 434). However, when the concurrent infection is itself immunosuppressive, the resulting immunosuppression usually will exacerbate both disease processes. Examples include IBDV, REV and CIAV (316, 677, 678, 713). Unfortunately, MDV stocks occasionally have become contaminated with other viruses, especially when propagated in chickens. Problems with CIAV contamination invariably interfere with the evaluation of MDV stocks for relative virulence (418).

Pathology

Gross Pathology

Pathologic changes in MD have been reviewed (482, 483, 485) and consist mainly of nerve lesions and visceral lymphomas. Enlarged peripheral nerves are a frequent finding in affected birds. Macroscopic changes are not seen in the brain, but gross enlargements can be found in spinal ganglia. Lesion distribution appears to be similar for naturally occurring and experimental diseases (471, 484). Goodchild (233) found that many nerves and plexi were commonly affected, but the celiac plexus was most commonly involved. Usually, plexi of the sciatic and brachial nerves are more enlarged than the respective trunks. Witter (697) has found the cervical vagus to be of particular diagnostic importance.

Nerves

Severely affected peripheral nerves may show loss of cross-striations, gray or yellow discoloration, and sometimes an edematous appearance. Localized or diffuse enlargement causes the affected portion to be 2–3 times normal size, in some cases much more. However, minimal enlargements may be important indicators of disease in experimental infections. Because lesions are often slight or unilateral, it is helpful to examine opposite nerves and, in experiments, to compare with age-matched normal controls to detect changes. Careful examination of the various nerve ramifications may be necessary to expose gross lesions in some

15.8.   Enlarged sciatic plexus (left) and normal plexus (right). (Peckham)

birds, because enlargements can vary in both presence and degree from one portion of an affected nerve to another. Fig. 15.8 illustrates unilateral gross enlargements in the sciatic plexus.

Visceral Organs

Lymphomas may occur in one or more of a variety of organs and tissues. Lymphomatous lesions can be found in the gonad (especially the ovary), lung, heart, mesentery, kidney, liver, spleen, bursa, thymus, adrenal gland, pancreas, proventriculus, intestine, iris, skeletal muscle, and skin. Probably no tissue or organ is without occasional involvement. Both the genetic strain of chicken and the virus strain can influence the organ distribution of lesions. Visceral lymphomas are common in more virulent forms of the disease (699). Visceral tumors can occur in the absence of gross nerve lesions, especially in certain strains of chickens. MD lymphomas in most viscera appear as diffuse enlargements, sometimes to several times the normal size, and a diffuse white or grayish discoloration is often present (Fig. 15.9B). Alternatively, lymphomas may occur as focal, nodular growths of varying size (Figs. 15.9E, F). Nodules are white or gray in color and are firm, and the cut surface is smooth. Necrosis is rare but may occur in the center of rapidly growing lesions.

Diffuse infiltration of the liver causes loss of normal lobule architecture and often gives the surface a coarse granular appearance. Nodular tumors may also be seen in the liver. Lesions in the immature ovary are observed as small to large grayish translucent areas (Fig. 15.9B). With large tumors, the normal foliated appearance of the ovary is obliterated. Mature ovaries may retain function, even though some follicles are tumorous. Marked involvement is indicated by a cauliflower-like appearance. The proventriculus becomes thickened and firm as a result of focal leukotic areas within and between the glands, which may be seen

through the serosal surface or, if involvement is diffuse, detected by palpation. Affected hearts are pale from diffuse infiltration or have single or multiple nodular tumors in the myocardium (Fig. 15.9F), or pinpoint foci may be seen in the epicardium. Involvement of the lung (Fig. 15.9E) and proventriculus may be indicated by increased firmness of the organ upon palpation. Muscle lesions may be present in both superficial and deep layers and are most common in the pectoral muscle (50). Gross changes vary from tiny whitish streaks to nodular tumors.

Integument

Skin lesions, probably the most important cause of condemnation in broiler chickens, usually are associated with feather follicles. The nodular lesions may involve few scattered follicles, or they may be numerous and coalesce. The distinct whitish nodules (Fig. 15.9A), especially evident in dressed carcasses, may become scablike with brownish crust formation in extreme cases (50). Lapen and Kenzy (362) found lesions in certain feather tracts more frequently than in others; the highest incidences were in external and internal crural and dorsal cervical tracts. Erythematous involvement of the shank integument is seen, especially in virulent forms of the disease in broiler chickens and is commonly known as "Alabama redleg." Swelling of the comb or wattles may indicate lymphoma growth in underlying tissues (199).

Eye

Gross ocular changes include loss of pigmentation in the iris ("gray eye") and irregularity of the pupil, both the result of mononuclear infiltration of the iris (Fig. 15.9C). Ficken *et al.* (214) described cases in which conjunctivitis, occasionally with multifocal hemorrhages and corneal edema, were observed. Witter (699) found that nearly all field isolates induced ocular lesions in nonvaccinated or HVT-vaccinated chickens; rates ranged from 5–100%.

Other Syndromes

Gross lesions are associated with at least some of the other syndromes that are associated with MDV infection. The lymphodegenerative syndromes, related to intense cytolytic infections of lymphoid organs, usually are characterized by severe atrophy of the bursa of Fabricius and thymus. The cytolytic infection is first evident 3–6 days after infection, but in some cases persists and is more obvious at 8–14 days after infection (Fig. 15.10) (113, 667, 721). After inoculation with highly virulent field strains, some chickens may die at 20–50 days without gross lesions except severe bursal and thymic atrophy (699). Some chickens also develop a transient splenomegaly within 4–12 days after inoculation (111). The splenomegaly is a nonneoplastic response to viral replication because it is induced by both virulent and avirulent serotype 1 strains as well as serotype 2 and 3 strains. Vascular syndromes are manifested principally by occlusive atherosclerosis (210). Susceptible P-line chickens inoculated with the CU2 isolate of MDV developed grossly visible fatty atheromatous lesions in large coronary arteries, aortas, major aortic branches, and other arteries (Fig. 15.9D). Lymphoid tumor transplants and local lesions are experimental syndromes characterized by nodu-

lar growths at the site of inoculation, although some transplantable tumors metastasize readily to the liver and spleen, causing diffuse enlargements (641). The gross appearance of transplants varies with the transplant, the host chicken, and the route of inoculation.

Microscopic Pathology

Histopathologic changes associated with MD lymphoproliferative lesions have been described by numerous workers who are in general agreement about the types of histologic lesions and the cells involved (480, 485).

Nerves

In peripheral nerves, 2 main types of lymphoproliferative lesions are recognized. One type is considered neoplastic, consisting of masses of pleomorphic lymphocytes; in some cases, demyelination and Schwann cell proliferation are associated with this lesion. The second type is essentially inflammatory and is characterized by diffuse, light-to-moderate infiltration by small lymphocytes and plasma cells, usually with edema, and sometimes, with demyelination and Schwann cell proliferation. A few macrophages may be found. Payne and Biggs (484) referred to these lesions as type A and B, respectively, and noted that the 2 types may be observed in different nerves of the same bird or even in different areas of the same nerve. Lawn and Payne (365) observed cellular infiltrations as early as 5 days PI, which gradually increased in intensity until 3 weeks when severe proliferative (type A) lesions were seen in the absence of paralysis or demyelination. Coincident with initial neurologic signs seen at 4 weeks PI, areas of widespread demyelination could be found within the

proliferative lesions. Finally, characteristic inflammatory (type B) lesions (edema, sparse infiltrations) appeared. The sequence of events has been reviewed in detail by Payne *et al.* (485). Characteristic changes in nerves are illustrated in Fig. 15.11.

Brain

Initial reports identified mild perivascular cuffing usually accompanied by gliosis but without primary demyelination as the principal CNS lesion in MD (reviewed in 485). Wight (682) found that the CNS of affected birds was often histologically normal or with only minimal lesions. Following experimental inoculation with less virulent MDV strains, lesions could be seen as early as 7–10 days PI and were of moderate severity (488, 592). However, lesions induced by vvMDV strains appeared earlier and were more extensive (228). The initial lesions (also described under "CNS Syndromes") involve vascular elements; endotheliosis occurs at 6 days PI and is followed at 8–10 days PI by a moderate to severe infiltration of lymphocytes and macrophages around blood vessels and scattered throughout the neuropil (228). The vasculitis and edema disappear and may be followed by lymphoproliferative infiltrations of large lymphocytes and glial cells. These lesions tend to persist and are associated with persistent neurological disease. Severe lymphoblastic infiltration, often accompanied by extensive vacuolated areas that may correspond with secondary demyelination, has been shown to occur 4 weeks after inoculation with a highly virulent MDV (228). Infection with the C12/130 (a hypervirulent strain) and RK-1 (a vv+ strain) showed infiltration with monocytes in addition to T cells in the perivascular cuffs. These monocytes were expressing pp38 after infection with C12/130 (43) but not after infection with RK-1 (451). However in RK-1-infected birds many of the monocytes were in mitosis and apoptotic cells were often observed first in the white matter and later in the gray matter. Cho *et al.* (147) reported severe necrotizing and nonnecrotizing lesions in the brains of chickens up to 10 weeks PI with vvMDV. Thus, as in nerves, brain lesions are both inflammatory and lym-

phoproliferative. In contrast with nerves, however, the inflammatory lesions are induced first (231). Severe lymphoid infiltration in the cerebellum is shown in Fig. 15.12.

Visceral Organs

Lymphomatous lesions in visceral organs are more uniformly proliferative in nature than those in nerves (Fig. 15.13). Cellular composition is similar to that of the proliferative lesions de-

scribed for nerves, consisting of diffusely proliferating small-to-medium lymphocytes, lymphoblasts, and activated and primitive reticulum cells (527) (Fig. 15.14). Plasma cells are rarely present (527). Macrophages are also present in the tumor mass, especially in slow-growing tumors, perhaps reflecting the host immune response (52). The cellular composition of tumors is similar from one organ to another, even though the gross pattern of involvement may vary. Ultrastructural features of tumor cells have been described by several workers (191, 219). Pradhan *et al.* (515) found immune complexes in the kidney, leading to glomerulopathy, in MDV-infected chickens. They suggested that these lesions might be one of the major causes of death in MD.

Integument
Lesions in the skin appear largely inflammatory but may also be lymphomatous. They usually are localized around infected feather follicles. In addition, compact aggregates of proliferating cells, often perivascular, and a few plasma cells and histiocytes may be seen in the dermis (255, 484). With small lesions, the architectural integrity of skin is maintained, but massive proliferative lesions may cause disruption of the epidermis, resulting in an ulcer. Moriguchi *et al.* (427) described both inflammatory and lymphoproliferative lesions in the feather pulp; the latter were closely related to the incidence of MD. Feather pulp lesions may

be useful for antemortem diagnosis. Lymphoproliferative nodules often surround feather follicles that contain MDV viral antigens and intranuclear inclusions in the FFE (110, 149).

Eye
The most constant change in the eye is mononuclear infiltration of the iris, but infiltrates may also be found in eye muscles, especially in rectus lateralis and ciliaris (324). Granular or amorphous material is sometimes present in the anterior chamber. Other, but more rarely, observed lesions involve the cornea (near Schlemm's canal), bulbar conjunctiva, pecten, and optic nerve. The unusually severe ocular lesions described by Ficken *et al.* (214) include uveal changes with increased aqueous humor protein and vascular engorgement and mild hyperemia to severe swelling of the iris. These authors also observed severe inflammatory changes and edema of the cornea, including intranuclear inclusion bodies. Sevoian and Chamberlain (591) and Smith *et al.* (629) reproduced ocular lesions experimentally. The latter reported that infiltration of proliferating lymphoreticular cells in optic and ciliary nerves and uvea were followed by similar infiltrations throughout the eye. Dukes and Pettit (193) found cataracts present in 7 of 18 spontaneous cases of ocular MD.

Blood
Blood leukocyte counts may be elevated, largely because of increased numbers of large lymphocytes and lymphoblasts (477). Payne *et al.* (487) identified the majority of leukemic cells as T cells. The leukemic response is not consistent and may be absent, or only a mild leukocytosis may be present (324, 592). Infection

with the hypervirulent C12/130 strain caused significant increases in the absolute number of blood monocytes around 8 days PI. B cells, CD4$^+$ and CD8$^+$ T cells decreased during the early cytolytic infection followed by an increase between 8 and 10 days PI, but these changes were also seen for T cells after infection with HPRS-16 (43). Bone marrow changes in MD have variously been reported to include multiple tumor nodules (592), aplasia (309) but the MDV strain was later found to be contaminated with CIAV (567), or changes were not observed (527). Gilka and Spencer (226) described an extravascular hemolytic anemia in MDV-inoculated chickens characterized by reduced packed cell volumes. The importance of this finding is not clear because hematocrit values are not routinely used as a MD parameter.

Lymphodegenerative Syndromes

Productive herpesvirus replication in the bursa of Fabricius and thymus results in transient, acute cytolytic changes in these organs accompanied by atrophy (citations in 105, 485). In experimental infections, bursal lesions consist of follicular degeneration, lymphoid necrosis with depletion, and cyst formation (Fig. 15.15 *top*). Thymic atrophy is often severe, and lymphocytes are depleted in both cortex and medulla (see Fig. 15.15 *bottom*). Intranuclear inclusions can sometimes be found in cells associated with degenerative lesions. Viral antigens can be abundant during the acute cytolytic phase, especially in the medullary regions of the thymus and in some but not all bursal follicles (see Fig. 15.16). Chicks infected in the absence of maternal antibody may develop focal or generalized necrosis in a variety of organs, including the kidney (100, 215, 309). Following the acute cytolytic phase, antigen-positive cells disappear, and at least partial repopulation with lymphocytes occurs. Bursal and thymic atrophy, however, may persist for several weeks or longer. In the

bursa, some interfollicular lymphoid infiltration with T cells may occur.

The early mortality syndrome, although normally characterized by severe lymphoid degeneration and death, often with enlarged, necrotic spleens (721), has recently been linked with central nervous system signs and lesions associated with transient paralysis (710).

CNS Syndromes (Transient Paralysis)
Swayne *et al.* (644, 645, 646) reported that the critical lesion in transient paralysis was vasculitis (Fig. 15.17), which resulted in vasogenic brain edema. Leakage of immunoglobulin G (IgG) and albumin around affected vessels resulted in vacuolization. The edema and vasculitis were expressed coordinately with clinical flaccid paralysis and resolved in 2–3 days. Other, apparently unrelated, brain lesions (perivascular cuffing, lymphocytosis, and gliosis) could be observed after clinical recovery or in infected but clinically normal birds. Ultrastructural changes did not include demyelination (355, 645). CNS pathology associated with an acute (lethal) form of transient paralysis was similar in nature, albeit somewhat more severe, than in the classical syndrome (231, 710).

Vascular Syndromes
Arterial lesions reported to be associated with MDV-induced atherosclerosis include proliferative and fatty-proliferative changes in aortic, coronary, celiac, gastric, and mesenteric arteries (210, 419) (Fig. 15.18A, B). Internal and medial foam cells, extracellular lipid, cholesterol clefts, and calcium deposits characterized the fatty-proliferative lesions. Also, MD viral antigens could be detected by immunofluorescence adjacent to the arterial lesions. An altered lipid metabolism is suggested by the finding of Fabricant *et al.* (211) that MDV infection of arterial smooth muscle cells *in vitro* induced accumulation of phospholipids, free

fatty acid, cholesterol, and cholesterol esters. *In vivo* studies supported this conclusion; Hajjar *et al.* (243) found that lipid accumulations in aortas resulted, in part, from altered cholesterol or cholesteryl ester metabolism during early stages of the disease.

Tumor Transplants and Local Lesions
Tumor transplants are composed of uniform, lymphoblastic cells with few, if any, infiltrating host cells (641) or, particularly in regressing tumors, may include small lymphocytes, heterophils, vascular invasion, and necrosis (216). Local lesions induced in the wing web or pectoral muscle by inoculation of MDV-infected, allogeneic kidney cells are inflammatory in nature, consisting of lymphocytes and macrophages and sometimes accompanied by hemorrhage and necrosis (118).

Pathogenesis
Several recent reviews on the pathogenesis of MD have been published (32, 107, 584). The review by Calnek (107) also provides several references for older reviews. The use of BACs and overlapping cosmid technologies has allowed the deletion of specific genes. Many of the deletion mutants have been examined in cell culture (467), but the importance of only a few genes has been established for the pathogenesis of MDV. These will be discussed in the appropriate sections of the pathogenesis. Unfortunately, the oncogenic RB-1B BAC clone (501) does not spread horizontally (313), which limits the information on specific genes for the replication in the FFE.

Four phases of infection *in vivo* can be delineated: 1) early

productive-restrictive virus infection causing primarily degenerative changes; 2) latent infection; 3) a second phase of cytolytic, productive-restrictive infection coincident with permanent immunosuppression; and 4) a proliferative phase involving nonproductively infected lymphoid cells that may or may not progress to the point of lymphoma formation (Fig. 15.19). This division is somewhat arbitrary and phases 2–4 can coexist in different cells in the same bird. Infection with some of the vv+ strains may not follow this general pattern, and mortality can occur without even entering into the latent phase. The next section, however, will describe the classical pathogenesis in lymphoid tissues, based mostly on studies in SPF chickens. The pathogenesis of infection in the FFE involves epithelial cells and will be discussed in the section on cytolytic infection in FEE.

Early Productive-restrictive Infection (Phase 1)
The virus enters the host via the respiratory tract and cell-free virus reaches the lymphoid organs within 24–36 hours after intratracheal inoculation (562). MDV is probably transferred to the lymphoid organs by phagocytic cells, presumably macrophages. Recently Barrow *et al.* (42) provided support for this hypothesis by demonstrating the presence of MDV transcripts in the cytoplasma and nucleus of splenic macrophages. Because virus particles could not be demonstrated, it is not sure if this is an abortive or productive infection. Shortly thereafter, cytolytic infection can be detected in the spleen, bursa of Fabricius, and thymus, peaking at 3–6 days. Shek *et al.* (612) discovered that the primary target cells in all 3 organs are B cells. Activated but not

resting T cells can also undergo cytolytic infection (122, 124, 125). Baigent *et al.* (33, 36, 37, 42) confirmed that the early cytolytic infection occurs mostly in B cells using dual staining techniques with MAb specific for B and T cell markers and a pp38-specific MAb. In addition, they demonstrated that a small percentage of CD4$^+$ and CD8$^+$ T cells expressing TCRαß1, TCRαß2, and TCRγδ can become cytolytically infected during the early phase of the pathogenesis. The consequence is a transient atrophy of the lymphoid organs, especially the thymus and the bursa. Depending on the virulence of the challenge strain, birds may recover between 8–14 days PI, or the atrophy may become permanent (111, 113). The cytolysis is likely initiated by the activation of the host shut-off protein (see "Virus Replication") leading to cell death by apoptosis (429). Although MDV-infected cells in the thymus are mostly B cells (612), thymocytes undergo massive apoptosis possibly as the consequence of viral infection (36) or virus-induced cytokine changes.

Changes in proinflammatory cytokine expression occur in splenocytes during the cytolytic phase. The level of upregulation and the cytokines involved may depend on interactions between the pathotype of the virus and the genotype of the host (311, 325). Several groups reported the upregulation of IFN-γ mRNA in splenocytes as early as 3 to 4 days PI (190, 311, 315, 325, 733), but not in circulating blood leukocytes (534). Upregulation of IL-1ß and IL-8 has been reported (311, 733) but not by others (325). Two other proinflammatory cytokines, IL-6 (311, 325) and IL-18, are also upregulated (325). In addition to the cytokines, inducible NO synthase (iNOS, officially named NOSII) is also upregulated during the cytolytic infection (733) (see "Immunity").

The increased expression of cytokines may also explain the hyperplasia of lymphoid and reticulum cells (485), causing splenomegaly (111). The level of infection is in general similar in genetically resistant and susceptible strains during the early cytolytic period (4, 213, 325, 740). However, genetically resistant line 6 chickens have a significantly lower level of infected lymphocytes than susceptible line 7 chickens. Lee *et al.* (372) suggested that this was due, in part, to a deficiency in the aggregate number of target cells in line 6. Baigent *et al.* (33, 36) showed that line 7 birds have more cells expressing pp38 during the cytolytic phase than line 6 birds, but that there are more B cells in the spleens of line 6 than line 7 chickens. In spleens of line 7 birds, dramatic changes occur with irregular patches of pp38$^+$ B cells becoming surrounded by TCRαß1$^+$ CD4$^+$ and CD8$^+$ cells, thus providing optimal conditions for virus transfer from B to T cells. These data suggest that MDV may replicate and spread more efficiently in line 7 than line 6 chickens. Interestingly, Calnek *et al.* (124) reported that B cells from line 7 are more susceptible to *in vitro* infection than B cells from line 6.

The early activation of IFN-γ may be important for the upregulation of the IL-8 receptor on activated T cells, so that vIL-8 can attract activated T cells to lytically infected B cells and facilitate the transfer of virus to T cells (475, 584). Recent studies using deletion mutants lacking vIL-8 or the first exon of vIL-8 clearly support the importance of vIL-8 for the early cytolytic infection. Infection with these mutants resulted in a significant reduction in virus replication during the early lytic infection and a subsequent

decrease in tumor incidence (163, 168, 314, 475). In addition to vIL-8, pp38 is also essential for the early cytolytic infection (229). Deletion of *meq*, RLORF4, RLORF5a, vLIP (LORF2), or viral telomerase did not significantly impact phase 1.

Several factors can modify the early pathogenesis. Prior vaccination and the presence of maternal antibodies reduce the cytolytic infection (100, 121, 574, 628). The reduction in cytolytic infection also will reduce the number of latently infected cells and reduce or delay tumor development. Exposure at 1 day of age prolongs the cytolytic infection compared to exposure at 2 or 7 weeks of age (97). Likewise, the pathogenicity of the virus strain may affect the severity of early infection. The vv strains (e.g., Md5) and vv+ strains (e.g., RK-1) can cause more severe lymphoid organ atrophy than the less oncogenic strains, resulting in an early mortality syndrome (113, 721).

The apoptosis of lymphocytes during the early cytolytic phase may cause transient or permanent immunosuppression, depending on the virulence of the challenge strain. In addition, a transient suppression of mitogen stimulation has been reported, but this may actually represent a protective response (581, 584). The importance of these observations is discussed in "Immunosuppression."

Latent Infection (Phase 2)

At about 6–7 days, the infection becomes latent when cytolytic infection can no longer be demonstrated, and tumors are not yet detectable. The development of latency coincides with the development of immune responses. The interactions between virus and cells during the induction of latency are incompletely understood. Impairment of cell-mediated immunity (CMI) delays the start of latency (97). The onset of latency is also delayed after infection with the more virulent pathotypes (740). Several soluble factors have been implicated in the induction of latency including IFN-α, IFN-γ, latency maintaining factor or LMF, and NO (96, 671, 734). Based on infection of CEF with RB-1B in the presence of IFN-containing supernatants, Levy *et al.* (381) suggested that IFN may block virus replication before translation of late genes.

Most latently infected cells are activated CD4$^+$ T cells, although CD8$^+$ T cells and B cells can also be involved (125, 376, 557, 612). Infection in genetically resistant birds often remains latent and can last for the lifetime of the bird (729), aside from a persistent low-grade productive infection in the FFE (101, 114, 372, 636). Apoptosis of T cells during latent infection has been described (428, 430), although it cannot be excluded that MDV was reactivated in these cells. Susceptible birds or resistant birds infected with vv or vv+ strains may develop a second wave of cytolytic infections after the second or third week, coincident with permanent immunosuppression.

The extent to which nonlymphoid cells are latently infected is not known, although apparent latent infection has been observed in Schwann cells and satellite cells in spinal ganglia (499).

Second Phase of Cytolytic Infection (Phase 3)

The second cytolytic infection phase has not been studied in great detail. It occurs in lymphoid organs, and localized foci of

infection can be found in tissues of epithelial origin in various visceral organs (e.g., kidney, pancreas, adrenal gland, proventriculus, etc.). Focal cell death and inflammatory reactions develop around affected areas (9, 107). The secondary cytolytic infection does not always occur. The development and extent of the secondary cytolytic infection depends on genetic resistance of the host and the virulence of the MDV strain.

Cytolytic Infection in FFE

Cytolytic infection occurs also in the FFE (114). The replication of virus in the FFE is unique in that it is the only known site of complete virus replication. The replication occurs in genetically resistant as well as susceptible birds independently of the virulence of the MDV strain. MDV most likely is transferred to the FFE by infected lymphocytes. Viral DNA of CVI988 was detected as early as 7 days PI by qPCR (38), although it is not known if this represents infectious cell-free virus. Lymphocyte aggregates consisting of small lymphocytes with nuclear inclusions can be detected in the perifollicular dermis as early as 7 days PI (148). The lymphoid aggregates can develop into either necrotic areas consisting of FFE cells and degenerating lymphocytes or into cutaneous tumors. The former is associated with strong expression of pp38, but the latter has only a few pp38$^+$ cells. It is likely that virus is reactivated from latency in the FFE, because mutant strains lacking vIL-8 (168) or pp38 (229) are able to produce virus in the FFE. Niikura et al. (450) examined the time course of protein expression in the FFE. pp38 is the first protein expressed in lymphocytes after reactivation, followed by the expression of gB in the inner layers of the epithelial cells. Finally, gD is expressed in the cell layer in contact with the feather shaft. The importance of expression of gD is unclear because gD deletion mutants do spread like wild-type virus (18).

Development of Lymphomas (Phase 4)

Lymphoproliferative changes, constituting the ultimate response in the disease, may progress to tumor development. Death from lymphomas may occur at any time from about 3 weeks onward. Regression of lesions has been reported after infection with vMDV strains and depends on the genetic resistance of the bird and the age at infection (89, 608).

The composition of lymphomas is complex, consisting of a mixture of neoplastic, inflammatory, and immunologically committed and noncommitted cells (490). Both T and B cells are present, although the former predominate (489). The transformed T cells are mostly CD4$^+$ cells expressing TCRαß1 or TCRαß2 and MHC class II (577). Infection of chickens in the wing web or breast muscle (118) or of chickens depleted of T cells (458) showed that other subsets (e.g., CD8$^+$ CD4$^-$, CD3$^-$CD4$^-$CD8$^-$ and CD3$^+$CD4$^-$CD8$^-$) can be transformed (458, 577). Burgess et al. (91) further characterized tumor cells using ex vivo lymphoma cells and tumor cell lines as MHC class I^{hi}, MHC class II^{hi}, CD4$^+$, TCRαß1$^+$ or TCRαß2, CD28$^-$, CD30^{hi}, IL-2Rα$^+$. The expression of high levels of CD30 using MAb AV37 led Burgess et al. (93) to suggest that MD could be a natural model for Hodgkin's disease. In addition to these markers, tumor cells may also express MATSA (731) and various poorly characterized fetal antigens (508).

The infection in transformed cells is nonproductive in vivo and in vitro. CD4$^+$ and CD30^{hi} tumor cells express Meq and SAR (see "Viral Genes and Proteins"), but are negative for pp38 and gB (91, 557). Additional genes, for example RLORF4 (312) and RLORF5a (456), may also be expressed in tumor cells, but the importance of their expression remains unknown. Low numbers of tumor cells may express pp38, which probably represents cells in which a productive-restrictive infection has been initiated. Based on in vitro studies it is suggested that the expression of pp38 and late genes in tumor cells may be under control of IFN (381, 672).

The possibility that MD tumors are of clonal origin has been proposed based on observations of random MDV DNA integration into the genomes of lymphoma cells (187). Although integration was random, the pattern of integration sites among cells from a given lymphoma or a given lymphoma-derived cell line was consistent. This work has fundamental implications regarding the pathogenesis of MD but awaits confirmation and further definition. Earlier studies by Schat et al. (577) showed that different lymphomas in the same bird could yield cell lines representing different T-cell phenotypes.

Studies of graft-versus-host reactions in different genetic strains led to the suggestion that low alloimmune competence and resistance to MD are very closely related through genetic linkage or functional dependence (398, 491). This prompted speculation by Schat et al. (578) and Calnek (105) that the activation of T cells in response to the lytic infection of B cells constitutes a significant event in the pathogenesis of MD by providing an abundant supply of cells that are the usual target cells for transformation. This hypothesis has been borne out by studies by Calnek et al. (108, 118) showing that tumor induction at the site of inoculation with MDV is enhanced by provoking a CMI reaction against allogeneic cells at the site. It is plausible that transformation requires 1) susceptibility to infection; 2) intrinsic or extrinsic control of virus replication (latency); 3) cell division to integrate virus genome; and 4) expression of viral oncogenes, activation of cellular oncogenes, or repression of the induction of apoptosis. Activated T cells infected at the time that cytokines and/or CMI responses cause a switch to latency could fit this model. Interestingly, cells present as early as 4 days after inoculation of MDV-infected allogeneic CKC can be grown in vitro as MD cell lines (118). Thus, transformed cells, or at least transformation target cells, may be present even during the early cytolytic phase of MD.

Factors Influencing Pathogenesis

The pathogenesis of infection with oncogenic MDV, which has become attenuated by passage in vitro, has been studied by Bradley et al. (quoted in 485) and Schat et al. (576). Both groups found that attenuated virus failed to cause cytolytic infection of lymphoid organs and that cell-associated viremia levels were low. The latter authors further learned that attenuated virus was not infectious for lymphocytes in vitro, perhaps explaining the in vivo observations.

The actual mechanism(s) by which pathogenesis is altered in the case of host resistance is not clear. CMI probably is involved,

however, and evidence (see "Immunity") suggests that immune responses of the host may be directed against either the early virologic events or the later proliferative phase and that an effective response at either stage might reduce the chance of overt disease. Both age and genetic resistance are dependent on immunologic competence (101, 610). The availability of appropriate target cells for viral replication is also important as was demonstrated for line 6 versus line 7 (33, 372). If the hypothesis is correct that tumor development is enhanced by a strong T-cell response against the early cytolytic infection of B cells, then factors that limit that response should reduce tumor incidence. Vaccinal immunity, embryonal bursectomy, and splenectomy suppress the active viral infection (121, 563, 573, 574, 628), thereby obviating an inflammatory response and reducing the incidence of tumors. Interestingly, evidence (citations in 103, 108, 117) shows that some genetic strains with unusually strong CMI responses are especially susceptible to MD, although this is not true in all cases.

Virus strains differ in oncogenicity, but the molecular basis for differences in pathogenesis associated with the strains are not well defined. All cause similar early cytolytic infections, although the vv+ strains may cause a prolonged and more severe cytolytic infection. Some of the new strains are capable of infecting macrophages leading to increased death of macrophages (37, 42, 44).

The immune response itself may be responsible for some lesions characteristic of MD. Nerve lesions have some characteristics suggestive of an autoimmune disease (523, 586), and MD has been identified as a model for the Landry-Guillain-Barré syndrome (499). Additional evidence supporting an autoimmune component for MD comes from studies showing immune complexes in the kidneys of MDV-infected chickens and quail (336, 515).

As indicated previously, these events are based on studies in SPF chickens under controlled conditions. However, the primary cytolytic infection is not an absolute prerequisite for tumor development. Schat *et al.* (573) found that MDV infection in embryonally bursectomized chickens resulted in the development of tumors in the absence of the primary cytolytic infection. These results are similar to the development of tumors in the absence of cytolytic infection during phase 1 of the pathogenesis after infection using vIL-8 and pp38 deletion mutants (168, 229, 314, 475). Apparently, enough activated T cells are available at the time of challenge to become infected. Thus, cytolytic infections may not be absolutely essential for the development of tumors, which also may be the case in vaccinated, commercial chickens. However, stress and immunosuppressive infections perhaps may induce secondary cytolytic infections, reducing the benefits provided by vaccination.

Pathogenesis of in ovo Infection

An understanding of the pathogenesis of infection after *in ovo* injection of the 3 serotypes has become important in view of the widespread use of *in ovo* vaccination. HVT could be isolated from embryonal lung tissues at 1 day PI in the amniotic fluid at ED 17, while chorioallantoic membranes, embryonal spleen, and proventriculus remained negative. However, spleens were virus positive at 4 days post hatch (605). Studies using *in situ* hybridization confirmed these findings (640).

The target cells for HVT in the lung are adherent fibroblastoid or epitheloid cells, but few cells underwent a lytic infection based on the absence of viral proteins (599) and the lack of apoptosis (639). It is possible that HVT did not replicate and that the high titers (605) are the consequence of rapid cell division of infected cells during embryonal development. Perhaps the expression of the anti-apoptotic ORF in HVT (347) and/or the induction of high levels of IFN (600) are responsible for the lack of apoptosis and virus replication.

Low levels of SB-1 or attenuated serotype 1 strain Md11/75C could be recovered from embryonal lung tissues shortly before hatching after inoculation in the amniotic fluid at ED 16 to 18 (598). Intravenous inoculation of RB-1B, a vvMDV strain, at ED 16 resulted in active virus replication in the bursa of Fabricius at ED 21, while intra-amniotic inoculation resulted in the presence of viral DNA in lung and thymus tissue (598, 639, 640). Pathogenic strains and HVT, but not SB-1 or Md11/75C, induce high levels of IFN in embryos after inoculation in the amniotic fluid (600).

Pathogenesis of Nontumor Diseases

MDV infection can cause several nonneoplastic disease syndromes (Table 15.4B). The pathogenesis of MDV-induced atherosclerosis has not been elucidated. Microscopic lesions consisting of fatty proliferative lesions with alterations in lipid metabolism in arterial smooth muscle cells could be detected as early as 1 month after infection (208, 243). CD4+ and CD8+ T lymphocytes infiltrated into the intima as early as 2 weeks PI. In addition, endothelial cells expressed MHC class II antigen in infected but not in normal chickens (452). These cells may have been responsible for the introduction of virus into the smooth muscle cells leading to occasional viral antigen expression and alterations in the lipid metabolism. In contrast to the original work by Fabricant *et al.* (210, 211) Njenga and Dangler (453) were unable to demonstrate arterial lipid accumulation without supplementation of the feed with cholesterol. Intimal cellular infiltrates were detected, and serum cholesterol was increased significantly compared to noninfected control chickens.

The pathogenesis of the neurological lesion complex consisting of classical transient paralysis (TP), acute TP resulting in mortality within 1–3 days PI, persistent neurological syndrome (PND), and late paralysis (LP) (231) is not fully understood. The difference between classical and acute TP is somewhat arbitrary (710) and the early pathogenesis is probably similar. The development of both types of TP is influenced by the MHC and the virulence of the MDV strain with the more virulent strains causing acute rather than classical TP (585, 710). B cells are required for the induction of transient TP (476). The brain lesions start with vasculitis at 6–8 days followed by leakage of albumin from blood vessels into vacuoles (646). This vasogenic edema is transient and correlates with the clinical paralysis associated with classical TP (643). Jarosinski *et al.* (311) noted that the development of neurological symptoms induced by vv+ RK-1 correlated with increased levels of iNOS mRNA in the cerebellum and NO

in blood serum (See "Nitric Oxide"). NO can cause vasodilation and could be the cause of the edema. Chickens inoculated with the vMDV JM-16 strain did not show neurological signs or iNOS mRNA in the cerebellum.

The degree of virus replication in the brain may be related to the severity of the disease. Low levels of virus replication (3) or absence of virus replication (230) correlated with the absence of neurological symptoms. The importance of virus replication in the brain was also shown by comparing JM-16 and RK-1. The former had very low levels of virus replication in the cerebellum and did not induce symptoms, while the replication of RK-1 was significantly higher and produced lesions in MHC resistant and susceptible chickens (311). During attenuation of the vv+ strain 648A by serial passage in CEF, reduction in transient paralysis induction occurred coordinately with a reduction in the level of viral replication in lymphoid organs and FFE (230).

Endothelial cells expressed no viral antigens but became hyperplastic and hypertrophic soon after the virus reached the brain and showed upregulation of MHC class II antigen as early as 6 days PI and downregulation of MHC class I antigens at 10 days PI (228). Infection with RK-1 or RB-1B also caused upregulation of proinflammatory cytokine transcription in the cerebellum including IFN-γ, IL-1ß, IL-6, IL-8, IL-12, and IL-18 (3, 311). The increased expression of IFN-γ, IL-6 and IL-18 was significantly higher in birds with RB-1B-induced classical TP than in asymptomatic MDV-infected chickens (3).

The clinical signs of PND are associated with a strong infiltration of lymphoblasts in the neuropil, many of which express Meq protein, and the later occurrence of this syndrome (about 3 weeks PI) suggests that its pathogenesis may parallel that of lymphoma induction in other tissues. Moreover, persistent neurological disease was shown to be closely related with the onset of lymphoproliferative lesions in peripheral nerves and visceral organs (230).

Immunity

Infection with pathogenic MDV or vaccine strains not only results in the activation of innate or nonspecific and acquired or specific immune responses, but may also cause immunosuppressive effects especially after infection with pathogenic serotype 1 strains. The importance of the interactions between immune responses and immunosuppression for the pathogenesis of MD cannot be overemphasized. A distortion in the balance toward immunosuppression will lead to disease. Immune responses and immunosuppressive features of MD have been extensively reviewed (182, 431, 565, 581, 584).

Immune Responses

The immune responses developing during the early cytolytic phase of infection are crucial for the outcome of infection. Impairment of immune responses during this phase delays establishment of latency resulting in prolonging the lytic infection and the subsequent continued destruction of immune cells by virus-induced apoptosis. Impairments include infection at 1 day of age when the immune responses are not yet fully developed or treatment with cyclosporin or neonatal thymectomy combined with

cyclophosphamide treatment (97). The importance of immune responses during latency is relevant for protection against the second cytolytic phase and is dependent on cell-mediated immunity. It has often been suggested that vaccine-induced immunity is an anti-tumor immune response because vaccination does not prevent superinfection with wild-type virus but does prevent tumor development. However, vaccination clearly reduces the early cytolytic infection (121, 574), thus preventing extensive damage to the immune system and reducing the number of latently infected T cells. Lesion regression, however, has been described (89, 608) suggesting that immune responses against tumor cells may occur. Burgess *et al.* (93) detected specific antibodies against CD30 in resistant line 6 but not in susceptible line 7 chickens after infection with the vMDV HPRS-16 strain. This important finding needs further study, because there is no evidence that HPRS-16 induced CD30^{hi} cells (See "Development of Lymphomas") in line 6 birds (89, 93).

Initiation of Immune Responses. Professional antigen-processing cells (APC), such as dendritic cells, encountering pathogens are activated by interactions between the pathogen-derived pathogen-associated molecular patterns (PAMS) and the pattern recognition receptors (PRR), e.g., Toll-like receptors, on the APC. These interactions result in the activation of cytokines which direct both the innate and acquired immune responses. There is currently no information on PAMS associated with any of the 3 MDV serotypes.

Although the distinction between innate and acquired immune responses has become less defined over the last few years, the innate and acquired responses will be discussed in separate sections.

Innate Immune Responses. Innate immune responses include changes in cytokine expression, natural killer (NK) cells and macrophages.

Cytokine Responses. Infection with MDV results in the upregulation of a number of proinflammatory cytokines (See "Early Productive-restrictive Infection (Phase 1)" for details) driving a T_{H1} type of immune response. It is of interest to note that the vv+ RK-1 strain caused strong proinflammatory cytokine responses in spleen and cerebellum of MHC susceptible and resistant strains of chickens with significantly higher levels of IFN-γ, ILß-1 and IL-8 in the resistant line between 4 and 10 days PI without beneficial effects for the host (311). The authors speculated that a strong genetic-based response was actually detrimental for the host by inducing high levels of NO production.

IFN-γ is an important pleiotrophic cytokine with many functions in antiviral immune responses, but few studies have been performed on the roles of IFN-γ in protective immunity to MD. *In vitro* studies indicate that IFN-γ is able to inhibit virus replication directly or indirectly through the induction of NO production and reactive oxygen intermediates (188, 734).

The importance of IFN-α for MD immunity has not been analyzed in detail. Xing and Schat (733) failed to show induction of INF-α mRNA in spleens of control and infected resistant chickens. Quéré *et al.* (534) found a decrease of INF-α mRNA in

blood cells at 1 day PI in a resistant line of birds but not in a susceptible line. Stimulation of IFN-α mRNA by inoculation of infected chickens with NDV showed that MDV was able to block transcription at 1 day PI in susceptible but not in resistant birds. It will be of interest to determine if this result can be repeated in additional lines. Mixtures of IFNs containing IFN-α and -γ produced by stimulation of CEF with Newcastle disease virus were able to upregulate MHC class I expression in CEF and to counteract the decreased MHC class I expression induced by RB-1B (382).

Nitric Oxide. NO is synthesized by 3 isoforms of NOS with iNOS (NOS II) being inducible in macrophages, glial cells, astrocytes and perhaps other cells as well. The induction of iNOS occurs as part of the nonspecific immune response to microorganisms and is part of the inflammatory response. NO and other reactive nitrogen species are very versatile molecules with many functions independent of the source. NO has been linked to beneficial effects by killing pathogens, but also to neurodegenerative processes in humans (79, 194).

NO can inhibit MDV replication *in vitro* (188, 734). Increased transcription of iNOS has been reported between 6 and 12 days PI with MDV (733) resulting in increased levels of NO in the plasma of genetically resistant chickens but not in genetically susceptible chickens (190, 315). The production of NO may be beneficial, because it can inhibit MDV replication *in vivo* when genetically resistant chickens were challenged with vMDV (734). However, Jarosinski *et al*. (311) noted that pathology may be associated with very high levels of NO production especially in genetically resistant birds after challenge with vv+ MDV.

NK Cells. NK cells are the first line of defense because these cells can lyse virus-infected and tumor cells without prior exposure to the pathogen. NK cells are also potent inducers of IFN-γ. In order to lyse target cells, NK cells must recognize the target cells as foreign (e.g., the MHC class I has been altered, or the expression is downregulated). Sharma and Coulson (604) reported that NK cells are cytotoxic for MDCC-MSB1 cells, but Heller and Schat (253) found that most MDCC lines are resistant to NK cell lysis. The importance of NK cells for MD immunity has not been elucidated. Sharma (596) reported that tumor-bearing, genetically susceptible chickens had decreased NK cell activity in contrast to enhanced NK cell levels in tumor-free, genetically resistant or vaccinated chickens. NK-like activity was demonstrated in genetically resistant N2a chickens for at least 14 days after infection with RB-1B, while NK-like activity could not be demonstrated after 8 days in susceptible P2a chickens (224). NK cells are also activated early after vaccination with SB-1 and HVT (254). The enhanced NK cell activity could be beneficial when chicks become infected shortly after vaccination, perhaps by providing a source of IFN-γ or lysing virus-infected cells. The recently reported downregulation of MHC class I during lytic infection (281) certainly supports a potential role for NK cells.

Macrophages. Activated macrophages can restrict virus replication and reduce tumor incidence (238, 239, 261). Schat *et al*.

(581, 584) suggested that these observations could be explained by the production of NO or by reactive oxygen intermediates (188). Macrophages harvested shortly after MDV infection can inhibit DNA synthesis and proliferation of MD lymphoblastoid cell lines *in vitro*, which was considered to be a transient immunosuppressive effect (373, 595). However, it is more likely that this inhibition is actually a protective response, because it limits the number of activated T cells during the critical switch of MDV from B to T cells (581, 584).

Humoral Immunity. Chickens infected with MDV develop precipitating and VN antibodies within 1–2 weeks; a transient immunoglobulin M (IgM) response is replaced by IgG (260). These antibodies are made against a large number of proteins (666). Most of these antibodies are not relevant for protective immune response, because they detect either nonstructural proteins or proteins that are not expressed in the virus envelope or on the surface of virus-infected cells. Due to the cell-associated nature of MDV antibodies are of limited importance in MD immunity. VN antibodies are important only when cell-free virus infects chickens or when MDV proteins are expressed on the surface of cells. In the latter case, antibodies plus complement or antibody-dependent, cell-mediated cytotoxicity can lyse infected cells. *In vivo* VN has indeed been demonstrated using cell-free and cell-associated virus (94). The presence of maternal antibodies reduces the cytolytic infection (100) and can reduce the efficacy of cell-associated vaccines with low titers or if cell-free HVT is used (e.g., 131, 346).

Few specific antigens involved in humoral immunity have been identified. Antibodies to purified gB neutralize cell-free MDV (292). Inoculation with recombinant fowlpox virus (rFPV) expressing gB (442) or inoculation with gB alone (463) resulted in the production of VN antibodies and protection against MDV challenge. Antibodies against other glycoproteins, such as gC, gE, and gI, are detected after infection. Inoculation with baculovirus-produced gC (310) or vaccination with rFPV expressing gC (442) did not protect against challenge.

The possibility that surface antigens found on MDV-transformed cells could be involved in immunity was raised by studies in which anti-idiotype antibodies against MATSA (see "Etiology") were shown to immunize chickens against challenge with virulent MDV (172).

A role for antibody-dependent cell-mediated cytotoxicity (ADCC) in MD immunity has been suggested (351, 549). However, the target antigens and effector cells have not been identified.

Acquired Immunity
Cell-Mediated Immunity. CTL (cytotoxic T lymphocytes) recognize small peptide fragments of 8–12 amino acids in the context of self-MHC class I antigens. These peptides are generated from *de novo* synthesized proteins through a complex process involving the proteasome and transporters associated with antigen-processing (TAP) 1 and 2. *In vitro* demonstration of antigen-specific CTL requires effector and target cells expressing the same MHC class I antigens (602).

Pratt *et al.* (521) stably transfected and expressed MDV genes in REV-transformed cell lines with known MHC antigens. These cell lines were used to show that CTL from infected or vaccinated chickens recognize peptides derived from pp38, Meq, ICP4, ICP27, gB, gC, gH, gI, and gE (409, 460, 584). The effector cells developed around 7 days PI and were characterized as typical CTL expressing CD3, CD8, and TCRαß1 but not CD4 (461). Important differences were noted in the recognition of proteins by CTL from resistant and susceptible chicken lines. CTL from resistant N2a (MHC: $B^{21}B^{21}$) but not from susceptible P2a (MHC: $B^{19}B^{19}$) chickens recognized ICP4 (460). Effective killing of infected cells as soon as ICP4 is expressed, e.g., when latently infected cells are reactivated, and before virus replication is completed could be one of the contributing factors to MHC-based genetic resistance. Two glycoproteins, gB and gI, were recognized by CTL from both lines. N2a-derived CTL also lysed cells expressing gC and gK and to a lesser degree gH, gL, and gM. CTL from P2a chickens recognized cells expressing gE. Chickens vaccinated with a rFPV vaccine expressing gB (rFPV-gB) developed CTL specific for gB (462) in addition to VN antibodies (442). Lee *et al.* (374) found that rFPV-gI, but not rFPV-gE or rFPV-gH, conferred protection to MDV challenge. It is likely that gB- and gI-specific CTL contribute to the protective immunity induced by recombinant vaccine. CTL against pp38 are likely to be important for immunity based on the observation that vaccination with rFPV-pp38 transiently reduced viremia levels in the absence of VN antibodies (442).

Vaccinal Immunity. HVT, attenuated MDV, and serotype 2 MDV protect against early replication of virulent viruses in the lymphoid organs of challenged birds and reduce the level of latent infection (121, 514, 574, 628). Based on current knowledge, the following sequence of events is proposed to explain vaccine-induced immunity with challenge occurring within 3 days after hatch as is typical in the field (See "Immunity" for references). NK cells are activated as early as 3 days post vaccination, probably producing IFN-γ and killing limited numbers of virus-infected B cells. IFN-γ is perhaps produced by other cells at this early stage (e.g., macrophages). IFN-γ can reduce virus replication and stimulate macrophages to initiate the transcription of iNOS, producing NO between 3 and 7 days post vaccination, thus limiting the replication of challenge virus. Antigen-specific CTL develop starting at 7 days post vaccination and may eliminate additional cells infected with challenge virus perhaps in combination with ADCC. The combination of these effector mechanisms will push the challenge virus into latency. Memory CTL will be able to quickly eliminate reactivated virus-infected cells.

Many factors can interfere with vaccine-induced immunity such as MDV-caused immunoevasion (see "Immunoevasion"). Concurrent infections with immunosuppressive viruses, e.g., CIAV (410) or stress may interfere with vaccine-induced cell-mediated immune responses. Deletion of humoral immunity by bursectomy and X-irradiation does not seem to have a major effect on protection conferred by attenuated MDV (203), although a similar treatment partially impairs vaccinal immunity from HVT (542).

Immunoevasion

Many viruses including MDV (568) have developed strategies of immunoevasion interfering with the development of immune response. Schat and Skinner (583) defined immunoevasion as "*Pathogen-initiated responses counteracting the immune responses to the specific pathogen*". *In vitro* infection with MDV causes downregulation of MHC class I (281, 340, 382) probably through retention of the class I molecule in the endoplasmic reticulum (281). Hunt *et al.* (281) suggested that HVT also downregulates MHC class I, but Levy *et al.* (382) were unable to confirm this. Transcripts for CD8α and ß chains are also downregulated during the cytolytic infection and at later stages resulting in a decreased expression of CD8 on T cells (428, 429) and perhaps NK cells. The production of INFs may upregulate expression of MHC class I to counteract the immunoevasive effects of infection (340, 382). The downregulation of CD28 on MD tumor cells (91) may interfere with antitumor responses. Other antigens, such as chicken fetal antigens, may interfere with NK cell activity (454).

Immunosuppression

Suppression of the immune response by MDV infection is a critical feature of the disease, contributing to the virulence of MDV isolates and altering susceptibility of the host to other pathogens (reviewed in 568). Initial impairment of the immune response is the results of the lytic infection of lymphocytes during the first cytolytic infection (see "Pathogenesis") (citations in 568). Permanent immunosuppression coincides with the second phase of cytolytic infection and tends to correlate with eventual tumor development (582) and may be seen only in birds that have already developed neoplasms (654). It is therefore difficult to distinguish between cause and effect especially because tumor cells might have suppressor activity (84, 253, 533, 653). Because immunocompetence is required for the maintenance of latency (97) it might be that immunosuppression associated with the appearance of transformed lymphoblasts results in additional reactivation of the lytic infection. This, in turn, will cause the loss of additional B and T cells, thus compounding the situation and resulting in the bursal and thymic atrophy seen in birds destined to succumb to MD. A possible association between immunosuppression, reactivation of cytolytic infection, and MD breaks during the laying cycle should be considered. However, immunosuppression may not be a prerequisite for the development of tumors. Witter *et al.* (716) found that the RM1 clone, derived from the JM strain of MDV by the insertion of a retroviral LTR following cocultivation with REV (318), was no longer oncogenic, but caused a severe early cytolytic infection. It will be important to further analyze the relationship between virus-induced immunosuppression and oncogenicity. Although the two properties are not invariably linked, they are often expressed concurrently and, in such cases, immunosuppression may serve to augment oncogenic potential.

Humoral and cell-mediated immunity can be suppressed by MDV infection leading to reduced antibody responses to a variety of antigens and alterations in T-cell functions, such as skin graft rejection, mitogen stimulation of lymphocytes, delayed hypersensitivity, reduced NK cell activity, primary and secondary

infections with coccidia, and impaired Rous sarcoma regression (citations in 485).

Diagnosis

Techniques for diagnosis of infection with MDV are different from those needed for differential diagnosis of the disease. The infection is ubiquitous, but the disease is not. The principal methods to identify the presence of infection are isolation of the virus, demonstration of viral DNA or antigens in tissues, and detection of antibody. The applications of different diagnostic procedures have been recently reviewed (457, 746).

Virus Isolation

Virus isolation is performed to confirm its presence for diagnostic purposes and to secure the infectious virus for further study. Techniques for isolation of all serotypes have been reviewed by Sharma (601).

Source of Virus

MDV can be isolated as early as 1 or 2 days PI (504) or 5 days after contact exposure (9) and throughout the life of the chicken. Intact viable cells are the preferred inoculum because, in most cases, infectivity is avidly cell-associated, although cell-free preparations from skin, dander, or feather tips of infected chickens may contain the virus (110). Inocula may consist of blood lymphocytes, heparinized whole blood, splenocytes, or tumor cells. The virus can often be recovered from infected cell suspensions following storage for 24 hours at 4°C, thus facilitating transport of samples (712).

Cell Culture Techniques

Probably, the most widely used method for primary isolation of MDV is inoculation of susceptible tissue cultures with blood lymphocytes or single-cell suspensions from lymphoid tissues of infected chickens. CKC and DEF cultures are preferred substrates for primary isolation of serotype 1 MDV; whereas CEF normally are used for isolation of viruses of serotypes 2 and 3 as well as for attenuated serotype 1 vaccine strains. Although CEF are less permissive for growth of low passage serotype 1 virus (152, 569, 715), some contemporary isolates appear to grow well in CEF, even on primary isolation (697). Cultures are inoculated with $1–2 \times 10^6$ cells, although some inhibition of viral plaque formation may be encountered with doses greater than 8×10^6 cells for some viruses (129). After 24–48 hours, the inoculum is washed off, and the culture is maintained under liquid or agar medium, usually without subculture.

Development of typical plaques (Fig. 15.3) in inoculated cultures within 3–12 days and the absence of such changes in comparable uninoculated (or sham inoculated) control cultures are evidence for isolation of MDV. The plaques induced by serotype 1, 2, and 3 viruses can be distinguished, with practice, by morphologic criteria (564, 689), but immunofluorescent staining with serotype-specific monoclonal antibodies provides a more accurate differentiation. Optimal time for observation of plaques varies with the cell substrate and serotype of the virus. MDV also has been isolated by direct culture of kidney cells from infected chickens or by inoculation of normal kidney cultures with trypsinized kidney cells from infected chickens (728).

Isolate Identification

MDV serotype 1 isolates should be free of contaminating MD vaccine strains. It normally is useful for the isolate to be plaque purified or cloned at the earliest possible passage. Serotype identity and purity can be confirmed using staining techniques with serotype-specific monoclonal antibodies (370). Pathotyping of serotype 1 MDVs, although not routine, may be accomplished by comparison of pathogenicity with that of prototype strains by inoculation of nonvaccinated chickens as well as chickens vaccinated with HVT or bivalent vaccines (699, 708). Freedom from extraneous viruses is also critical, because contamination with passenger viruses may alter the apparent pathogenicity of the isolate (316, 418, 677). Propagation of MDV isolates for up to 6 passages in CEFs or CKC cultures appears to exclude contaminants such as CIAV (738) and permits preparation of seed and working stocks, which can be more easily standardized and titrated. Although the possibility of attenuation during cell culture propagation must be considered, effects on pathogenicity are difficult to detect until after 20 cell-culture passages. To preserve virulence, some workers have preferred to propagate serotype 1 viruses *in vivo*, preparing stocks of cryopreserved spleen or buffy coat cells from infected chickens.

Virus Assay and Titration

Viruses of serotypes 1, 2, and 3 can be assayed by *in vitro* techniques similar to those described for virus isolation. Methods differ for different serotypes, but most rely on plaque induction in susceptible cell cultures. Enumeration should be done as soon as plaques become mature (time varies with isolate), because secondary plaques may occur when cultures are maintained with liquid medium. Agar overlay methods have been described (635) but are not commonly used, probably because plaque formation is often delayed under agar and because secondary plaque formation under liquid medium has not been considered a significant problem. Procedures for titration of vaccine viruses have been reviewed (656) and are not fundamentally different from those for pathogenic isolates.

Viral Markers in Tissues

It is often desirable to detect the presence of viral infection in chickens without isolating the virus in culture. Such infection markers also have value for the identification of putative MDV isolates in cell cultures.

Viral Antigen Detection

MAb prepared against type-common and type-specific epitopes of all 3 MDV serotypes (370) are now used in preference to polyclonal antibodies for the detection of antigens in tissues. Viral antigens can be detected in feather tips and FFE, cytolytically infected lymphoid tissues, brain, or infected cell cultures with appropriate antibodies by fluorescent antibody tests (636), immunohistochemistry (134, 227), agar gel precipitin tests (242,
15.20. Marek's disease lymphoma showing expression of pp38 antigen (black) in some tumor cells. Immunoperoxidase staining with monoclonal antibody H19 and counterstaining with hematoxylin. ×450. (700) (Witter)

379), and enzyme-linked immunosorbent assays (178, 587). Antigen-positive cells are relatively rare in lymphomas and latently infected tissues, although pp38 and Meq have been identified frequently in the brain (228). In MD lymphomas, pp38-positive cells occasionally are observed (437) (Fig. 15.20), and Meq expression may be relatively common (557).

Polymerase Chain Reaction (PCR) Assays
The availability of the nucleotide sequences of different genes from a large number of viruses including the complete genome sequence of the 3 serotypes of MDV allows the use of PCR-based methods of specific detection of MDV. Primers designed to amplify 132 bp sequences specific to MDVs of serotype 1 have been described (49, 616, 750). PCR assays using these primers can discriminate between attenuated and wild-type strains and may detect viral DNA in lymphomas (177, 617). A wide variety of other primer sequences have also been used. However, PCR may not always be sensitive enough to detect latent infection due to the lower frequency of positive cells and the lower number of viral genomes per cell. qPCR assays using various primer sequences recently have been used to assay viral load in tissues from infected chickens (34, 87, 90, 302, 538) and are becoming essential tools for diagnosis and epidemiological studies of MD. For example, qPCR assays have been adapted for the detection of related MD vaccine strains (87) and PCR assays have been used to differentially detect MDV and HVT in both blood lymphocytes and feather tips of field chickens (248). Because clinical samples may contain inhibitors that can reduce DNA polymerase activity and produce false-negative results, an internal control is useful to establish the absence of such inhibitors. More recently, qPCR assays were carried out to study different aspects of MD biology including replication kinetics of MDV in feathers and lymphoid tissues (38, 303), correlation between protection and vaccine load (39), the association between replication rates of viral genomes and virulence (740) and the impact of specific gene deletions on replica-

tion (78). qPCR tests for the absolute quantitation of serotype 2 and serotype 3 MDV have also been developed (301, 543).

DNA Probes
Methods using DNA-DNA dot-blot hybridization with DNA probes for the detection of MDV DNA in feather tip extracts have been described (180). Furthermore, localization of virus-infected cells has been accomplished by *in situ* hybridization for both MDV (205, 553) and HVT (273).

Electron Microscopy
Herpesvirus particles can be detected by electron microscopy in the FFE and in productively infected cells *in vitro* (110).

Antibody Detection
Tests for identifying the presence of specific antibodies in chicken sera are useful in studies of viral pathogenesis and for monitoring SPF flocks. A number of procedures including agar gel precipitin, fluorescent antibody, enzyme-linked immunosorbent assays (747), and virus-neutralization tests are in common use; methods have been described (601). Commercial reagents are available only for the agar gel precipitin test, which is the least sensitive test but is adequate to detect serologic responses in infected or vaccinated chicken flocks. None of these tests, however, can differentiate antibodies of the 3 serotypes. The biologic significance of antibodies detected by different methods may vary (99).

Diagnosis of the Disease
Despite long-established guidelines for the pathologic diagnosis of MD (615), diagnosis of the clinical disease remains difficult in practice for several reasons. First, no truly pathognomonic gross lesion exists for MD. Gross lesions of MD can resemble those of other neoplasms and unrelated conditions characterized by tumors in visceral organs or grossly enlarged nerves. Finally, MDVs, ALVs, and REVs are widespread in commercial poultry, often resulting in simultaneous infections (176), complicating diagnostic efforts that depend on virological methods. The absence of a generally accepted confirmatory test makes even properly performed pathologic diagnoses subject to controversy. No currently accepted diagnostic standard exists for MD. However, the following model is suggested.

Diagnosis of MD must primarily be addressed by consideration of the characteristics of the proliferating cell populations that constitute the disease. Other disease-specific criteria, such as epidemiological factors, are also valuable. Virological criteria are less valuable but can help establish the presence of the causative agent or, more importantly, the absence of certain other agents. The process commences with the acquisition of a flock history and a sufficient number (5–10) of representative sick and dead chickens showing the lesions of the disease and proceeds as a series of steps.

Step 1—Clinical Data and Gross Pathology
Although enlarged peripheral nerves and visceral lymphomas are common in MD and one or both are invariably present, neither lesion occurs consistently nor is pathognomonic. Thus, other crite-

ria, such as age and lesion distribution, must be considered in the postmortem diagnosis of MD. Chickens may be diagnosed provisionally as MD if at least one of the following conditions is met: 1) leukotic enlargement of peripheral nerves; 2) lymphoid tumors in various tissues (liver, heart, gonad, skin, muscle, and proventriculus) in birds under 16 weeks of age; 3) visceral lymphoid tumors in birds 16 weeks or older that lack neoplastic involvement of the bursa of Fabricius; or 4) iris discoloration and pupil irregularity, as in Figure 15.9C. Proper examination of the bursa is particularly important and requires incision of the organ with close inspection of the epithelial surface. However, diagnoses based only on gross pathologic criteria are not definitive and additional steps are required.

Step 2—Histology, Cytology, and Histochemistry of Tumor Cells

Affected tissues, fixed in formalin or fresh-frozen, are used to prepare paraffin and cryostat sections, respectively. Impression smears of tumors may also be used. Essential diagnostic features may be seen in routine histologic sections stained with hematoxylin and eosin or touch preparations stained with methyl green pyronin or Shorr's stain (615). Cellular and viral antigens can be demonstrated in frozen or, in some cases, paraffin sections by immunohistochemistry. A mixed population of small to large lymphocytes, lymphoblasts, plasma cells, and macrophages are typically found in MD tumors and nerve lesions (484). The proportion of cell types varies with the stage of the disease and virulence of the virus, and the most aggressive lymphomas may contain high numbers of lymphoblasts. MD tumors are a mixed population, and most cells express MHC class II antigen and T-cell markers, especially CD4 (although CD8$^+$ cells may also be present) (577), but IgM is present on less than 5% of cells. CD30 is also commonly found in MD tumor cells (557). MATSA (731) can be demonstrated with polyclonal or monoclonal (369) antibodies on 5–40% of MD tumor cells but is also present on activated T cells (412). Tumor lesions tentatively identified as MD in step 1, which are composed of pleomorphic lymphoid cells that predominately express CD4/CD8 markers and where expression of IgM or B-cell markers is limited or absent, may be diagnosed provisionally as MD. Demonstration of CD30 or MATSA may potentially be useful, but more data are needed.

Step 3—Virologic Criteria

For tumors that satisfy MD criteria listed in steps 1 and 2 or for atypical tumors, the association of MDV with the tumor cell is a useful confirmatory procedure. Viral antigens such as pp38 or Meq may be detected in tumor cells by immunohistochemistry or fluorescent antibody tests (437, 557), but because neither antigen is expressed in all cells or in all tumors, negative results are less helpful than positive results. Also, very small numbers of positive cells may reflect the presence of inflammatory T cells, incidentally infected with MDV, which are unassociated with the primary tumor. *In situ* hybridization is another technique to localize MDV genome in tumor cells (557). PCR assays may also detect MDV DNA in tumors, especially in tissues with high concentrations of tumor cells (e.g., tumor nodules). PCR assays on other

tissues and virus isolation from buffy coat or spleen cells demonstrate the virus in the bird but do little to associate the virus with the tumor cells. Similar information is provided by antibody tests. There may be a quantitative association between virus load and MD tumors. Low levels of virus or viral DNA may be detected in lymphocytes from nontumor-bearing chickens, but most tumor-bearing chickens have high viremia titers (729) and are usually PCR positive (177, 624). Therefore, the possibility that infection criteria in excess of some arbitrary threshold level, as yet undetermined, would better correlate with lymphomatous lesions could be explored. Thus, the demonstration of high quantities of virus or viral antigens in tumor cells at the exclusion of other relevant tumor viruses should be sufficient, along with other criteria in steps 1 and 2, to establish a diagnosis of MD.

Applications

Steps 2 and 3 do not invariably need to be performed in sequence. Because PCR assays are quick to perform, establishing whether single or multiple tumor virus infections are present can, in some cases, help determine additional procedures to be conducted. However, characteristics of the tumor itself should be paramount.

Pathotyping of MDV Strains

The concept of MDV pathotypes has arisen from the recognition of the existence of strains that are associated with increased virulence, which show correlation with breaking of vaccinal immunity in the field (708). Methods to differentiate between classical strains of MDV and the more virulent pathotypes have been examined. However, the ADOL (Avian Disease & Oncology Laboratory) method of pathotyping, based on the induction of lymphoproliferative lesions in chickens vaccinated with different vaccination regimes, has been the most widely used. This method was used to characterize more than 45 isolates into distinct vMDV, vvMDV, or vv+MDV pathotype groups (699). Even though ADOL method stipulates the use of line 15×7 chickens for pathotyping, experiments with other lines of birds also have given similar results (98, 708).

Differential Diagnosis

Lymphoid leukosis is a clonal, bursal lymphoma induced by ALV and, under some conditions, by REV in chickens older than 16 weeks of age. Chickens usually have gross tumors in the bursa of Fabricius, and tumor cells are uniform, blast-like, and pyroninophilic and express B-cell markers and IgM. Also, the tumor cells have clonal insertions of proviral DNA near the *c-myc* gene (see "Leukosis/Sarcoma Group"). Nerve enlargements, runting, and nonbursal T-cell lymphomas can be induced by REV but, thus far, have only been observed under experimental conditions or where chickens have been inoculated with contaminated vaccines. Lymphocytes obtained from REV-induced nerve lesions or tumors are not known to express pp38 or Meq. Cells from nonbursal RE lymphomas are negative for MHC class II and predominantly stain for CD8 antigen (162). (See "Reticuloendotheliosis.") Exclusion of ALVs or REVs, where possible, through negative PCR, histochemical assays on tumors, or antibody tests may provide strong support for a diagnosis of MD when other MD-related criteria are positive.

Peripheral neuropathy is a neurological disease of uncertain etiology that causes paralysis and nerve enlargement in a low proportion of commercial chickens 6–12 weeks of age (31, 321) and has been described in commercial (704) and SPF chicken flocks (67). Affected chickens lack visceral lymphomas; the nerve lesions are uniformly B-type; and MDV is rarely, if ever, demonstrated. Other diseases that may present confusing gross lesions or paralytic signs are myelocytomatosis (myeloid leukosis), myeloblastosis, erythroblastosis, carcinoma of the ovary, various other nonviral neoplasms, riboflavin deficiency, tuberculosis, histomoniasis, genetic gray eye, Newcastle disease, avian encephalomyelitis, and joint infections or injuries. Myeloid leukosis is a common tumor in broiler breeder flocks that superficially resembles MD but can be differentiated histologically. The tumor cells are myeloid in nature and lack T cell and MD viral markers. Multicentric histiocytosis (240) is a disease of broiler chickens characterized by enlarged mottled spleens and lesions in other viscera composed mainly of histiocytes. No lymphocytes were identified, and MDV was not demonstrated in tumors, although an association with subgroup J ALV has been suggested (24).

Diagnosis of Other MD Syndromes

Transient paralysis occasionally is observed in the field, especially in chickens not vaccinated against MD. Most cases represent the classical form in which chickens experience flaccid paralysis of neck or limbs for 1–43 days and then undergo a complete recovery. This syndrome can be differentiated from the neurological form of MD (fowl paralysis) by its transient nature and flaccid rather than spastic paralysis. Transient paralysis can be differentiated from peripheral neuropathy by its transient nature and the absence of enlarged peripheral nerves with B-type lesions. Davidson *et al.* (180) differentiated transient paralysis from peripheral neuropathy on the basis of PCR tests for MDV on brain tissue; however, brains from MDV-infected chickens without transient paralysis may also be detected as positive by PCR assays (710). In contrast, detection of viral antigens in the brain appeared to correlate with the onset of paralytic signs (228).

Skin leukosis (the skin form of MD) can be differentiated from dermal squamous cell carcinoma, which is commonly observed in defeathered broiler chickens at processing (241). MD lesions are nodular and contain lymphoid cells, whereas squamous cell carcinomas have a craterlike gross appearance and are composed of squamous epithelial cells. Both occur in feather tracts in association with feather follicles (361).

Lymphodegenerative lesions of lymphoid organs characterized by organ atrophy and immunosuppression are difficult to diagnose, because many diseases produce similar changes. However, lymphoid organs atrophied consequent to productive infection with MDV may also contain MD viral antigens, such as pp38, at least for a short period.

Intervention Strategies

The development of successful vaccines for control of MD (157, 459, 546) was a significant achievement. Vaccination represents,

for now and the foreseeable future, the central strategy for the prevention and control of MD. Genetic resistance and biosecurity, however, are critical adjuncts to vaccination. No effective practical treatment exists for the disease in individual chickens or infected flocks. An integrated strategy to prevent early infection, to slow the acquisition of virulence of field strains, and to provide superior immune responses seems most likely to succeed (701). Detailed reviews on MD vaccines and control procedures are available (82, 566, 703).

Vaccination

Types of Vaccines

Several different types of MD vaccines are in common use, both individually and in various combinations. The most widely used products are low pathogenic serotype 1 MDV (545, 546), naturally avirulent HVT (459), and serotype 2 viruses (571, 725). The serotype 2 strains usually are combined with HVT to take advantage of the synergistic activity documented between serotypes 2 and 3 (574, 688). All vaccine types are protective but to varying degrees. HVT, mainly strain FC126 (718), continues to be extensively used because it is effective and economical to produce and combines well with other products. Although both cell-free and cell-associated forms of HVT are available, the latter has been most widely used because it is more effective than cell-free virus in the presence of maternal antibodies (707). Bivalent vaccines based on combinations of HVT and either SB-1 (571) or 301B/1 (692) strains of serotype 2 MDV were introduced in the mid 1980s. The CVI988 strain (546) used in The Netherlands (403) and other countries since the early 1970s, was introduced to the United States in the early 1990s. Another attenuated serotype 1 strain, R2/23 (694), was also introduced in the 1990s. Serotype 1 and 2 vaccines are available only as cell-associated products.

Vaccine Administration

MD vaccines are administered to chicks at or before hatch because early immunity is essential. Both cell-associated and cell-free vaccines are given by subcutaneous or intramuscular inoculation at a dose usually in excess of 2000 plaque-forming units per chick. Vaccines are also effective when administered to embryos at ED 18 (603). *In ovo* vaccination is now performed by automated technology (317) and is widely used for vaccination of commercial broiler chickens, mainly because of reduced labor costs and greater precision of vaccine administration. Deposition of the vaccine by the amniotic or intraembryonic route is essential for optimal protection (680). Proper handling of vaccine during thawing and reconstitution is crucial to ensure that adequate doses are administered (245, 306).

Factors Affecting Efficacy

Vaccines typically are given at doses of 2000–6000 plaque forming units per chick, but these may be significantly reduced in broilers. Higher doses (196, 689) or revaccination (40) offered little improvement. Revaccination at 7–12 days continues to be popular in Europe and occasionally is used in the United States, but the effectiveness of this procedure has not been validated by laboratory studies. Maternal antibodies reduce the ef-

fectiveness of cell-associated vaccines but do not abrogate the protective effect (131). Vaccination of breeders with a serotype 1 or 2 virus leaves progeny more responsive to vaccination with HVT (346).

The shorter the interval is between vaccination and exposure to the virulent field virus, the poorer the level of protection (459). Early exposure is undoubtedly one of the most important causes of excessive MD in vaccinated flocks because field exposure usually occurs very soon after placement of chickens (717) and because at least 7 days is required to establish solid immunity after vaccination (45). The vaccine strain of virus also has a major influence on vaccine efficacy. Immunity induced by weaker vaccines such as HVT may be excellent against low virulence challenge but can be completely overwhelmed by early challenge with highly virulent strains (699). Although high virulence strains commonly are invoked to explain field outbreaks of disease, many alternate causes should be considered.

The strain of chicken is also an important determinant of vaccine efficacy. Schat *et al.* (574) found that HVT vaccine in genetically resistant chickens resulted in a stronger immunity than did the bivalent (HVT + SB–1) vaccine in susceptible chickens.

Stress appears to interfere with the maintenance of vaccinal immunity. In chickens properly vaccinated at hatch and well protected following challenge, Powell and Davison (507) induced MD lesions and mortality by immunosuppressive treatment at 10 weeks of age. The possibility that immunosuppressive stress may play an important role in MD outbreaks in vaccinated flocks, especially those that occur after the onset of egg production, deserves consideration (703). IBDV (597), REV (713), reoviruses (547), and CIAV (469, 470, 739) have been reported to interfere with the induction of vaccinal immunity, although very specific conditions are sometimes required.

Vaccination Strategies

Efficacy data that compare certain groups of vaccines are available (citations in 566, 691, 703). Bivalent serotype 2+3 vaccines and R2/23 are clearly more effective than HVT (695). The most effective vaccine, however, appears to be the original CVI988 vaccine (695), a result consistent with earlier reports from Europe (669). Efficacy rankings of vaccines, however, have not always been reproducible when performed in different laboratories and should be interpreted with caution.

MD vaccines as a class are unusually effective, often achieving greater than 90% protection under commercial conditions (703). However, attention is often focused on flocks in which MD losses are perceived to be excessive (305, 357, 744). Causes for such vaccine failures are difficult to ascertain by retrospective analysis (703), although early exposure and the emergence of new MDV strains with increased virulence may be important.

The propensity of MDVs to evolve to greater virulence (699) is critical to the strategic use of vaccines for MD control. Vaccination itself no doubt contributes to this virulence increase, which, in turn, tends to make earlier vaccines obsolete. Kreager (359) has noted that the useful life of a MD vaccine has been about 10 years under current management conditions. Although this is perhaps an overstatement, the implications are serious.

Since CVI988 was introduced in the United States, some evidence already suggests that contemporary strains have increased their virulence in CVI988-vaccinated chickens (702).

Choice of a vaccine program is an important consideration for MD control. A rational approach is to use the least effective product required to control the disease on a particular farm at a particular time (700). In practice, HVT alone provides adequate protection to many broiler flocks under normal conditions. Broiler flocks, especially during winter months, and layer/breeder flocks often require bivalent (serotype 2+3) vaccines rather than HVT alone. Where these vaccines are insufficient, the CVI988 strain is used. Mixtures of CVI988 with HVT or both serotype 2+3 vaccines are also used, although little evidence exists for synergistic activity of CVI988 with other vaccine serotypes (714).

Research continues to be directed toward the development of improved vaccines through recombinant DNA approaches (551), but with limited practical success. Recombinant fowl poxvirus (374, 445), HVT (552), and MDV (268) vaccines expressing various MDV genes have shown some protective efficacy. The rFPV vaccines were effective to some degree in chickens positive for maternal antibodies to MDV, but were not tested in chickens with maternal antibodies to FPV. Incorporation of cytokines in vaccines in recombinant vaccines may improve vaccine efficacy as suggested by the inclusion of the gene for avian myelomonocytic growth factor in FPV (189). However, the lack of protection with rFPV vaccines expressing avian influenza genes against avian influenza in birds with antibodies to FPV (642) suggests that rFPV vaccines are unlikely to yield improved MD vaccines.

Some progress has been made with deletion mutant vaccines. MDV strains lacking vIL-8 (167) or with mutations in the CtBP-interaction domain of the *meq* (78) were protective against challenge with vv or vv+ MDV. In a limited experiment, DNA vaccination using pBAC20, derived from attenuated MDV, provided limited protection against challenge (658).

Efforts to derive more efficacious serotype 1 vaccines through classical virological approaches (702) or retroviral insertion (716) yielded several promising candidates. However, these strains did not protect better than the best commercial CVI988 vaccines (711). These authors questioned if the efficacy of MD vaccines is limited by some type of biological threshold.

The emergence of increasingly virulent viral strains, coupled with an apparent reduction of vaccine efficacy during the past 20 years, has prompted justifiable concern. This suggests that vaccination by itself does not provide a complete control program and is not the ultimate solution for MD. Strict biosecurity procedures to reduce early exposure and the presence of genetic resistance are essential adjuncts to a successful vaccination program.

Genetic Resistance

The well-known variation in susceptibility of different lines of chickens to MD challenge is determined by genetic factors (159) and provides a unique opportunity to consider genetic approaches to the control of MD. Indeed, poultry breeders have included resistance to MD in selection programs for many years. However, genetic resistance can be overcome by challenge with

highly virulent MDVs and is best applied in concert with vaccination and biosecurity to achieve optimal control. Literature on genetic resistance against MD is extensive (see reviews 25, 86). Genetics influences virtually every aspect of host response to MD. However, only those issues germane to disease control programs are considered here.

Characteristics of genetic resistance to MD are generally favorable for inclusion in selection programs by primary breeders. The magnitude of the effect, at least under certain conditions, is large enough to have considerable economic impact (159). Resistance is not associated with undesirable production traits (68) and in one study (15) was correlated with higher egg production and egg weight. Variation of MD susceptibility in single-sire families indicated that sufficient heterogeneity exists to warrant selection for resistance in commercial chickens (68), which is still the case in recent commercial genetic stock (204). Moreover, estimates of the heritability of resistance, although variable, were often relatively large (reviewed in 25).

Selection Methods

Selection programs for resistance historically have been based on progeny testing or family selection (158) or reproduction from survivors of exposed breeding flocks through mass selection (402). Resistance traditionally has been measured by challenge of unvaccinated chickens with virulent MDV, but recent studies (26) conclude that resistance may better be determined in vaccinated stocks. Acquisition of resistance consequent to selection can occur rapidly. Maas *et al.* (402) reduced susceptibility from 76% to 8% in 6 generations upon mass selection. Probably the most dramatic example was the development of lines N and P from Cornell Randombred control stock by family selection, resulting in divergent susceptibilities of 4% and 96%, respectively, after 4 generations (158). Family selection may be more appropriate than mass selection for commercial breeders in order to avoid high loss of genetic material on initial challenge exposure (25).

Selection based on blood typing relies on the close relationship between MD resistance and certain alleles of the B-F region of the MHC, especially B^{21} (76, 77). In theory, such a selection procedure may simplify production of resistant stocks in populations containing a specific allele for resistance although the possibility of negative associations with productivity traits needs to be measured (232). Furthermore, the value of selection for MHC-associated markers may vary considerably among commercial lines and crosses (69, 252).

Evidence that non-MHC genes may also be involved in resistance is provided by the observation that RPL line 6 and line 7 chickens, which are both homozygous at the B locus for the B^2 allele, differ markedly in MD susceptibility (166). Furthermore, non-MHC effects were considered more important than MHC effects in studies on several commercial lines (236). Studies to identify and map quantitative trait loci associated with MD resistance may provide new tools to enhance selection programs for MD resistance. Up to 14 or more putative quantitative trait loci have been identified (85, 665, 737), and some of these presently are being evaluated in commercial stocks. Using microsatellites, McElroy *et al.* (413) identified several markers associated with resistance to MD. The combination of QTL analysis and microarrays (392) or the use of 2-hybrid screen approaches (448) may further facilitate the identification of useful markers for selection. Resistance has been considered dominant, although this varies to some extent (258), and, in most cases, resistance of crosses has been intermediate to that of the parent strains (69, 103).

Applications to Control

The knowledge that genetically resistant chickens are protected by vaccination to a greater extent than more susceptible strains (637) has fueled interest by commercial breeders to emphasize MD resistance in selection programs. However, synergy between host genetics and vaccines is complex. Some resistant B-haplotypes were demonstrated only by challenge of previously vaccinated chickens (26). However, the relative efficacy of MD vaccines is also influenced by B-haplotype (27). Serotype 1 vaccines provided the best protection for certain B-haplotypes, but serotype 2 vaccine was best for B^5 chickens (28), suggesting that one could select the most appropriate vaccine based on the predominant B-haplotypes in a particular strain (29). In practice, this issue has been either ignored or addressed through the use of vaccines containing multiple serotypes.

In light of the selection tools available, the absence of negative correlations, and the major benefits to be derived, it is not surprising that some breeders place a high priority on this approach. Although selection for B-haplotype has been practiced with variable success and has proven to be complex, especially in meat strains (416), breeders acknowledge the value of improved genetic resistance to offset virulence increase by viral strains and the limitations of current vaccines (357).

Management Procedures

Strict biosecurity practices to limit the extent of early MDV exposure, although impractical as a primary control procedure, are a crucial and cost-effective adjunct to vaccination. MD control is compromised because modern poultry management too often places replacement flocks of different ages in close proximity to each other or requires the reuse of litter from a previous broiler flock. The failure to prevent early exposure is perhaps the most important single cause of vaccine failures. Improved hygiene has often appeared to play a key and cost-effective role in the elimination of excessive MD losses in vaccinated flocks. However, management decisions in commercial poultry operations appear linked to cost analyses and procedures advantageous for disease control are not always implemented (356). Relevant sanitation principles have been reviewed (57, 478).

For SPF flocks, higher standards of biosecurity are required and become cost effective. Most SPF operations rely on the use of filtered-air, positive-pressure houses (20, 192), which, along with strict biosecurity measures, successfully can maintain large flocks free of MDV infection for long periods. In this case, biosecurity becomes a substitute for vaccination and provides a practical demonstration that MDV can be eradicated in certain flocks, at least under specialized conditions.

Nononcogenic Turkey and Chicken Herpesviruses

Turkey herpesviruses and serotype 2 MDV are not recognized as pathogens in avian hosts. Interest in these viruses derives mainly from their use to immunize chickens against MD. However, both viruses occur in nature independent of vaccination, and it seems appropriate to also consider some aspects of their epizootology and pathogenesis in their natural or alternate avian hosts that have not been addressed elsewhere in this chapter. Review papers by Calnek (104, 107) may be consulted for additional details on pathogenesis of these infections.

Turkey Herpesvirus (HVT)

HVT was isolated from normal turkeys by Kawamura *et al.* (338) and Witter *et al.* (718). The virus is endemic and ubiquitous in domestic turkeys (726). Isolations have also been reported from wild turkeys (161). In chickens, the virus has also become ubiquitous because of its widespread administration to day-old chickens to prevent MD. The genome of HVT showed close structural and sequence similarity (11, 347) to that of serotype 1 strains even though distinct genes do exist in each of these viruses. Analysis of the functions of HVT genes will be facilitated with the recent success in the construction of BAC clones of HVT (35).

In turkeys, the virus spreads rapidly through exposed flocks, presumably by contact exposure. Virtually all individual turkeys become viremic and develop antibodies within a few weeks (726). The virus appears to mature in the FFE, because cell-free skin extracts are infectious (727) although viral antigen was found only infrequently and at low levels in the FFE of infected turkeys (212). No vertical transmission has been demonstrated (726). HVT may be transmitted from turkeys to chickens under experimental conditions (727), which is probably rare in the field. Only limited contact spread occurs among chickens (144, 146) but transmission could not be demonstrated by the airborne route (140). Replication of virus in the FFE of infected chickens appears limited and transient (111, 139, 751). The virus also appears to replicate less efficiently than MDV in skin (519), although increased levels of HVT DNA were observed in FFE of HVT-vaccinated chickens after MDV challenge (386).

Fabricant *et al.* (212) studied the early pathogenesis of HVT infection in chickens and turkeys. Chickens had no cytolytic infections in any lymphoid organ. Turkeys infected with HVT did have some viral antigen-positive cells at 4–14 days post exposure in the spleen, but no cytolytic infections in bursa or thymus were seen. In chickens, there was no depression of bursa or thymus size, although a transient splenomegaly was variably present (111, 212). B cells are rarely infected, but latent infection is probably established in MHC class II-positive T cells (104). Holland *et al.* (274, 275) detected expression of gB in the spleen, to a lesser degree in the thymus, and to very limited degrees in the bursa of infected chickens; nervous tissue was uniformly negative. NK cell activity was stimulated through at least 8 week PI (605). HVT can be recovered from infected chickens for long periods, and antibodies persist for life (525, 723). The virus is apparently nononcogenic in turkeys (687, 718), but the possibility

of fertility problems in HVT-infected toms has been raised (10, 657). The virus generally causes no clinical disease in intact or immunosuppressed chickens (606, 718) and is not normally detrimental to the immune response (220). However, atrophy of the bursa and thymus was noted following administration of high doses (244), and minor cellular infiltrations in nerves were observed (212, 723). In contrast, when S-line chickens were infected with HVT *in ovo* (ED 8) and then hatched and raised, up to 19% developed clinical paralysis and gross nerve enlargement due to inflammatory type lesions were observed (121). Chickens exposed to HVT at ED 14 or earlier showed higher incidence of immunological tolerance resulting in a persistent HVT viremia (748). A possible role for HVT as a predisposing factor in autoimmune disease is suggested by its implied involvement in peripheral neuropathy (31) and autoimmune vitiligo (207); both syndromes are restricted to certain strains of chickens.

Serotype 2 Marek's Disease Virus

Apathogenic strains isolated from clinically normal chickens (63, 143) subsequently were determined to be a separate serotype on the basis of FA and AGP tests (675, 676). Natural infection with such strains provided protection against MD challenge (63, 742). Other unique features of this virus group were further elucidated following the isolation of the SB-1 strain (571). Prior to their widespread use as vaccines, serotype 2 viruses were common, although not universal in commercial chicken flocks in England and the United States (63, 690). Avirulent isolates were also prevalent in Australia (517). However, the epidemiology has been complicated by the artificial distribution of the virus in the United States through a seeder chick program (742, 743) and through nearly 20 years of administration of serotype 2 vaccines (123, 722). The virus must now be considered ubiquitous in chickens. Chickens appear to be the only natural host, although apathogenic isolates that resembled the HN strain were isolated from Japanese silkies, red jungle fowl, and Ceylon jungle fowl reared in a zoo (145).

Serotype 2 viruses spread readily by contact (571, 725) and replicate in the FFE (142). Following inoculation of day-old chickens, the virus can be first isolated 5–6 days PI (111). The virus reaches peak titers at 2–4 weeks and persists for long periods (111, 725). Antibodies are induced readily and persist.

A transient splenomegaly was induced between 4–12 days after inoculation of chicks with the SB-1 strain, but no bursal atrophy and only occasional thymic atrophy was seen and cytolytic infection of lymphoid organs was not observed (111). In contrast, Lin *et al.* (391) found that viral antigens were expressed in spleen and bursal tissues 5–14 days after infection, primarily in B cells, but no gross or microscopic changes were observed. Calnek (104) considered B cells and macrophages relatively refractory to infection, and the cells supporting latent infection lacked MHC class II antigens, thus differing from those in HVT infections. However, T cells may not be very susceptible either because CD4$^+$ and CD8$^+$ cells from SB-1-infected chickens induced few, if any, plaques in cell culture assays (376). Certain subpopulations of bursal cells appear to support latent infections that interact with ALV, and serotype 2 was isolated from a B lymphoblas-

toid cell line (262). SB-1 did not suppress humoral immunity (200) and is not normally considered immunosuppressive. However, Friedman *et al.* (220) found a diminished response to a B lymphocyte-specific mitogen and decreased antibody responses to bovine serum albumen in chickens vaccinated with the SB-1 strain in combination with HVT.

The SB-1 strain did not produce neoplastic lesions in either normal or immunosuppressed chickens, but because some cytolytic lesions were noted in immunosuppressed chickens, the virus was designated nononcogenic rather than apathogenic (571). Also, a variety of lesions were induced by *in ovo* inoculation of SB-1, but none were neoplastic (121, 571, 715). The absence of lymphoma induction has been confirmed by other workers (63, 141, 725) but Pol *et al.* (506) described visceral lymphomas in 2 of 48 chickens inoculated with the HPRS-24 strain.

Vaccination with serotype 2 viruses causes a pronounced enhancement of B cell lymphomas in certain genetic strains of chickens exposed at an early age to subgroup A ALV (30) or REV (14). Salter *et al.* reported that spontaneous lymphomas are also enhanced by SB-1 exposure (see "Leukosis/Sarcoma Group"). Apparently, the subpopulation of B cells susceptible to transformation is also uniquely susceptible to infection by serotype 2 MDVs but not by HVT (222). The ability of serotype 2 virus to enhance LL was attenuated without abrogation of its protective properties against MD challenge (696). ALV (subgroup A) has now been eradicated from most of the chicken lines susceptible to serotype 2 enhancement and field problems due to serotype 2 enhancement of LL are rare (see "Leukosis/Sarcoma Group").

Leukosis/Sarcoma Group

Aly M. Fadly and Venugopal Nair

Introduction

Definition and Synonyms

The leukosis/sarcoma (L/S) group of diseases designates a variety of transmissible benign and malignant neoplasms of chickens caused by members that belong to the family Retroviridae (210). Lymphoid leukosis has been the most common form of L/S group of diseases seen in field flocks, although myeloid leukosis has also become prevalent. The neoplasms and their synonyms are listed in Table 15.5. Members of this group of avian viruses are characterized, as are all members of the Retroviridae, by possession of an enzyme reverse transcriptase, which directs the synthesis of the proviral DNA form of the RNA virus that forms part of the retroviral life cycle and from which the family name is derived. These avian retroviruses, including avian leukosis virus (ALV)-related viruses, formerly were placed in a subgenus termed avian type C oncornaviruses (329), but they recently have been termed alpharetroviruses (210). Members of this group of viruses have similar physical and molecular characteristics and share a common group-specific antigen.

Because of the relationships between these viruses (145), they are discussed as a group in most parts of this chapter. Sections reflecting the host response ("Pathology" and "Pathogenesis") are discussed under the pathologic entities without regard for the properties of the inducing virus (es) other than their inclusion in the L/S group.

Economic Significance

Infection of chickens with ALV is the most common L/S virus infection encountered in field flocks and is known to be of significant economic importance. Economic losses from ALV-induced diseases are attributed to 2 sources. First, tumor mortality commonly amounts to around 1–2% of birds, with occasional losses of up to 20% or more. Second, subclinical infection by ALV, to which most flocks are subject, produces a depressive effect on a number of important performance traits, including egg production and quality (226, 228). Economic losses due to ALV tumor mortality and reduced productivity are estimated to be in millions of U.S. dollars each year. In 1991, the benefits to a major

Table 15.5.   Neoplasms caused by viruses of the leukosis/sarcoma group.

Neoplasm	Synonyms
Leukoses	
Lymphoid leukosis	Big liver disease, lymphatic leukosis, visceral lymphoma, lymphocytoma, lymphomatosis, visceral lymphomatosis, lymphoid leukosis
Erythroblastosis	Leukemia, intravascular lymphoid leukosis, erythroleukosis, erythromyelosis, erythroblastosis, erythroid leukosis
Myeloblastosis	Leukemic myeloid leukosis, leukomyelosis, myelomatosis, myeloblastosis, granuloblastosis, myeloid leukosis
Myelocytoma(tosis)	Myelocytoma, aleukemic myeloid leukosis, leukochloroma, myelomatosis
Connective tissue tumors	
Fibroma and fibrosarcoma	
Myxoma and myxosarcoma	
Histiocytic sarcoma	
Chondroma	
Osteoma and osteogenic sarcoma	
Epithelial tumors	
Nephroblastoma	Embryonal nephroma, renal adenocarcinoma, adenosarcoma, nephroblastoma, cystadenoma
Nephroma	Papillary cystadenoma, carcinoma of the kidney
Hepatocarcinoma	
Adenocarcinoma of the pancreas	
Thecoma	
Granulosa cell carcinoma	
Seminoma	Adenocarcinoma of the testis
Squamous cell carcinoma	
Endothelial tumors	
Hemangioma	Hemangiomatosis, endothelioma, hemangioblastomas, hemangioendotheliomas
Angiosarcoma	
Endothelioma	
Mesothelioma

egg-laying breeder company from successful eradication of ALV infection were estimated to be $15 million per year (92). During the 1990s, the broiler breeder industry identified an ALV-induced myeloid leukosis (377) as its highest disease priority, as losses due to this disease (485, 491) have threatened the economic viability of the entire broiler industry (529).

Public Health Significance

Recent studies have addressed the relationship between avian tumor viruses, particularly ALVs, and human health. Evidence for the presence of antibodies to ALVs in humans usually has been lacking or at best is presumptive (276). However, using enzyme immunoassays and Western blots, low-titer antibodies to ALVs were detected in sera from poultry workers (277–279). Endogenous and exogenous ALV also were detected in the albumen of commercial eggs using reverse transcription polymerase chain reaction (397, 398), but the public health significance was not determined. In a serological survey that included 549 human subjects, including groups exposed and not exposed to chickens, significant differences between men and women were found for

the prevalence of antibodies to ALV but were not related to exposure to chickens (100). Robertson *et al.* (423) discussed the significance of detecting reverse transcriptase activity in vaccines derived from chicken cells. Reverse transcriptase activity was detected in all chicken cell-derived measles and mumps vaccines, suggesting the presence of endogenous ALV elements; however, no evidence of antibodies or proviral sequences of ALV was found in the vaccines or the sera from vaccine recipients (266, 268, 457, 519). Clearly, no strong unequivocal evidence suggests that ALV constitutes a danger to public health.

History

The earliest reports of leukotic diseases in fowl are those of Roloff (428), who described a case of "lymphosarcomatosis" in 1868, and of Caparini (88), who in 1896 described cases of "fowl leukemia." In 1905, Butterfield (81) diagnosed "aleukemic lymphadenosis" in the United States. In 1908, Ellermann and Bang (177), working in Copenhagen, founded the discipline of viral oncology when they transmitted erythroleukemia and myeloge-

nous leukemia by inoculation of chickens with cell-free filtrates. The significance of their discovery was not fully appreciated, because at that time leukemia was not recognized as a neoplastic disorder. Ellermann and Bang also proposed the word "leucosis" to designate leucemic and aleucemic cases.

Ellermann also provided further classification of the pathological forms of avian leukosis that essentially still holds today (176). He described in his monograph "The Leucosis of Fowls and Leucemia Problems," (176) (1) "lymphatic leucosis," with lymphoblastic hyperplasia; (2) "myeloic leucosis," with leukemia and general hyperplasia of "myeloic" cells (myelocytes, "large mononuclear cells," and "poikilonuclear cells"); and (3) "intravascular lymphoid leucosis," involving "lymphoidocytes," which he concluded were erythrocytic cells and that this intravascular form was erythroleukosis.

Also in the early decades of the twentieth century, Rous, working in New York, was undertaking studies on the transmissibility of avian sarcomas. In 1909, he suceeded in transplanting a spindle cell sarcoma from one hen to another (432) and soon after showed that the transplantable tumor could be transmitted by cell-free filtrates (431). Over the next two decades, some 20 transplantable tumors of fowl were shown by a number of workers to be filterable (103). As with the leukoses, however, doubt existed about the nature of these avian tumors and their relevance to malignant neoplasms in mammals.

In the 1920s and 1930s, many transmission studies were also conducted on the avian leukoses by notable workers including Furth (222) in the United States, Jérmai (275) in Hungary, Engelbreth-Holm (179, 180) in Denmark, and Oberling and Guérin (358) in France, and numerous strains of avian leukosis virus were isolated (75). An important question was whether the same or different agents caused the 3 forms of leukosis. In general, erythroid and myeloid leukosis were readily transmissible, either in pure or mixed forms, lymphoid leukosis was not. Furth provided evidence of transmission of lymphoid leukosis with filtrates (222), and conclusive proof of the viral etiology of this form came from transmission experiments of Burmester and his coworkers in 1946–1947 (66, 68, 69).

Much of the early research on avian leukosis and sarcomas was motivated by basic scientific and medical interest. From 1920–1940, however, the expansion of the poultry industry in the United States and elsewhere brought increasing losses from the so-called "avian leukosis complex." Research was carried out particularly at land-grant colleges and state agricultural stations in the United States, with the aim being practical control of these diseases (75). The disease picture was complicated by the inclusion in the leukosis complex of neurolymphomatosis (range or fowl paralysis), and visceral lymphomas associated with this disease, which were increasing in prevalence. There was much uncertainty and argument as to whether or not neurolymphomatosis (now termed Marek's disease) was caused by the agents that caused the leukoses (376). The use of the term "visceral lymphomatosis" (282) to cover both lymphoid leukosis and lymphomas associated with neurolymphomatosis did not help the debate (44, 85). In 1939, the U.S. Department of Agriculture established the Regional Poultry Research Laboratory at East Lansing, Michigan, (later renamed the Avian Disease and Oncology Laboratory) to study the cause and control of fowl paralysis (and other neoplastic conditions). In 1959, a similar center, the Leukosis Experimental Unit of the Houghton Poultry Research Station, was established in England. It is known now, from work at these and other centers, that the 3 forms of leukosis, caused by retroviruses, are distinct from the neural and visceral forms of Marek's disease, caused by a herpesvirus.

Numerous other solid tumors have been associated with the avian leukoses occurring in the field and in transmission experiments, including connective tissue tumors, nephromas and nephroblastomas, various other epithelial tumors, endothelial tumors, and neural tumors (34, 204). Also included in the avian leukosis complex is a hypertrophic bone disorder osteopetrosis, first reported by Pugh in 1927 (407) and described and reproduced in 1938 by Jungherr and Landauer (283). The latter workers, and later Burmester and coworkers (66, 215), noted the association of osteopetrosis with lymphoid leukosis.

A rapid increase in knowledge of the leukosis/sarcoma group and the causative viruses occurred after 1960, when tissue culture techniques were developed for studying avian tumor virus-host interactions at the cellular level. The use of Rous sarcoma virus (RSV) as a model to study neoplastic transformation was largely responsible for this. A number of important biological phenomena were discovered by biomedical research groups, most notably those of H. Hanafusa, H. Rubin, H. M. Temin, and P. K. Vogt, which led to knowledge of the biochemistry and molecular biology of avian retroviruses and which benefited the work of the avian disease research laboratories.

More detailed reviews of the history of avian retrovirus research are available elsewhere (75, 164, 374, 534).

Etiology

Classification

Viruses of the avian leukosis/sarcoma group are placed, in a new classification of the International Committee on Taxonomy of Viruses (ICTV), in the *Alpharetrovirus* genus of the family Retroviridae (210). Members of this family are RNA viruses characterized by the possession of the enzyme reverse transcriptase, which is necessary for the formation of a DNA provirus that is integrated in the host genome during virus replication. Under the new taxonomy, *avian leukosis virus (ALV)* is the type species of the genus (Figures 15.21 and 15.22). Other species in the genus are *Rous sarcoma virus* (RSV) and a number of replication defective viruses carrying various oncogenes.

Morphology

Ultrastructure

In thin-section electron microscopy, avian leukosis/sarcoma viruses (ALSV) have an inner, centrally located electron-dense core about 35–45 nm in diameter, an intermediate membrane, and an outer membrane. This appearance typifies the C-type retroviral morphology. The overall diameter of the virus particle is 80–120 nm, with an average of 90 nm. Immature virions budding from the cell membrane can be visualized (Fig. 15.23).
15.21. Schematic diagram of avian leukosis virus particle. The viral envelope is a lipid bilayer in which the gp37 transmembrane (TM) and the gp85 surface (SU) proteins, encoded by the env gene, are inserted. Internal components encoded by the gag/pro gene are p19 matrix (MA) protein, p27 capsid (CA) protein, p12 nucleocapsid (NC) protein, and p15 protease (PR). The pol gene encodes the reverse transcriptase (RT) and p32 integrase (IN). The core of the particle contains 2 viral RNA strands.

15.22. Key features of the viral RNA and proviral DNA forms of the genome of avian leukosis virus. CAP, 5′end structure; AAA, polyadenylation of 3′end; R, repeat sequence; U5, unique 5′ end sequence; U3, unique 3′ end sequence; LTR, long terminal repeat. For other abbreviations, see Figure 15.21 and the text.

Negatively stained preparations reveal essentially spherical particles that are readily distorted under certain conditions of drying (35). Characteristic knobbed spikes about 8 nm in diameter are present on the surface of the particles and comprise the viral envelope glycoproteins. These projections can also be seen in thin sections.

Size and Density
By filtration through membranes of graded pore size, ultracentrifugation, and electron microscopy, viruses have a diameter of 80–145 nm. The value of 1.154–1.17 g/mL for the buoyant density in sucrose is characteristic for C-type retroviruses (29, 427).

Symmetry
Although the particle and core of ALSV show no obvious symmetrical features, the cores of some C-type retroviruses have icosahedral symmetry.

Chemical Composition
The overall composition of avian myeloblastosis virus (AMV), which has been studied extensively, is 30–35% lipid and 60–65%

protein, of which 5–7% is glycoprotein, 2.2% is RNA, and small amounts of DNA are present, apparently of cellular origin (30, 33, 537).

Viral Nucleic Acids
The major class sizes of RNA sediment at 60–70S, which is the viral genome, and at 4–5S, most of which is host tRNA, are thought to be accidentally included in the virion and to play no role in viral replication. A tRNA is also associated with the 70S RNA and is a primer for the DNA polymerase during transcription of viral RNA to DNA. Small amounts of 18 and 28S RNA, viral and cellular mRNA, and DNA are also present. The 60–70S genomic RNA is a dimer and can be split into two subunits of about 34–38S, which are believed to represent the diploid genome. These subunits of genomic RNA are mRNAs, and their genes have been mapped for a number of avian retroviruses.

The sequence of the structural genes of ALV, from the 5′ end to the 3′ end of the RNA molecule, is *gag/pro-pol-env*; these genes encode, respectively, the proteins of the virion group-specific (gs) antigens and protease, RNA-dependent DNA polymerase (reverse transcriptase, or RT), and envelope glycoproteins
15.23.   Ultrastructure of leukosis/sarcoma viruses. A. BAI-A of avian myeloblastosis virus (AMV), unfixed, and negatively stained with neutralized phosphotungstic acid. Peripheral fringe about particles is resolved in some places into discrete "knobs." ×150,000. B. Ultrastructure of leukosis/sarcoma virus release. Virus budding at cell membrane of a leukemic myeloblast. Surface of buds and particles peripheral to outer membrane is irregular and indistinct (pnu, dense prenucleoid). ×215,000. C. Thin section of BAI-A of AMV sedimented from plasma, fixed in osmium tetroxide, and stained with lead subacetate. Inner and outer membranes and granular character of nucleoid can be seen. Impression of granules might be derived from sectioning of filaments. Some granules appear to be hollow. ×510,000. D. Purified BAI-A of AMV fixed and shadowed with chromium. ×50,000. (Bonar and de Thé)

(Fig. 15.22). The structural genes are flanked by terminal genomic sequences with gene promoter and enhancer activities, and that, in the DNA provirus, form the long terminal repeat (LTR) regions. The viral genome is about 7.3 kb in size.

The so-called acutely transforming viruses possess additional viral oncogene sequences that initiate neoplastic transformation. Acquisition of a viral oncogene usually is accompanied by genetic defects elsewhere in the viral genome (see "Pathogenicity"). Nondefective RSV has the genetic composition *gag/pro-pol-env-src*. The additional gene, *src*, responsible for sarcomatous transformation, evidently was acquired originally from a normal cellular oncogene, cellular *src*. The inclusion of this gene is responsible for the approximately 35S subunits of RSV RNA being slightly larger than those of slowly transforming leukosis viruses. The gene cellular *src* is an example of a number of host cell genes, termed proto-oncogenes or *onc* genes, concerned with acute transformation (181, 542). Viral and cellular versions of *onc* genes, and of the specific varieties such as *src*, are distinguished by the prefixes v- and c-. Specific v-*onc* genes, with c-*onc* counterparts in normal cells, are present in other acutely transforming viruses, as listed in Table 15.6.

Slow transformation, as in LL, is caused by an indirect mechanism independent of a v-*onc* but dependent on activation of a c-*onc*, namely c-*myc* in LL, by adjacent integration of ALV provirus (303, 304). This mechanism is called insertional mutagenesis.

Viral Lipids

Viral lipids, mainly phospholipid, occur in the virion envelope and are of cellular origin. They have a bilayered structure similar to the outer cell membrane from which the virion envelope is derived (30, 48).

Viral Proteins

The nature, location, and synthesis of proteins that constitute avian retroviruses have been extensively studied (501) (Figs. 15.21 and 15.22). The virion core contains 5 non-glycosylated proteins encoded by the *gag/pro* gene: MA (matrix, p19); p10; CA (capsid, p27), which is the major gs antigen (Gag) in the core shell; NC (nucleocapsid, p12), involved in RNA processing and packaging; and PR (protease, p15), involved in cleavage of protein precursors. Other minor polypeptides have been reported.

The *pol* gene encodes the enzyme reverse transcriptase (RT) present in the core. It is a complex consisting of the b subunit (95 kD) and the a subunit (68 kD) derived from it and has RNA- and DNA-dependent polymerase and DNA:RNA hybrid-specific ribonuclease H activities. The b subunit also contains the IN domain (integrase, p32), the enzyme necessary for integration of viral DNA into the host genome.

The virion envelope contains 2 glycoproteins encoded by the *env* gene: SU (surface, gp85), the viral surface knob-like structures that determine viral envelope subgroup specificity of the ALSV; and TM (transmembrane, gp37), representing the transmembrane structure that attaches the knobs to the envelope. These 2 envelope (Env) proteins are linked to form a dimer, termed virion glycoprotein (VGP).

Enzymes and other proteins are found in virions and are considered to be cellular components incorporated during virus maturation (501). Of practical value is the presence in AMV obtained from blood of infected chickens, or from myeloblast cultures, of adenosine triphosphatase derived from the cell membrane and incorporated into the virus particle during maturation. This enzyme will dephosphorylate adenosine triphosphate, and this activity can be used for virus assay and purification. Cells without this enzyme, such as fibroblasts, release virus that is devoid of this activity.

Virus Replication

As with other retroviruses, replication of ALSV is characterized by the formation, under the direction of reverse transcriptase, of a DNA provirus that becomes linearly integrated into the host cell genome (Fig. 15.22). Subsequently, the proviral genes are transcribed into viral RNAs, which are translated to produce precursor and mature proteins that constitute the virion. Great effort has been made since the 1970s to elucidate these events, details of which have been reviewed extensively (320, 506). Only an outline of the main events is provided here.

Penetration of the Host Cell

Detailed reviews describing the recent understanding of the early ALV interactions with the host cells are available (27, 28). Although adsorption of the virion to the cell membrane is nonspecific, occurring even in cells resistant to infection, penetration of cells is dependent on the presence, in the cell membrane, of host gene-encoded receptors specific for particular virus envelope subgroups and on fusion of viral and cell membranes. Virions are taken into the cell in vacuoles and viral RNA in the nucleus within 120 minutes of attachment (141). In recent years, considerable progress has been made in understanding the nature of the receptors used by the different ALV subgroups (27). The receptor for subgroup A ALV, designated TVA, is related to the human low-density lipoprotein receptor (29, 571). Binding of the virus to the receptor for subgroup A ALV triggers a conformational change in the viral envelope glycoprotein that allows viral fusion with the cell membrane and viral entry (231). The receptors for ALV subgroups B, D, and E, designated TVB[s3] and TVB[s1], resemble a receptor for cytokines of the tumor necrosis factor family (1–3, 298); the resistance to these viruses is due to a premature stop codon within this allele (296) and molecular tests to evaluate TvB haplotypes have been developed (577). The TVB receptors are functional death receptors capable of inducing death-signalling pathways leading to apoptosis (56, 297). The receptor for the subgroup C avian sarcoma and leukosis viruses, Tvc, is related to mammalian butyrophilins, members of the immunoglobulin superfamily (175). The host cell receptor used by the ALV subgroup J, which has a distinct envelope with limited homology to those of other subgroups, has recently been identified as the chicken Na(+)/H(+) exchanger type 1 (chNHE1) protein (91).

Synthesis and Integration of Viral DNA

Detailed review on the synthesis and integration of viral DNA have been provided elsewhere (58). Major stages in formation of retroviral DNA are (1) synthesis of the first (minus) strand of viral DNA by reverse transcription of viral RNA by reverse transcriptase, forming an RNA:DNA hybrid; (2) removal of RNA from the hybrid by RNase-H and formation on the template of minus-strand DNA of second (plus) strands of viral DNA, giving rise to linear DNA duplexes (these duplex molecules are detectable in cytoplasm of the cell within a few hours of infection); and (3) migration of linear DNA to the cell nucleus.

Linear viral DNA becomes linearly integrated into the host DNA under the influence of the enzyme integrase. This integration can occur at many sites, and infected cells can contain up to 20 copies of viral DNA. The proviral genes occur in the same order as their RNA copies occur in the virion, and they are flanked on either side by identical sequences of nucleotides—the long terminal repeats (LTRs) (Fig. 15.22). These are composed of repeated sequences derived from terminal regions of viral RNA and include promoter and enhancer sequences controlling transcription of viral DNA to RNA. The LTR promoters may also cause abnormal transcription of host genes usually downstream of the proviral DNA, leading to oncogenesis.

Transcription

Formation of new virions in the infected cell is the result of transcription and translation of proviral DNA, the major events being as follows: (1) Transcription of viral RNA on a template of proviral DNA occurs under the influence of a host RNA polymerase.

Table 15.6. Acutely transforming avian sarcoma and leukemia viruses classified according to viral oncogene.

Virus strain	Oncogene(s) carried	Oncogene product	Predominant neoplasm(s)	Cells transformed *in vitro*

Transcription of the *pro* sequence of the *gag/pro* gene to produce protease (PR) involves a frame shift. Viral RNA molecules give rise to mRNA in association with polyribosomes, and they also serve as genomic RNA in newly formed virions. New viral RNA is detectable within 24 hours of infection. (2) mRNA species, bound to polyribosomes, are translated to form the *gag*, *pol*, and *env* gene-coded proteins that comprise the virion. The *gag/pol* gene product is a large protein precursor (180 kD) Pr180, which is cleaved to give a precursor polyprotein Pr76 (76 kD) from which virion core proteins MA (p19), CA (p27), NC (p12), PR (p15) and p10 are derived. The Pr180 polyprotein also gives rise to RT (p63 and p95) and integrase (IN, p32) enzymes. The *env* gene product is a precursor protein gPr92 (92 kD) from which the viral envelope proteins SU (gp85) and TM (gp37) are derived. Translation of *env* is from a spliced subgenomic RNA. The viral proteins localize at the plasma membrane of the cell, where crescent-shaped structures develop and virions that bud off from the cell may be visualized.

Defectiveness and Phenotypic Mixing
A number of avian retroviruses (Table 15.6) have been shown to have defective genomes and arise either spontaneously or as a result of experimental mutagenesis (255). Some viruses (certain strains of RSV and acute leukemia viruses) are defective for genes required for replication and are termed replication-defective (*rd*) mutants. They will transform cells but require the presence of a helper leukosis virus to enable them to replicate (e.g., BH-RSV and AMV lack the *env* gene, and AEV and MC29

lack the *pol* and *env* genes). Other acutely transforming viruses, such as certain strains of RSV, have lost their v-*onc* gene and ability to transform rapidly: They are called transformation defective (*td*) mutants and have an oncogenic potential similar to that of nondefective ALVs (45). *Td* and *rd* mutants are defective under all conditions (nonconditional mutants). Conditional mutants function under permissive conditions, not under nonpermissive conditions, and are exemplified by the temperature-sensitive (*ts*) mutants.

BH-RSV is the classic example of an *rd* mutant and is of practical importance in the non-producer (NP) cell activation test for ALVs (see "Diagnosis"). On single infection of chick embryo fibroblasts, the defective virus genome of BH-RSV functions to bring about replication of viral RNA, transformation of infected cells, and production of gs antigen. However, only noninfectious progeny particles are produced, which are unable to enter new host cells because of an alteration in their envelope glycoproteins. The morphologically altered cells are called NP cells. A nondefective ALV added to these cells acts as a helper virus by complementing the defective genome of BH-RSV and causes both infectious RSV and progeny ALV to be produced simultaneously. Thus, the presence of infectious RSV in the NP test denotes the presence of ALV in added test material. This RSV has envelope antigens identical to those of the helper virus, which, thus, determines infectivity and range of infectivity in genetically different cells, interference patterns among and between virus subgroups (see "Strain Classification"), and envelope antigenicity.

Stocks of *rd* mutant RSV must by their existence contain
15.24. Endogenous viral (ev) loci detected in 6 inbred lines of white leghorns by restriction fragment polymorphisms generated after Sac-1 endonuclease digestion of red blood cell DNA and hybridized to ^{32}P-labeled RAV-2 genomic sequences. (464)

helper viruses; these originally were referred to as Rous-associated viruses (RAVs). Infectious RSVs formed in these circumstances are called pseudotypes, and their designation includes the helper virus when this is identified (e.g., BH-RSV(RAV-1) when RAV-1 strain ALV helper virus is used). This phenomenon is an example of the phenotyping mixing (PM) (47) that occurs readily when 2 related viruses infect the same cell, and in which virions with the genome of one virus may possess envelope and other structural proteins of the other parent, or both. The phenomenon of PM is also used in the PM test for detection of ALV (see "Diagnosis"). Genetic recombination, in which exchanges of genes between 2 viruses (and consequent stable phenotypic changes) occur, are well recognized and must be distinguished from PM (552, 569). Use of defective strains of RSV enables tailor-made RSV to be produced with envelope properties of the helper ALV. Determinations of host range, interference pattern, and neutralization can be performed more easily with the appropriate RSV pseudotype than with the ALV, because the former can be readily quantified in cell culture.

These factors notwithstanding, infectious RSV may be generated with BH-RSV and other *rd* mutants following solitary infections in the absence of added helper viruses in certain types of chicken cells that carry endogenous ALV genomes (see "Endogenous Leukosis Viruses"). Such RSV has the subgroup E host range of the endogenous virus, however, and may be distinguished from helper viruses of other subgroups when NP tests are conducted.

Phenotypic mixing may also occur between unrelated viruses, such as vesicular stomatitis virus (VSV) and ALVs (550) or between reticuloendotheliosis virus (REV) and RSV (450). The VSV with ALV viral envelope may be used in rapid interference, host range, and neutralization tests because it is rapidly cytopathic.

Endogenous Leukosis Viruses

ALVs that are transmitted as infectious virus particles are termed exogenous viruses. The normal chicken genome also contains several classes or families of avian retrovirus-like elements (117) that are transmitted genetically and are termed endogenous viruses. These include the endogenous viral (*ev*) loci, recognized some 30 years ago, and the more recently discovered moderately repetitive elements EAV (endogenous avian virus) (53, 169) and ART-CH (avian retrotransposon from chicken genome) (50, 357, 440) and the highly repetitive elements CR1 (chicken repeat 1) elements (499). Endogenous retroviruses in chickens are examples of the numerous retroelements present in eukaryotes. Certain retroelements are believed to represent stages in the evolution of retroviruses from cellular movable genetic elements (transposons); whereas others are thought to be degenerate proviral forms of exogenous retroviruses that have lost the ability to produce infectious virus due to mutations. The significance of these elements is currently the subject of much research.

The genetic sequences of the *ev* loci are related to subgroup E ALVs and are present as either complete or defective genomes in almost all normal chickens (116, 119, 424, 464) (Fig. 15.24). The chromosomal locations of a number of *ev* loci have been determined (509) and the availability of the chicken genome sequence (108) has enabled the identification of their genomic locations. They occur in somatic and germ line cells and are transmitted genetically in a Mendelian fashion to their progeny by both sexes (8, 127). At least 29 *ev* loci have been identified (246, 464) and locus-specific PCR tests for their identification have been described (39). Each chicken has been reported to carry on average about 5 *ev* loci (433). The phenotypic expressions of these loci vary, depending on the viral genes present and on poorly understood control mechanisms (Tables 15.7 and 15.8). When the complete endogenous viral genome is present, the cell may produce subgroup

[b] The presence of 5 *ev* loci in Reaseheath line w birds precludes definitive assignment with the V-E^1 phenotype. Definitive association requires further segregation of *ev* genes. Hyline FP birds also carry *ev*1, *ev*3, and *ev*6.

E ALV, either spontaneously or after induction by chemicals such as bromo-deoxyuridine (BUDR). When the endogenous virus is incomplete (defective), genes present may be expressed phenotypically in the cells, but infectious virus is not produced. This is because of the absence of the complete set of genes needed for infectious virion production (e.g., the defective *ev*3 locus possesses the *gag* and *env* genes of subgroup E ALV, and cells carrying this locus contain gs antigen and subgroup E viral envelope glycoproteins). However, the locus has a genetic deletion around the *gag-pol* junction, and infectious virions are not formed. The presence of *ev* genes in such cells is responsible for their positive reactions in the enzyme-linked immunosorbent assay (ELISA) test, the complement-fixation test for avian leukosis viruses (COFAL), and the chick helper factor (chf) test (see "Diagnosis"). In the chf test, genetic defectiveness in the envelope of BH-RSV is complemented by endogenous envelope proteins, resulting in an infectious form of RSV with subgroup E host range and other properties. Genetic characteristics of *ev* loci are described in detail (117, 464, 594, 551). The expression of endogenous *ev* genes is responsible for a dominant form of genetic resistance of chicken cells to infection by subgroup E ALV from a block of virus receptors by envelope protein (392, 425). Transmission of *ev* genes from parent to offspring has been called genetic transmission of ALV (548), distinguishing it from the vertical (congenital) and horizontal (contact) transmission of viruses in an infectious state. However, fully expressed infectious endogenous virus may sometimes also be transmitted vertically and horizontally (475). Related *ev* loci occur in several species of fowl, other than domestic chickens, including red jungle fowl and some strains of pheasant, partridges, and grouse, but the distribution does not support a phylogenetic relationship (219, 230). Rather, it is considered that the ALV genomes have become incorporated at various loci relatively recently in the history of *Gallus* and independent of integration in other genera. The presence of ALSV *gag* genes in 26 species of galliform birds recently was reported (153, 154). Evidence of congruence of ALSV and host phylogenies exists but also of horizontal ALSV transmission between hosts of different phylogenies. It is not known whether endogenous viruses arise from exogenous viruses of other subgroups, from which they differ genomically at the *env* gene and the LTR region, or vice versa.

Subgroup E ALV, typified by the RAV-0 strain of ALV, has little or no oncogenicity (346), apparently because of the weak promoter activity of the LTR. Persistence of these viral loci suggests that birds carrying them are not at a great disadvantage, and they may be beneficial. Thus, Crittenden *et al.* have shown that the presence of *ev*2 or *ev*3 protects birds from a unique non-neoplastic syndrome caused by infection with an exogenous subgroup A ALV (122, 133). Endogenous viruses will have either beneficial or detrimental effects, perhaps by their induction of immunity or tolerance to tumor virus antigens, depending on when they are expressed. Embryonic infection with endogenous ALV, RAV-0, caused more persistent viremia and more neoplasms following infection with exogenous ALV, apparently due to tolerant depression of specific humoral immunity (125). Similarly, subgroup E recombinants of endogenous and exogenous viruses have been reported to be capable of inducing neoplasm (123). Endogenous viruses of the *ev* family are not essential, because it has been possible to produce chickens free of *ev* genes (7). A line of such chickens has been produced, designated line 0 (121), that is of value in research studies and certain diagnostic tests in which birds or cells free from *ev* loci are needed. Other chickens lacking *ev* loci have been recognized (117), but the great majority have these endogenous sequences. More re-

cently, methods of developing commercial chicken strains free of endogenous retroviruses have been described (15).

Of particular importance is the *ev*21 locus, which is linked tightly in white leghorn stock to the dominant sex-linked gene, *K*, on the Z chromosome (16), which regulates slow feathering. It is possible that insertion of the *ev*21 sequence into a feather growth locus is responsible for the slow feathering mutation (117). Some breeders producing feather-sexed crosses have reported reduced egg production and higher leukosis mortality associated with an increased incidence of viremia with exogenous ALV in fast-feathering female progeny from dams carrying the *K* gene. The *ev*21 gene is expressed as an infectious endogenous ALV, EV21, in the dam, which is transmitted congenitally to the progeny, inducing immunological tolerance and, consequently, increased susceptibility to infection by exogenous ALV (16, 252, 466, 468). Strategies to overcome the *ev*21 locus effect have been studied (470, 471, 473).

The biologic functions, if any, of the other endogenous elements described, namely EAV, ART-CH, and CR1, remain to be determined. Members of the EAV family are not expressed as infectious virus, but RT activity can be expressed and has been found in live virus vaccines (266, 267, 423, 519, 556). A member of the EAV family, EAV-HP (also termed ev/J), is believed to be the origin of the *env* gene of subgroup J ALV (21, 41, 42, 149, 438, 440, 478). The 5′ sequences of ART-CH and EAV-HP are almost identical (442). Embryonic expression of EAV-HP env has been suggested to be associated with the induction of immunological tolerance, a feature observed in a significant proportion of meat-type chickens infected with ALV-J. In support of this hypothesis, it was recently demonstrated that EAV-HP loci are still segregating within the chicken population (442). Recently the strongest evidence of the role of EAV-HP in the emergence of ALV-J by recombination was obtained from the identification of an intact chicken EAV-HP locus showing a uniquely close relationship to the ALV-J prototype clone HPRS-103 env region (441).

CR1 elements are non-LTR-containing retroelements (retroposons) possessing RT sequences. They are very numerous and are considered ancient and primitive sequences, preceding the evolution of birds, and are not functionally expressed (178, 318, 527, 546, 558).

Susceptibility to Chemical and Physical Agents

Lipid Solvents and Detergents
Avian retroviruses have a high lipid content in the envelope, and their infectivity is abolished by ethyl ether (217). The detergent sodium dodecyl sulfate disrupts the virions and releases RNA and core proteins (427).

Thermal Inactivation
The half-life of various ALSVs at 37°C varies from 100–540 minutes (average, around 260 minutes), depending on the medium in which the virus is suspended, the tissue of origin, and the virus strain. ALSVs are inactivated rapidly at high temperatures; the half-life for RSV at 50°C is 8.5 minutes and at 60°C is 0.7 minutes (163).

Thermal lability of infectivity of these viruses is a critical factor in storage. Even at −15°C, the half-life of AMV is less than 1 week (172); it is only at temperatures below −60°C that avian retroviruses can be stored for several years without loss of infectivity (61). Freezing and thawing degrade the virus, and the gs antigen is released.

pH Stability
The stability of viruses of this group changes little between pH 5 and 9; outside this range, inactivation rates are markedly increased.

Ultraviolet Irradiation
RSV and field strains of ALV are relatively resistant to exposure to ultraviolet light (217, 435).

Strain Classification

Antigenicity
ALSVs that occur in chickens have been divided into 6 envelope subgroups, A, B, C, D, E, and J, on the basis of differences in their viral envelope glycoproteins, which determine antigenicity, viral interference patterns with members of the same and different subgroups, and host range in chicken embryo fibroblasts of different phenotypes (105, 555). The other subgroups, F, G, H, and I, represent endogenous ALVs occurring in pheasants, partridge, and quail (374).

Viral interference patterns (Table 15.9) and host range patterns (Tables 15.10 and 15.11) are the most reliable methods for subgroup classification. Antigenicity, as determined by the production of neutralizing antibodies or neutralization by known subgroup-specific antibodies, can also be used for strain classification, but is less dependable. Viruses within a subgroup usually cross-neutralize to varying extents, but with the exception of partial cross-neutralization between subgroup B and D viruses, viruses of different subgroups do not. However, antisera against particular isolates of subgroup J virus do not always cross-neutralize other J isolates, or they may show one-way cross-

Table 15.9. Interference patterns between ALV and RSV of subgroups A–E and J.

Subgroup of interfering ALV	Subgroup of challenge RSV					
	A	B	C	D	E	J
A	1	2	2	2	2	2
B	2	1	2	1	1	2
C	2	2	1	2	2	2
D	2	2	2	1	2	2
E	2	2	2	2	1	2
J	2	2	2	2	2	1

Note: Susceptible avian embryo fibroblast cultures are infected with ALV of each subgroup and challenged several days later with RSV of each subgroup. Reduction in RSV foci in infected cultures compared with uninfected controls is indicative of viral interference. 1, interference; 2, no interference.

Table 15.10. Examples of host range of subgroup A–E and J avian leukosis/sarcoma viruses in chicken embryo cells of different phenotypes.

Phenotype of cells	Examples (chicken or cell lines)	Subgroup of virus					
		A	B	C	D	E	J
C/0	15B1	S	S	S	S	S	S
C/AE	C, alv6	R	S	S	S	R	S
C/A,B,D,E	7₂	R	R	S	R	R	S
C/E	0, 15I, BrL	S	S	S	S	R	S
C/EJ	DF-1/Jᵃ	S	S	S	S	R	R

Note: S, susceptible; R, resistant. The cell phenotype designation denotes chicken (C) cells resistant to (/) the specified subgroup (0, no subgroup; AE, subgroups A and E; etc.).

Turkey	S	S	S	S	S	S
Peking duck	R	R	S	R	R	R
Goose	R	R	S	R	R	R

Note: Embryo fibroblast cultures from avian species are challenged with RSV and susceptibility to RSV focus formation determined. S, susceptible; R, resistant. Data from Payne *et al.* (389).

neutralization (193, 204, 206, 211, 532). In general, antiserums raised against a particular strain of virus tend to neutralize the homologous virus more strongly than heterologous viruses of the same subgroup (101). These findings indicate the occurrence of varying antigenic epitopes within subgroups. Subgroup B viruses appear to be more heterogeneous than those of subgroup A, and subgroup J viruses are especially variable (528, 532, 543).

Molecular Characteristics
Sequence analysis of the gp85 encoding sequences of the *env* genes of ALVs of subgroups A–E have identified 2 hypervariable regions, hr1 and hr2, and 3 less variable regions, vr1, vr2 and vr3, in which differences between the subgroups are present (51, 52, 162). Studies of recombinants indicated that hr1 and hr2, and to a lesser extent vr3, play the major role in determining receptor tropism (161). However, the exact locations and nature of the dif-

ferences that determine host range and antigenicity have not yet been identified. The gp85 sequence of the *env* gene of subgroup J ALVs differs more extensively from those of the other 5 subgroups, notably at hr1, hr2, vr2, and vr 3, and to a lesser extent also between these regions (21, 22). Different subgroup J isolates also vary at particular hypervariable regions of gp85 (42, 461, 462, 532, 543). Primers from the variable regions of the *env* gene of subgroups A–E and J have been used in PCR tests to identify subgroups of ALV isolates (225, 289, 477, 573, 575). These tests have the potential to be used in strain classification, although more extensive studies are needed of multiple isolates within subgroups to evaluate their specificity fully.

Pathogenicity
Numerous strains of ALSVs exist, many of which were isolated from naturally occurring or experimentally induced neoplasms over many years. Some of these have been designated viral species under the new ICTV taxonomy of avian retroviruses (210). Many induce a predominant type of neoplasm and can be named accordingly; e.g., lymphoid leukosis virus (LLV), although ALV is most commonly used rather than LLV; avian erythroblastosis virus (AEV); avian myeloblastosis virus (AMV); and avian sarcoma virus (ASV) (Table 15.12). Commonly, however, the virus strains induce other neoplasms in addition to the predominant one, and the tumor spectrum can be wide. The oncogenic spectrum tends to be characteristic of a particular virus strain, but often overlaps with other strains. Thus, the RPL12 strain of ALV induces lymphoid leukosis, erythroblastosis, osteopetrosis, hemangiomas, and sarcomas; the BAI A strain of AMV induces myeloblastosis, lymphoid leukosis, osteopetrosis, nephroblastomas, sarcomas, hemangiomas, thecomas, granulosa cell tumors, and epitheliomas (34).

The spectra of tumors induced have several explanations. Some strains of virus consist of mixtures of viruses either fortuitously or because some may require coinfecting helper viruses for replication (see later discussion). However, clone-purified strains of ALV can cause a variety of neoplasms in addition to lymphoid leukosis, including erythroblastosis, osteopetrosis, and nephroblastomas (415), and clone-purified AEV can induce both erythroblastosis and sarcomas, irrespective of the helper virus (244). The relatively high mutation rate of retroviruses no doubt contributes to strain variability. The tumor spectrum of a virus strain can also be modified in passage experiments according to the type of neoplasm used to harvest virus.

Virus dose is an important factor in determining tumors induced. Thus, high doses of strain RPL12 of ALV mainly cause erythroblastosis; whereas low doses cause lymphoid leukosis (73). Factors that influence effective dose, including route of inoculation and age and genotype of the host, also influence the oncogenic spectrum.

Strains of ALSV can also be placed into two major classes in respect of rapidity of induction of tumors:

1. *Acutely transforming viruses.* These viruses can induce neoplastic transformation, *in vivo* or *in vitro*, within a few days or weeks. They cause various types of acute leukemia (leuko-

sis) or solid tumors (usually sarcomas) (181, 183, 243, 303, 342). The acutely transforming viruses are those that carry viral oncogenes in their genome (Table 15.6). Details of viral oncogenes and the biochemical functions of their products have been reviewed elsewhere (105, 303, 535). All avian acute leukemia viruses are genetically defective and require a helper leukosis virus to complement them and enable replication. The acutely transforming viruses are replication-defective (*rd*) mutants, lacking in genes required for replication. Some sarcoma viruses (e.g., Bryan high-titer strain of RSV [BH-RSV]) are also genetically defective and require a helper virus for replication.

2. *Slowly transforming viruses.* These ALVs do not carry viral oncogenes. They induce tumors by a "promoter insertion" or a related mechanism that activates a cellular oncogene to bring about neoplastic transformation and development of tumors over many weeks or months (105, 183, 221, 303).

Nomenclature

A variety of conventions, which reflect the classification methods outlined previously, are used in designating ALSVs; many of these are illustrated in Table 15.12. They are given a full and an abbreviated designation based on the predominant neoplasm they induce, with an affix to indicate their origin with an individual (e.g., Rous sarcoma virus [RSV]) or a location (e.g., Regional Poultry Research Laboratory isolate 12 [RPL12 of ALV). Substrains of RSV are designated according to individuals who worked with them (e.g., Bryan's high-titer strain [BH-RSV]) or to location (e.g., Prague [PR-RSV]). Subgroups (e.g., subgroup A) may be designated also: PR-RSV-A. The general terms *avian leukosis* (or *leukemia*) *virus* (ALV) and *avian sarcoma virus* (ASV) are used widely to designate members of the group.

Helper viruses isolated from stocks of defective viruses are named, for example, as Rous-associated virus (RAV) or myeloblastosis-associated virus (MAV), and isolates are numbered (RAV-1, MAV-1, etc.). Where a helper virus is used for replication of a defective virus, this is indicated. Thus, BH-RSV grown with RAV-1 as a helper is designated BH-RSV(RAV-1). Endogenous ALV is abbreviated EV (e.g., EV21). Strains of ALV that act as resistance-inducing factors (see "Diagnosis") were designated RIFs, but this term is now rarely used. Further details of the origins of the abbreviations (374) are given in Table 15.12.

Laboratory Host Systems

Chick Inoculation

Rous sarcoma and other sarcoma viruses produce tumors when injected by the subcutaneous (SC), intramuscular (IM), or intra-abdominal (IA) routes and at times by contact with inoculated chickens. Subcutaneous injection into the wing web or IM injection can be used for sarcoma virus isolation and propagation (340, 416), and SC inoculation has been used for TD_{50} assays of stocks of RSV (60). Following wing-web injection of high doses of RSV, tumors are first palpable at about 3 days. In susceptible chickens, these may grow rapidly, ulcerate, and metastasize; in resistant chickens, the sarcomas may regress. Extensive reviews on assay methods and interpretation of results are available (60).

ALVs may be inoculated IA or IV into day-old susceptible chicks to obtain a tumor response. Burmester and Gentry (72) inoculated strain RPL12 of ALV IA into day-old line 15I chicks and obtained a tumor response in 200–270 days. This procedure was used for initial isolation of virus from field cases (71). Time required for quantitative assay of certain strains passaged in the laboratory was shortened to 63 days by using the less sensitive erythroblastosis response (62). In these transmission experiments, all sources of virus that cause LL also caused erythroblastosis. Osteopetrosis, hemangiomas, and fibrosarcomas were also observed in chickens of certain strains and passages (70, 73).

AMV can be titrated in susceptible chicks by IV inoculation at 1–3 days of age (170, 171). AMV in chicken plasma can be assayed by its adenosine triphosphatase activity, a method useful for routine and large-scale studies (38).

Osteopetrosis-inducing activity of virus strains can be examined by IV or IM inoculation of day-old chicks (70, 260). Guinea fowl are particularly susceptible to osteopetrosis induced by MAV-2(O) (290, 291, 293, 294).

Embryo Inoculation

When RSV and other sarcoma viruses are inoculated onto the chorioallantoic membrane (CAM) of 11-day-old susceptible embryos, tumor pocks develop (Fig. 15.25), which can be counted 8 days later and are related linearly to virus dose (167). This technique is also useful for detecting genetic resistance to infection.

ALVs have been quantitated by IV inoculation into 11-day-old susceptible chicken embryos. Depending on the virus, within 2 weeks of hatching, a high incidence of neoplasms (mainly erythroblastosis) can occur, although hemorrhages and solid tumors can develop including fibrosarcomas, endotheliomas, nephroblastomas, and chondromas. When chicks are held for a postinoculation period of 46 days, responses are higher by 1–2 log_{10} dilutions than those following chicken inoculation. Most chickens that survive the acute neoplasms develop LL after 100 days postinoculation (400).

AMV produced a myeloblastosis response within a few weeks when injected by IV into susceptible embryos (23, 24, 25). When the HPRS-103 strain of subgroup J ALV was inoculated by IV into 11-day-old embryos, first death from tumor (myelocytoma) was not until 9 weeks of age, and median tumor mortality was at 20 weeks (383).

Cell Culture

RSV and other sarcoma viruses induce rapid neoplastic transformation of cells when inoculated onto monolayer cultures of chicken embryo fibroblasts (414). The transformed cells proliferate to produce within a few days discrete colonies or foci of transformed cells (Fig. 15.26), which under agar can be used for quantitative assay of virus (508). Such cell culture methods are preferred for virus assay.

Most leukosis viruses replicate in fibroblast cultures without producing any obvious cytopathic effect. Their presence can be detected by a variety of tests (see "Diagnosis"). ALVs of subgroups B and D may induce cytopathic plaques that may be used for virus assay (242). The cytopathic effect of these 2 subgroups

Table 15.12. Laboratory strains of avian leukosis/sarcoma viruses of the chicken classified according to predominant neoplasm induced and virus envelope subgroup.

Virus class according to neoplasm	Virus class according to envelope subgroup						No subgroup (defective virus)[a]

[a]Defective viruses have the envelope subgroup of their helper virus.

is explained by their use of the death receptor of the tumor necrosis factor receptor family (56, 99, 151, 152). Morphological alterations have also been reported after prolonged passage of ALV-infected fibroblasts (84).

Acutely transforming ALVs will transform hematopoietic cells *in vitro* (342). Yolk sac and bone marrow cells in culture are transformed to neoplastic myeloblasts on infection with AMV (343), and bone marrow cells transform to erythroblasts with AEV (241). Transformation of hematopoietic cells by MH2, MV29, and OK10 viruses was observed by Graf and Beug (243). Such acutely transforming ALVs have been used extensively to study avian hematopoietic cell lineages and differentiation (43, 330, 331). Acutely transforming variants of subgroup J ALV can also transform bone marrow cells and blood monocytes *in vitro* (95, 384). *In vitro* transformation of B-lymphocytes by nondefective ALV has not been reported, and bone marrow cultures were not transformed by nondefective subgroup J ALV (384).

Tumor cell lines derived from tumors induced *in vivo* by the ALVs have been developed, including LL (360, 459), myeloblastosis (311), erythroblastosis (241), and myelocytoma (312).

The properties of ALSVs in cell culture are described in more detail under "Diagnosis."

Pathogenicity

As discussed previously (see "Strain Classification"), strains of ALVs may produce more than one type of neoplasm, and the oncogenic spectrum of each strain tends to be characteristic but often overlaps with responses to other strains. Viral factors including the origin and dose, and host factors such as route of inoculation, age, genotype, and sex influence the oncogenic patterns of different virus strains.

Origin of Virus

Differences in tumor spectrum may be seen in virus strains newly isolated from the field, as exemplified by tumor spectrums of RPL26, RPL27, and RPL28 isolates of ALV (215). Within a par-

ticular strain, differences may be obtained that depend on the type of neoplasm used for virus isolation. Fredrickson *et al.* (215, 216) observed that serial transfer from donors with LL resulted primarily in LL; whereas virus from donors with erythroblastosis predominantly caused erythroblastosis. In another instance, selection of virus donors with hemangiomas resulted in a larger proportion of birds with this tumor than in a previous passage (73). In some situations, such events may be due to a virus-dose effect, but in other instances, an acutely transforming ALV with a transduced oncogene may have been generated (257).

Virus Subgroups

Usually no relationship has been observed between virus subgroup and oncogenicity except for endogenous E subgroup ALVs, such as RAV-0, which have little or no oncogenicity (346). However, the low oncogenicity of RAV-0 is believed to be related to the weak promoter activity of the subgroup E LTR and not to the *env* gene. Subgroup J ALV induced myelocytomatosis (383), and the *env* as well as other elements are thought to be associated with the unique oncogenicity (95, 96, 97, 322, 323).

Unstained focus of transformed round and fusiform cells infected 6 days previously with Popken's preparation of RSV. ×100.

Virus Dose

High doses of RPL12 ALV mainly induced erythroblastosis; whereas doses close to the endpoint predominantly induced LL (73). Sarcomas, endotheliomas, and hemorrhages were also more common with high virus doses. Occurrence of osteopetrosis showed no dependency on dose (216).

Route of Inoculation

Responses obtained after virus administration by less efficient portals of entry into the host apparently reflect the decreased effective dose. Thus, exposure of susceptible birds by contact with birds inoculated with a high dose of strain RPL12 of ALV resulted in a LL response similar to that expected with 1/1000 of the inoculated dose (73). Intramuscular inoculation of strain RPL26 of ALV favored sarcoma induction; whereas IV inoculation mainly produced erythroblastosis and hemorrhages (216). These differences may reflect variations in amounts of virus that reach the target cells by different routes.

Age of Host

In general, resistance of birds to the development of neoplasms of all types increases with age, the rate varying with route of inoculation. Resistance increases rapidly between 1 and 21 days of age with oral or nasal administration but relatively slowly when virus is inoculated intravenously (70). Types of tumors produced also reflect the decreased effective dose (73). However, the incidence of some tumors decreases more rapidly than expected from the dose effect alone. For example, certain preparations of strain RPL12 ALV given via IV at 1 day of age caused a high incidence of osteopetrosis; the proportion of chickens inoculated at 3 weeks of age and developing osteopetrosis was only one-tenth that of chickens inoculated at 1 day of age (70). Induction of tolerant viremia at 1 day may be a factor.

Genotype and Sex of Host

The genetic constitution of the host has a strong influence on response to ALSVs (see "Pathobiology and Epidemiology"). Females are more susceptible to LL than males. Castration increases the incidence of disease, and treatment with testosterone increases resistance of males and capons (74). These effects are probably a consequence of hormonal effects influencing regression and, hence, target cell numbers in the bursa of Fabricius.

Pathobiology and Epidemiology

Incidence and Distribution

ALVs are still considered ubiquitous in commercial chickens, notwithstanding the eradication programs instituted by many primary breeding companies. With few exceptions, infection occurs in all chicken flocks; by sexual maturity, most flocks and most birds within a flock are already exposed. Nevertheless, the incidence of subgroup A ALV-induced LL, the most common neoplasm observed in infected flocks, is usually low, in the order of 1 or 2%, although losses of up to 20% can occur.

Incidence of Disease

Although sporadic cases of ALV-induced neoplasia occur in most flocks, it is only occasionally that even the most common neoplasm, LL, produces heavy losses (196, 204, 380, 394). De Boer (144, 146) reported LL mortality in the Netherlands as 2.18% of 11,220 white layers and 0.57% of 7920 brown layers, recorded in random sample tests from 1973–1979. The incidence of LL in chickens may be reduced by the widespread occurrence of infectious bursal disease virus (137, 410, 412). Conversely, serotype 2 MDV was found to enhance the development of LL in certain lines of chickens following exposure to ALV after hatch (19, 195, 198, 207). Also, an increased frequency of spontaneous bursal lymphoma (139) in white leghorn chickens inoculated with serotype 2 MDV has been reported (444) . Molecular and *in situ* hybridization analysis of the bursa from chickens co-infected with ALV and serotype 2 MDV proved that MDV was closely associated with transformed, but not with nontransformed, bursa cells (223, 326). *In vitro* studies also showed that serotype 2 MDV can increase ALV as well as RSV gene expression (26, 408, 513).

Under field conditions, erythroblastosis occurs less frequently than LL (409). However, a rare epizootic of erythroblastosis has been reported in 5-week-old birds (251). Very few reports have been made of natural occurrence of myeloblastosis, but cases occur sporadically.

Until recently and before the recognition of subgroup J ALV (381, 394), myelocytomatosis was mainly a sporadic disease seen among young and adult birds (409). An overall incidence of 27% myelocytomatosis was reported in meat-type chickens inoculated with strain HPRS-103 of ALV-J (385). High incidence of ALV-J tumors have been reported in many countries (20, 512, 528) with mortalities up to 1.5% in excess of normal levels per week in some commercial broiler breeder flocks (206).

Of all tumors other than leukotic tumors, hemangiomas make up 25% and 19%, and nephroblastomas 19% and 3–10%, in broilers (87) and layers (409), respectively. Epizootic outbreaks of hemangiosarcomas recently have occurred in layers in Israel (79, 80).

Connective tissue tumors, which are often not the primary cause of death, make up about 20% of nonlymphoid tumors in broilers (87). The incidence of connective tissue tumors in chickens is probably less than 1 in 1000 (409), but epizootics have occurred. Outbreak of histiocytic sarcomas was reported in a flock of 600 1-year-old hens, during which tumors were found in 90% of 400 birds examined during a 4-month period (395). Low incidence of histiocytic sarcomatosis associated with ALV-J has also been reported (4).

Osteopetrosis occurs much less frequently than LL, and epizootics occur sporadically in broilers. In all types of chicken, males are more frequently affected than females. It occurs very rarely in turkeys.

Incidence of Virus Infection

Subgroup A ALV is the most common subgroup of L/S viruses isolated from field outbreaks of LL; it is encountered more frequently than subgroup B. In one study (83), 1.6–12.5% of the

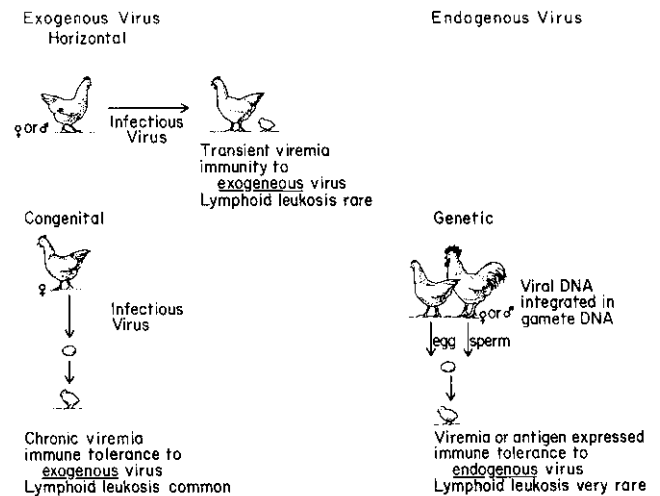
embryos from 8 commercial flocks representing a variety of sources contained subgroup A ALV, and there was significant shedding in every flock. In contrast, subgroup B ALVs were relatively rare and were shed in eggs much less frequently than subgroup A. In general, fewer studies of the prevalence of ALV in meat lines have been made compared with those in egg lines. Antibodies to the novel subgroup J ALV were found in 3 of 5 meat-type chicken lines, but not in 7 layer lines examined in the United Kingdom (388). Using virological and serological assays, the incidence of ALV-J infection in affected broiler breeder flocks was reported to be as high as 87% (206). Similar high levels of ALV-J infection have been reported in other countries also (20, 310, 325, 512, 528, 570). The incidence of infection with subgroup ALV-J was also influenced by other factors such as age at exposure (560, 561).

Subgroups A, B, C, and D of ALV have been isolated from commercial flocks in Finland; 5 of 10 flocks surveyed had antibody to all 4 subgroups (445).

Antibodies to subgroups A and B are common among wildfowl and domestic chickens in Kenya and Malaysia, and some evidence exists of antibody to subgroup D viruses in Kenya. Subgroup F viruses have been found in ring-necked and green pheasants, and subgroup G viruses in Ghinghi, silver, and golden pheasants. Subgroup H virus has been isolated from Hungarian partridges and subgroup I virus from Gambel's quail (see "Virus Subgroups"). Viruses that do not fit within known subgroups have been isolated from Mongolian and Swinhoe pheasants, Chinese quail, and chickens. However, none was found in Japanese quail, pigeons, geese, and Pekin and Muscovy ducks (94).

In most vertebrate species, endogenous retroviral genomes are inherited in a Mendelian fashion and occur at distinct chromosomal loci. DNA sequences related to RAV-0, the endogenous avian retrovirus, occur in the germ lines of most domestic chickens and several species of galliform birds. For example, partridges, true pheasants, grouse, and jungle fowl contain sequences complementary to RAV-0; whereas guinea fowl, quail, peafowl, ruffed pheasants, gallo-pheasants, and turkeys do not (218). The structure, function, and regulation of endogenous retroviruses in the genome of the chicken have been reviewed (117).

Natural and Experimental Hosts

Chickens are the natural hosts for all viruses of L/S group (375); these viruses have not been isolated from other avian species except pheasants, partridges, and quail (see "Virus Subgroups"). Experimentally, however, some members of the L/S group of avian retroviruses have a wide host range and can be adapted to grow in unusual hosts by passage in very young animals or through the induction of immunologic tolerance prior to inoculation of the virus. RSV has the widest host range; it will cause tumors in chickens, pheasants, guinea fowl, ducks, pigeons, Japanese quail, turkeys, and rock partridges. Ducks were shown to be an ideal experimental system for studying persistence of ALV as the virus appeared to persist even up to 3 years with no viraemia or neutralizing antibodies after embryonic infection (350). However ducks infected as embryos with subgroup C showed wasting disease soon after hatching (496, 500, 518).


15.27.   Horizontal and vertical transmission of exogenous LLV and genetic transmission of endogenous virus. (116)

There has been one report of lymphoid leukosis in ostriches (224). Some strains of RSV induce tumors in mammals (533), including monkeys (299–302). Osteopetrosis can be produced in turkeys by inoculation of fresh whole blood from affected chickens (260). Also, turkeys were susceptible to ALV-J infection and tumors induced by the acute form of strain HPRS-103 of ALV-J (531).

Transmission

Exogenous ALVs are transmitted in 2 ways: vertically from hen to progeny through the egg and horizontally from bird to bird by direct or indirect contact (113, 436, 437) (Fig. 15.27). Although usually only a small percentage of chicks are infected vertically, this route of transmission is important epizootiologically because it affords a means of maintaining the infection from one generation to the next. Most chickens become infected by close contact with congenitally infected birds. Although vertical transmission is important in the maintenance of the infection, horizontal infection may also be necessary to maintain a rate of vertical transmission sufficient to prevent the infection from dying out (382). The infection does not spread readily from infected birds to birds in indirect contact (in separate pens or cages), probably because of the relatively short life of the virus outside the birds (see "Thermal Inactivation"). However, contact exposure at hatch was shown to be an effective method of spread of ALV-J among broiler breeder chickens (206, 562, 563) and was prevented by small group rearing (566).

Four classes of ALV infection are recognized in mature chickens: (1) no viremia, no antibody (V-A-); (2) no viremia, with antibody (V-A+); (3) with viremia, with antibody (V+A+); and (4) with viremia, no antibody (V+A-) (436, 437). Birds in an infection-free flock and genetically resistant birds in a susceptible flock fall into the category V-A-. Genetically susceptible birds in an infected flock fall into one of the other three categories. Most are V-A+, and a minority, usually less than 10%, are V+A-. Most

V+A- hens transmit ALV to a varying but relatively high proportion of their progeny (386, 437). A small proportion of V+A+ hens transmit the virus congenitally and do so more intermittently; the tendency for congenital transmission of ALV in this category was found to be more frequent in hens with low antibody titer (521). Congenitally infected embryos develop immunologic tolerance to the virus and after hatching make up the V+A- class, with high levels of virus in the blood and tissues and an absence of antibodies. By 22 weeks of age, up to 25% of meat-type chickens exposed to ALV-J at hatch were found to be V+A-. Older hens (2 or 3 years of age) transmit virus in their eggs less consistently and at a lower level than birds under 18 months (78).

The role of males in the transmission of ALV is at best equivocal. Infection of the cock apparently does not influence the rate of congenital infection of progeny (436, 489). The genetics of the host and the strain of ALV influence shedding and congenital transmission after horizontal infection (133). With electron microscopy, virus budding has been seen on all structures of reproductive organs of cocks except germinal cells (150), indicating that the virus does not multiply in germ cells. The cock, therefore, acts only as a virus carrier and source of contact of venereal infection to other birds (456, 469, 488). Congenital infection of embryos is strongly associated with shedding by the hen of ALV into egg albumen and with presence of virus in the vagina of hens (386, 486). These traits are also highly correlated with viremia. Witter *et al.* (563) reported on the association between various infection profiles of subgroup J ALV in broiler breeders and transmission of virus to progeny.

Shedding of ALV into egg albumen and transmission to the embryo is a consequence of virus production by albumen-secreting glands of the oviduct. In most hens, congenitally transmitting ALV, the highest titers of virus were found in the ampulla of the oviducts, suggesting that embryo infection is closely related with ALV produced at the oviduct but not with ALV transferred from other parts of the body (520). Electron microscopy studies have revealed a high degree of virus replication in the magnum of the oviduct (155). Virus budding also occurs in various cell types in the ovary but not in the follicular cells or ovum, and transovarial infection does not seem to be important (386). Not all eggs that have ALV in the albumen give rise to infected embryos or chicks; in the studies of Spencer *et al.* (486), Payne *et al.* (386), and Tsukamoto *et al.* (521), only about one-half to one-eighth of embryos were infected from eggs with virus in the albumen. This intermittent congenital transmission may be a consequence of neutralization of virus by antibody in the yolk and of loss because of thermal inactivation. Congenital transmission of ALV has been found in the absence of detectable shedding of group-specific antigen (268).

Electron microscopy has revealed virus particles in many organs from infected chicken embryos, and virus has been observed to bud and accumulate in large amounts in pancreatic acinar cells of embryos (578). These particles, which are highly infectious, are shed in droppings of newly hatched chicks (65). Infectious virus is also present in saliva and feces of older birds that provide a source of horizontal infection to other birds (65).

In flocks infected with subgroup A ALV, only a minority of ALV-infected birds develop LL; the others remain as carriers and shedders. Viremic-tolerant (V+A-) birds are reported to be several times more likely to die of LL than those with antibody (V-A+) (436). Incidence of leukosis decreases rapidly if infection by natural routes occurs after the first few weeks of age (70); there are well-established genetic differences in susceptibility to LL development in chickens that are equally susceptible to virus infection (131).

Endogenous ALVs (see "Etiology") usually are transmitted genetically in germ cells of both sexes (Fig. 15.26). Many are genetically defective and incapable of giving rise to infectious virions, but some are not and may be expressed in an infectious form in either embryos or hatched birds. In this form, they then are transmitted similarly to exogenous viruses, although most chickens are genetically resistant to such exogenous infection. Endogenous viruses have little or no oncogenicity (346) but may influence response of the bird to infection by exogenous ALV (122, 468). Immunodepression induced by infectious bursal disease virus increased the rate of shedding of ALV (209); also strain of virus can influence incidence of tolerantly infected chickens (197).

Incubation Period

Members of the L/S group of viruses are multipotent viruses capable of inducing a variety of neoplastic diseases. The incubation period for these diseases is dependent on strain and dose of virus, route of and age at exposure and genetic constitution of the host. Susceptible chicks inoculated as embryos or at 1–14-days of age with a standard strain of ALV-RPL12 (73), B15, F42 (46), or RAV-1 developed LL between weeks 14 and 30 of age. It is very seldom that LL cases occur in chickens under 14 weeks. Certain laboratory recombinant viruses have been shown to cause LL within 5–7 weeks (285), although such short incubation periods are not found in field outbreaks. In field outbreaks, LL cases can occur any time after 14 weeks of age; however, incidence is usually highest at about sexual maturity.

Another determining factor is whether the virus strain lacks or possesses a viral oncogene. For example, diseases such as erythroblastosis, induced by slowly transforming viruses lacking oncogene, usually develop after a long latent period (96, 220, 303), as in such cases transformation is induced by promoter insertion activation of the cellular oncogene c-*erbB*. After IA inoculation of the slowly transforming RPL12 strain virus into susceptible day-old chicks, the incubation period varies from 21–110 days (73). On IV inoculation of 11-day-old embryos, chicks occasionally have been found to have erythroblastosis on hatching. Strain R virus produces a much more rapid response, and in some experiments, birds inoculated with high doses have all died between 7 and 12 days postinoculation (33). Field strains and viruses passaged in cell culture induce erythroblastosis after a longer incubation period (71). Passage from donors with erythroblastosis greatly shortens the incubation period (215).

Other strains of virus including F42 (46), ES4, and strain 13 (33) also produce erythroblastosis. Field cases usually occur in birds older than 3 months of age. Viruses such as RPL12 and F42 are nondefective and slowly transforming; whereas ES4 and R are defective and acutely transforming (243).

Strain BAI-A of ALV predominantly induces myeloblastosis. Virus stocks are defective and contain helper viruses of both A and B subgroups (272). After inoculation of susceptible day-old chicks with large doses of virus, changes in the blood can be observed in 10 days, and birds die a few days thereafter. Mortality continues for about 1 month, and only a few deaths occur after this (77, 170). The virus E26 (243) also predominantly induces myeloblastosis.

Virus-induced myelocytomatosis generally has a longer incubation period than erythroblastosis and myeloblastosis induced by the acutely transforming virus strains, but shorter than LL. On IV injection of MC29 into young chicks, myelocytomas were obtained in 3–11 weeks (338). The incubation period in field cases is unknown, but most cases are observed in immature birds. The virus CMII also induces myelocytomas (243). Myelocytomatosis induced by the HPRS-103 strain of ALV, which lacks a viral oncogene, had a long latent period (median time to death was 20 weeks) (383). However, median time to death with the acutely transforming 879-strain variant of HPRS-103, believed to carry a viral oncogene, was 9 weeks (384). Field cases of subgroup J-induced myelocytomatosis were reported in broiler breeder chickens as young as 4 weeks of age (206).

Most strains of ALV have been found to cause hemangiomas (66, 216). These tumors can be found in birds of various ages. In naturally occurring outbreaks, most mortality from hemangiosarcomas occurred at 6–9 months (79, 80). Induction of lung angiosarcomas by subgroup F ALVs is reported (465). After experimental inoculation of young chicks with field strains of virus (215), hemangiomas appeared in 3 weeks to 4 months.

In field cases, ALV-induced renal tumors are rarely seen in chickens younger than 5 weeks; most cases are seen in birds between 2 and 6 months of age. Nephroblastomas induced by strain BAI-A may reach an incidence of 60–85% in birds not dying of myeloblastosis (77). Renal carcinomatous lesions induced by strain MC29 are found as soon as 18 days or as late as 7 weeks after virus inoculation. Incidence in inoculated chickens may be 60% or more, but incidence in field flocks is not known.

Osteopetrosis may develop any time after 1 month following experimental inoculation of day-old chicks with strain RPL12-L29 of ALV (447) or other viruses (258, 260, 406); it is most commonly seen in birds 8–12 weeks of age. The disease probably has a similar incubation period in the field. MAV-2(O) virus will induce palpable osteopetrosis 7–10 days after hatching in chicks inoculated at 1 day of age or as 11–12-day-old embryos (214).

Sarcomas may occur any time after inoculation with ALVs but are most frequently observed in the first 2–3 months (76). In field flocks, connective tissue tumors may occur in birds at any age (576). Sarcomas also develop readily and are palpable within 3 days after inoculation of chicks with high doses of acutely transforming RSV.

Clinical Signs

Outward signs of the leukotic diseases are mostly nonspecific. They include inappetance, weakness, diarrhea, dehydration, and emaciation. In LL especially, there may be abdominal enlarge-ment. The comb may be pale, shriveled, or occasionally cyanotic. In erythroblastosis and myeloblastosis, hemorrhage from feather follicles also may occur. After clinical signs develop, the course is usually rapid, and birds die within a few weeks. Other affected birds may die without showing obvious signs.

In myelocytomatosis, skeletal myelocytomas may cause protuberances on the head, thorax, and shanks. Myelocytomas may occur in the orbit of the eye, causing hemorrhage and blindness. Hemangiomas may occur in the skin, appearing as "blood blisters," and these may rupture causing hemorrhage. Renal tumors may cause paralysis due to pressure on the sciatic nerve. Sarcomas and other connective tissue tumors may be seen in the skin and musculature. When advanced, these various other tumors may be accompanied by the nonspecific signs given previously. Benign tumors may follow a long course, malignant tumors a rapid one.

In osteopetrosis, the long bones of the limbs are commonly affected (Fig. 15.45). Uniform or irregular thickening of the diaphyseal or metaphyseal regions can be detected by inspection or palpation. The affected areas are often unusually warm. Birds with advanced lesions have characteristic "bootlike" shanks. Affected birds usually are stunted and pale and walk with a stilted gait or limp.

In recent years, ALV has been shown to be associated with the "so called fowl glioma" (359), associated with cerebellar hypoplasia and myocarditis (253, 273, 274, 514–517).

Pathology

Introduction

One or more specific neoplasms induced by ALSVs may occur in a given flock of chickens, and more than one type of neoplasm may occur in an individual bird. This is particularly true in flocks infected with subgroup J ALV. The presence of a tumor similar to that produced experimentally is only provisional evidence that a bird was infected with a virus of this group. Firmer evidence is provided by ALSV detection or isolation, and if appropriate by experimental reproduction of tumors by a virus isolate.

In this section, the pathology of the different neoplasms is discussed without regard for virological properties of the inducing agent(s). Only entities that have been reproduced with ALSVs are described.

Nonneoplastic Conditions

The clinical consequences of infection of chickens with exogenous ALV vary. Some chickens, principally those with a tolerant viremic infection (arising from congenital or early neonatal infection, see "Immunity"), may show a variety of clinical signs, as detailed later in this chapter, including depression of body weight and of other production traits. Birds with tolerant viremic infections are also those most likely to develop neoplasia. Ultrastructural and virological studies of congenitally or neonatally infected birds have shown the virus to be widespread in most tissues and organs of the body (5, 6, 156, 165, 426, 495, 516). Dougherty and DiStefano (155–157, 165) observed virus budding in cells of every type of tissue examined, except germ cells and neurons. In contrast, other chickens, particularly those that

develop an immune response, show no obvious clinical signs of infection, even though the virus persists in the body, although in lower amounts and at fewer sites (5).

ALV infection in the absence of overt disease can adversely affect the productivity of egg-laying chickens. Compared with nonshedders, hens that shed virus produced 20–35 fewer eggs per hen housed to 497 days of age; matured later sexually (i.e., age at first egg); and produced smaller eggs (485), at a lower rate, and with thinner shells. Mortality from causes other than neoplasms was 5–15% higher, fertility was 2.4% lower, and hatchability was 12.4% lower in shedders than nonshedders (228). In this study, shedding refers to the transfer of ALV to egg albumen and nonshedders, as well as shedders, and would likely be ALV-infected; shedders are mostly viremic birds; whereas nonshedders are immune with ALV antibody. ALV infection has similar effects on broiler breeders and causes a consistent, although often small, reduction in broiler growth rate (130, 227). However, these effects are more marked in meat-type chickens infected with subgroup J ALV (491, 492, 494, 495). In broiler breeder flocks affected by myeloid leukosis caused by subgroup J ALV, smaller eggs were associated with the presence of gs antigen in allantoic fluid and virus in the embryo (485). Other studies on reduced productivity in chickens with ALV infections and the genetic consequences have been reviewed (226, 270, 484). The presence of ALV in semen was not associated with reduced semen production, but some evidence suggested an effect on semen quality and fertility (456). The physiological bases for these effects have not been studied.

A number of other nonneoplastic effects of ALV infection have been observed, mostly in experimental infections.

Chickens, turkeys, and jungle fowl exposed when young to certain ALVs (RAV-1, RAV-60, MAV-2(O), and ALVs of subgroup B and D develop anemia, hepatitis, immunodepression, and wasting; some may die (122, 479). A myocarditis and chronic circulatory syndrome was reported in chickens inoculated with RAV-1 ALV (232). Intracytoplasmic viral matrix inclusion bodies have been observed in the myocardium of adult ALV infected chickens (235, 348). Chickens inoculated with RAV-7 develop neurologic signs including ataxia, lethargy, and imbalance resulting from a nonsuppurative meningoencephalomyelitis (557). A persistent infection of the central nervous system, with inflammatory lesions and clinical signs, followed *in ovo* infection with RAV-1 (186). Fowl glioma-associated virus also shows involvement of brain with cerebellar hypoplasia (516).

In MAV-2(O) infection, anemia occurs due to an aplastic crisis in the bone marrow in which erythrocytes fail to incorporate iron into hemoglobin and exhibit a decreased survival time (140). Administration of antiviral antibody will prevent anemia (406). The immunodepression may involve atrophy or aplasia of lymphoid organs, hypergammaglobulinemia, decreased mitogen-induced blastogenesis, and decreased antibody response (479). The changes in the immune system are likely a result of cessation of B-cell maturation and a block in the development of T-suppressor cells, possibly due to interference with the synthesis of functional interleukin-2 (258, 307).

In addition to stunting and atrophy of the lymphoid organs,
15.28.   Nodular lesions in liver and spleen of bird with LL inoculated at 1 day of age with RPL12 virus. Bursa also has a small tumor.

RAV-7 caused obesity, high triglyceride and cholesterol levels, reduced thyroxine levels (hypothyroidism), and increased insulin levels. The frequent occurrence of stunting may relate to the virus's suppression of thyroid function. Stunting of chicks with congenital subgroup J ALV infection was also associated with hypothyroidism, possibly mediated via effects on the pituitary (59) or other effects (491, 492, 494).

Lymphoid Leukosis

Gross. Fully developed LL occurs in chickens of about 4 months of age and older. Grossly visible tumors almost invariably involve the liver (Figs. 15.28 and 15.33A), spleen, and bursa of Fabricius (Figs 15.29 and 15.33G). Other organs often grossly involved include kidney, lung, gonad, heart, bone marrow, and mesentery.

Tumors are soft, smooth, and glistening; a cut surface appears grayish to creamy white and seldom has areas of necrosis. Tumor growth may be nodular (Fig. 15.28), miliary, diffuse (Fig. 15.33A), or a combination of these forms. In the nodular form, the lymphoid tumors vary from 0.5–5 cm in diameter and may occur singly or in large numbers. They are usually spherical but may be flattened when they are close to the surface of an organ. The miliary form, which is most obvious in the liver, consists of numerous small nodules less than 2 mm in diameter uniformly distributed throughout the parenchyma. In the diffuse form, the organ is uniformly enlarged, slightly grayish in color, and usually very friable. Occasionally, the liver is firm, fibrous, and almost gritty.

Microscopic. All tumors are focal and multicentric in origin. Even in organs appearing diffusely involved when examined grossly, the microscopic pattern is one of coalescing foci. As tumor cells proliferate, they displace and compress cells of the organ rather than infiltrate between them (Fig. 15.30). Nodules in the liver usually are surrounded by a band of fibroblast-like cells that have been shown to be remnants of sinusoidal endothelial cells (245). In the bursa, a follicular pattern of tumor growth usually can be seen.
15.29. Large tumor of bursa of Fabricius (B) and kidneys (arrow) in a naturally occurring case of lymphoid leukosis in the adult hen.

15.30. Liver tumor from a 20-week-old chicken inoculated at 1 day of age with RAV-1 ALV. Note displacement and compression of hepatic parenchyma. ×700. (191)

Tumors consist of aggregates of large lymphoid cells (lymphoblasts) that may vary slightly in size but are all at the same early developmental stage. They have a poorly defined cytoplasmic membrane, much basophilic cytoplasm, and a vesicular nucleus in which there are margination and clumping of the chromatin and one or more conspicuous acidophilic nucleoli (374).

The cytoplasm of most tumor cells contains a large amount of RNA, which stains red with methyl green pyronin, indicating that the cells are immature and rapidly dividing (109–111). Characteristic features of the cell can best be seen in wet-fixed impression smears that have been stained with May-Grunwald-Giemsa, methyl green pyronin, or other cytological stains. The tumor cells have B-cell antigen markers and produce and carry IgM on their surface (113, 393).

No consistent or significant changes occur in cellular elements of circulating blood. Rarely, lymphoblasts predominate in frank leukemic cases.

Ultrastructural. Vacuoles are found infrequently in lymphoid cells of birds with LL, but some virus particles have been observed budding from the plasma membranes of lymphoblasts (158–160, 165).

Pathogenesis. ALVs multiply in most tissues and organs of the body (165). Transitory lymphoid foci may occur in various tissues and are considered to be inflammatory in nature (82) (Fig. 15.31). The infection persists longer in bursal lymphocytes than in other hematopoietic tissues (10, 11), and cells of the bursa of Fabricius are the target cells that neoplastically transform. The target cells must be resident in the bursa, because surgical bursectomy up to 5 months of age and other treatments that destroy the bursa of Fabricius will eliminate the disease (64, 98, 284, 396, 410, 412, 429). Medullary macrophages appear to be the principal bursal cells for virus replication and may be important in transmitting infection to the lymphoid cells (234). At a variable time after infection, which can be as short as 4 weeks in ex-

15.32. Lymphoblastic transformation in single bursal follicle in chicken with lymphoma leukosis (LL). All surrounding follicles are histologically normal in this and other sections from a 16-day-old chicken infected with RPL12 virus at hatching. Methyl green pyronin, ×40. (Dent)

perimental studies, a proliferation of lymphoblasts occurs in one or more lymphoid follicles in the bursa. These altered bursal follicles are termed transformed follicles (10, 352, 409), and the change is regarded as a focal preoplastic hyperplasia (262, 263) (Fig. 15.32). The transformed follicle is a consequence of activation of the c-*myc* gene by nearby insertion of ALV. This places the c-*myc* gene under the control of the enhancers of the viral LTR, resulting in overexpression of *myc*, causing a maturation arrest and proliferation of bursal stem cells, associated with changes in global gene expression profiles and genomic instability (353, 354). Arrest of maturation of the transformed B cells results in interference of the normal intraclonal switch of immunoglobulin production from IgM to IgG, hence the surface IgM that characterizes LL cells. The cells grow within the confines of the bursal follicle and are not neoplastic. Sometimes, many follicles are transformed, but the majority of these appear to regress, and only a few continue to grow to give rise to nodular tumors in the bursa, which are visible grossly from about 14 weeks of age (112, 352). Progression of the transformed follicle to the fully neoplastic state requires additional genetic changes, and other putative oncogenes, *Blym*-1 (239, 351) Mtd/Bok (57) and c-*bic* (104, 502), have been implicated. Recent studies have suggested that the oncogenicity associated with the non-coding c-*bic* transcript is due to a novel microRNA designated miR-155 (503). Oncogenicity assays demonstrated that *bic* can cooperate

with c-*myc* in lymphomagenesis and erythroleukemogenesis, providing direct evidence for the involvement of untranslated RNAs in oncogenesis (504). Evidence suggests that apoptosis of neoplastic bursal cells is inhibited by an antagonist of apoptotic cell death, NR-13, related to the *Bcl*-2 proto-oncogene (316). Induction of angiogenic factors from the transformed cells also contributes to the generation of *myc*-induced lymphomas (55). From about 12 weeks of age, cells in the clonal bursal tumors metastasize to other organs and tissues and result in the terminal disease. Metastatic tumors in the viscera usually have the same DNA fragments as bursal tumors from the same birds, supporting their clonal origin (124), but multiple bursal tumors can give rise to polyclonal metastatic disease (474).

Experimentally, B-cell lymphomas also have been induced by c-*myb* activation, following embryonic infection with ALV (285, 401). The tumors were unusual in that metastatic disease occurred within 7 weeks of infection, and preoplastic and primary bursal neoplasms were not detected. Spontaneous bursal lymphomas of unknown etiology have also been observed in lines of chickens free of exogenous ALV including line 0 free of *ev* loci (138, 139). REV (see "Reticuloendotheliosis") can also induce LL associated with c-*myc* activation.

Transplantable LL tumors can be developed from ALV-induced tumors. The RPL12 transplantable tumor, from which the RPL12 strain of ALV was isolated, is a well-known example. Several other new LL transplantable tumors have been described (365). Transplantable LL tumors grow to a palpable size within 5–10 days and become widely disseminated, inducing rapid mortality.

Erythroblastosis

Gross. Natural cases of erythroblastosis (erythroid leukosis) usually occur in birds between 3 and 6 months of age. The liver and kidney are moderately swollen, and the spleen often is greatly enlarged. The enlarged organs are usually cherry red to dark mahogany (Fig. 15.33) and are soft and friable. The marrow is hyperplastic, semi-liquid, and red in color. Petechial hemorrhages occur in various organs such as muscles, subcutis, and viscera. Thrombosis, infarction, and rupture of the liver or spleen may be observed. Edema of the lungs, hydropericardium, and a fibrinous clot on the liver may occur.

With severe anemia, atrophy usually is seen in visceral and lymphoid organs, particularly the spleen.

Changes in the blood reflect those in other organs, such as liver, spleen and bone marrow, and depend largely on the extent of anemia or leukemia. When severe anemia exists, the blood is watery and light red and clots slowly. In contrast, acute cases may show no grossly apparent changes, although usually the blood appears dark red with a smoky overcast.

Microscopic. Examination of the marrow in early cases reveals blood sinusoids filled with rapidly proliferating erythroblasts that fail to mature. In advanced cases, marrow consists of sheets of homogeneous erythroblasts with small islands of myelopoietic activity and little or no adipose tissue. With concurrent anemia, the number of erythropoietic cells may be reduced.

Alterations in visceral organs are primarily due to hemostasis, resulting in an accumulation of erythroblasts in the blood sinusoids and capillaries (Fig. 15.34). The liver sinusoids, splenic red pulp, bone marrow, and sinusoids of other organs are filled with proliferating erythroblasts.

The sinusoids become greatly distended, resulting in pressure atrophy of the parenchyma. Although accumulations of erythroblasts may be extensive, they always remain intravascular, unlike those in LL and myeloblastosis.

Varying degrees of anemia may occur. Sometimes erythroblastosis occurs, and there may be only severe anemia. Extramedullary erythropoiesis is common.

The primary cell involved is the erythroblast. The cell has a large round nucleus with very fine chromatin, 1 or 2 nucleoli, and a large amount of cytoplasm that is basophilic. A perinuclear halo, vacuoles, and occasionally fine granules are present. The cell is irregular in shape and often has pseudopodia. Erythroblasts have cell markers that identify them as members of the erythrocytic series.

Stained blood smears reveal a variable number of erythroblasts (see Fig. 15.33D). These vary in maturity from the early erythroblast, which is the dominant cell, to the various stages of polychrome erythrocytes. The more mature cells often appear early in the course of the disease or during remission, if it occurs. The thrombocytic series of cells may be somewhat increased in number and immaturity. Similarly, in most naturally occurring cases, immature cells of the myelocytic series appear in the peripheral circulation. Occasionally, they are as prominent as the erythroblasts. Cases of mixed erythroblastosis and myelocytomatosis may occur.
15.34.   Erythroblastosis. Liver sinuses permeated with erythroblasts in bird 40 days after inoculation with strain MC29 leukosis virus. ×280. (Beard)

Ultrastructural. Numerous studies have been made of the primitive cells in erythroblastosis induced by different strains of ALV (35, 36, 249) and RPL12 (160). Neoplastic erythroblasts are for the most part indistinguishable from corresponding cells in the normal bird, except that virus particles may be present in extracellular spaces and within vacuoles inside cells. In erythroblasts in the circulating blood, as in cell culture, there is a great increase in membrane activity, with vacuolization of the cytoplasm and budding of virus particles from the cell membrane. Only occasionally are aberrant structures seen in erythroblasts (160).

Pathogenesis. Inoculation of slowly transforming strains (i.e., those lacking a viral oncogene) of ALV such as RPL12 into 11-day-old chick embryos induces erythroblastosis from the first week of age (400). When day-old chicks are inoculated, the incubation period varies from 21 to more than 100 days (73). Induction of erythroblastosis by slowly transforming ALV involves activation of the cellular oncogene c-*erb*B by LTR insertion (96, 221, 306), and new acutely transforming AEV strains with transduced c-*erb*B genes may arise (257, 334). Whether such acutely transforming viruses spread naturally and induce more erythroblastosis is not clear.

Experimentally, acutely transforming AEV strains, such as ES4 and R, cause mortality from erythroblastosis 7–14 days after inoculation (243). ES4 carries the gene v-*erb*A, which blocks erythroid precursor cell differentiation, in addition to the v-*erb*B oncogene (142, 181, 319, 331). Two subgroup J ALV isolates, 1B and 4B, have been shown to be acutely transforming and to in-
15.35. Myeloblastosis. Distribution of myeloblasts in liver of bird with myeloblastic leukemia 19 days after inoculation with BAI-A virus. ×280. (Langlois)

duce erythroblastosis as well as myelocytomatosis and other tumors (530). Their viral oncogenes have not yet been identified.

When birds are exposed to an acutely transforming AEV, the first alterations are found in 3 days as foci of proliferating erythroblasts in bone marrow sinusoids. By day 7, the primitive cells reach the circulating blood, and some foci of erythroid proliferation are present in sinusoids of the liver and spleen. Erythroblasts continue to accumulate in hepatic sinusoids and elsewhere until death of the host and transplantable erythroblastosis tumors can be developed (402).

Myeloblastosis
Gross. Natural cases of myeloblastosis (myeloblastic myeloid leukosis) are uncommon and usually occur in adult chickens. The liver is greatly enlarged and firm with diffuse grayish tumor infiltrates, which give a mottled or granular ("Morocco leather") appearance (Fig. 15.33C). The spleen and kidneys are also diffusely infiltrated and moderately enlarged. The bone marrow is replaced by a solid, yellowish-gray tumor cell infiltration.

A severe leukemia exists, with myeloblasts comprising up to 75% of peripheral blood cells and forming a thick buffy coat and usually an anemia and thrombocytopenia.

Microscopic. Parenchymatous organs, notably the liver, show a massive intravascular and extravascular accumulation of myeloblasts with a variable proportion of promyelocytes (Fig. 15.35). In the spleen, these tumor cells accumulate in the red pulp. In the bone marrow, myeloblastic activity is confined to extrasinusoidal areas.

Myeloblasts in leukemic blood smears are large cells with slightly basophilic clear cytoplasm and a large nucleus containing 1–4 acidophilic nucleoli, which do not stain prominently

(Fig. 15.33E). Often, promyelocytes and myelocytes are also present; they easily can be identified by their specific granulation, which in the early forms is primarily basophilic. The disease may result in a secondary anemia, with the presence of polychrome erythrocytes and reticulocytes. Such a secondary anemia is distinguished easily from the conditions in which erythroblastosis and myeloblastosis occur together, because then blast cells of both cell series are present in the circulating blood.

Ultrastructural. In circulating myeloblasts from birds with myeloblastosis induced by BAI-A AMV, virus particles are only rarely found and then in small numbers in clear vacuoles (33, 160, 249, 250). However, reticular and phagocytic elements of the spleen and bone marrow frequently are packed with virus particles. When myeloblasts are transferred to cell culture, large numbers of lysosomes appear in the cytoplasm. After some time in cell culture, virus particles can be seen in lysosomes, in vacuoles, and budding at the cell membrane. No other changes are observed in these cells.

Pathogenesis. The v-*myb* gene of AMV is responsible for neoplastic transformation of the target myeloblasts (181). Experimental infection is followed within a few days by the appearance of multiple foci of proliferating myeloblasts in the extrasinusoidal areas of the bone marrow, followed rapidly by leukemia and infiltration of the liver, spleen, and other organs (308, 309).

Myelocytomatosis
Gross. Tumors of myelocytomatosis (myelocytic myeloid leukosis) are distinctive and can be recognized on gross examination with some degree of certainty. Characteristically, they occur on the surface of bones in association with the periosteum and near

cartilage, although any tissue or organ can be affected. Myelocytomas often develop at the costochondral junctions of the ribs, on the inner sternum, pelvis, and on the cartilaginous bones of the mandible and nares. Flat bones of the skull are also commonly affected (Fig. 15.33H). Tumors may also be seen in the oral cavity, trachea, and in and around the eye (403). The tumors are usually nodular and multiple, with a soft, friable consistency and of creamy color. In the disease caused by subgroup J ALV, myelocytomatous infiltration often causes enlargement of the liver and spleen and other organs, in addition to skeletal tumors (559). Myelocytic leukemia may also occur (381).

Microscopic. Tumors consist of masses of uniform, usually well-differentiated, myelocytes. Their nuclei are large, vesicular, and usually eccentrically located, and a distinct nucleolus is usually present. The cytoplasm is usually tightly packed with acidophilic granules, which are usually spherical. When imprint preparations of fresh tumors are stained with May-Grunwald Giemsa, granules appear brilliant red (Fig.15.33F). Areas of less well-differentiated myelocytes are not uncommon within the myelocytomas, and areas of undifferentiated cells, which may be stem cells of the myelocyte-monocyte series, may also be found. In the liver, accumulations of neoplastic myelocytes occur around blood vessels and in the parenchyma. In the spleen, tumor cells are present in the red pulp. In the marrow, the extrasinusoidal myelopoietic areas are greatly expanded by uniform neoplastic myelocytes. A detailed description of bone and bone marrow lesions in myelocytomatosis apparently caused by subgroup J ALV is provided by Nakamura *et al.* (349).

Although the naturally occurring disease has been stated to be usually aleukemic, myelocytomatosis induced by subgroup J ALV frequently is accompanied by a marked leukemia of myeloid cells. Laboratory strains of myelocytomatosis-inducing virus, such as MC29, also cause leukemia (Fig. 15.36).

Ultrastructure. Ultrastructural features of myelocytoma cells vary from those of well-differentiated myelocytes to those of undifferentiated, nongranulated myeloid cells (338).

Pathogenesis. Acutely transforming strains of ALV that induce myelocytomatosis, such as MC29 and CMII, carry the v-*myc* oncogene (181, 342). Slowly transforming strains of subgroup J ALV that also induce myelocytomatosis, such as HPRS-103 and ADOL-Hc1, do not carry an oncogene, but molecular studies of HPRS-103-induced myelocytomatosis indicate that c-*myc* is activated (95–97). The acutely transforming strain 966 ALV, derived from myelocytoma and induced by strain HPRS-103 of subgroup J ALV, has been shown to carry v-*myc* (95, 384). Studies on HPRS-103 and 966 showed that they have a tropism for the myelomonocytic cell lineage, which may relate to their ability to cause myelocytomas (5, 6). Recently, a recombinant ALV with envelope of subgroup B and LTR of subgroup J (ALV-B/J) was isolated from a field outbreak of myeloid leukosis in commercial layers (236). However, inoculation of experimental and commercial strains of white leghorn chickens with this recombinant ALV-B/J resulted in primarily LL, but not myeloid leukosis, suggest-
15.36.   Myelocytomatosis. Granulated myelocytes in blood smear from bird 23 days after inoculation with strain MC29 leukosis virus. ×750. (Beard)

ing that differences in the genetic makeup of the commercial layers from which ALV-B/J was originally isolated and lines of chickens used in experimental inoculations studies may be responsible for the differences in pathogenicity observed (321).

The earliest alterations occur in bone marrow in which there is crowding of intrasinusoidal spaces, principally by myelocytes, and destruction of sinusoid walls. The spaces may contain 2 types of cells—the primitive hemocytoblast-like cell (myeloid stem cell) and the neoplastic myelocyte. The latter appears to arise directly from the stem cell, and differentiation is arrested both at the nongranulated and granulated myelocyte level (338). Myelocytes proliferate and soon overgrow the bone marrow. Tumors form by expansion of marrow growth and may crowd through the bone and periosteum. Extramedullary tumors may also arise by blood-borne metastasis.

Hemangioma
Gross. This tumor is found in the skin or in visceral organs in chickens of various ages. They appear as blood-filled cystic masses (blood blisters) (Fig. 15.37) or more solid tumors and consist of distended blood-filled spaces lined by endothelium or as more cellular, proliferative lesions (86). They are often multiple and may rupture, causing fatal hemorrhage (480).

Microscopic. The cavernous form is characterized by greatly distended blood spaces with thin walls composed of endothelial

15.37.   Hemangioma of gizzard serosa of RPL12 virus-inoculated bird. Note the dark circumscribed and raised tumor nodules. (245)

15.38.   Cavernous hemangioendothelioma of mesentery. (Feldman and Olson)

cells (Fig. 15.38). Capillary hemangiomas are solid masses in which endothelium may proliferate into dense masses (hemangioendothelioma), leaving mere clefts for blood channels (Fig. 15.39); develop into a lattice with capillary spaces; or grow into collagen-supported cords with larger interspersed blood spaces. Solid and papillary forms have also been described (347).

Ultrastructural. Hemangiomas consisted mainly of undifferentiated mesenchymal cells and had an alveolar structure (327).

Pathogenesis. Sequence analysis of an avian hemangioma-inducing virus isolated from layer hens revealed unique elements in both *env* gene and LTR that were thought probably responsible for its biologic and pathogenic characteristics (80). This virus was cytocidal and had an affinity for endothelial cells (418, 419). Apart from this, the molecular basis for hemangioma induction is not known.

Hemangiomas are tumors of the vascular system and as such usually involve all layers of blood vessels. In some instances, the endothelium may proliferate more than the supporting tissue. Hemangiosarcomas have been associated with subgroup J ALV infection (237, 377).

Nephroma and Nephroblastoma

Gross. Two types of renal tumor occur: nephroblastomas (Wilms' tumor) and adenomas and carcinomas. Nephroblastomas vary from small, pinkish gray nodules embedded in the kidney parenchyma to large, yellowish gray lobulated masses that replace most of the kidney tissue (Fig. 15.40). Tumors may be pedunculated and connected to the kidney by a thin fibrous vascular stalk. Large tumors are often cystic and may involve both kidneys. Adenomas and carcinomas vary in size and appearance, similar to nephroblastomas. They are often multiple and within cysts.

Microscopic. In nephroblastomas, the histologic variation between different tumors or areas of the same tumor is striking. There is usually neoplastic proliferation of both epithelial and mesenchymal elements, although their proportion and differentiation vary widely. Epithelial structures vary from enlarged tubules with invaginated epithelium and malformed glomeruli; through irregular masses of distorted tubules; to groups of large, irregular, cuboidal, undifferentiated cells with little tubular organization (Fig. 15.41). The growth may be embedded in a loose mesenchymal or sarcomatous stroma. There may be islands of keratinizing stratified squamous epithelial structures (epithelial pearls), cartilage, or bone (148, 256, 271). Primary multiplicity of tumors may occur, but metastases are rare.

Adenomatous or carcinomatous growths also vary greatly in microscopic appearance. In tubular adenocarcinomas, primitive

abnormal glomeruli frequently occur in large numbers among abnormal tubules. Papillary cyst adenocarcinomas are frequent. At times, solid carcinomas with little evidence of renal tubules develop (37, 338). Rarely is there cartilage and never other mesenchymal tumor tissues. A trabecular fibrous tissue stroma may separate masses of epithelial tumor tissue.

Ultrastructural. In the epithelial nephronic elements of nephroblastomas induced by strain BAI-A of ALV (33), cytoplasmic aberrant structures occasionally are seen in large or small aggregates. Virus particles bud from cell membranes of epithelial cells, fibroblastic elements of the stroma, and chondrocytes. Sarcomatous elements consist of cells similar in morphology to those in other avian sarcomas. Virus particles have been observed budding from epithelial cells in cystadenomas and adenocarcinomas induced by strain MC29 myelocytomatosis virus (340). Large accumulations of particles in spaces in the cysts and tubules probably were related to a lack of tubule and glomerular drainage.

Pathogenesis. A target oncogene for ALV-induced nephroblastomas was not consistently identified (106). More recently, a new proto-oncogenes such as *nov*, (281) and *twist* (366) were identified as common integration sites in nephroblastomas (367).

Nephroblastomas originate from nephrogenic blastema (embryonic nephrons and embryonal rests) (86, 271). This blastema tissue is present in the metanephros (functional kidney) at hatching until at least 6 weeks of age and appears as wedge-shaped foci of immature renal tissue particularly beneath the capsule. These epithelial structures enlarge and become neoplastic. The supporting stroma of mesenchymal elements also proliferates and, in turn, may be altered. There is extensive multiplication of tumor cells (usually convoluted tubules and/or stroma) and varying degrees of differentiation, some abnormal. In the most differentiated form, nephrogenic cells form glomeruli, tubules, or keratinized epithelium; whereas cells of the stroma form sarcomas, cartilage, and bone. Anaplasia of kidney cells can result in sheets of large epithelioid cells with almost no tubular organization. Malformed and blocked tubules result in cysts. Nephroblastomas have been induced by BAI-A strain AMV (34, 77, 541), MAV-2(N) (443), MAV-2-O (49), and subgroup J-related strain 1911 (383). Transplantable nephroblastomas have been developed (541).

Carcinomatous growths originate only from the epithelial part of the embryonal blastema and not from mesenchymal elements. Depending on the degree of anaplasia of epithelial elements, tumors formed may be adenomas, adenocarcinomas, or solid carcinomas (34). These tumors have been induced by MC29 (34), ES4 (90), and MH2 (89) virus strains and by various field isolates (216). Renal adenomas and carcinomas can be caused by slowly and acutely transforming subgroup J ALV (381, 383).

Fibrosarcoma and Other Connective Tissue Tumors

Gross. A variety of benign and malignant connective tissue tumors occur naturally, usually sporadically, in young and mature chickens, and transmission of many of these by cell-free filtrates has been demonstrated. These tumors include fibromas and fibrosarcomas, myxomas and myxosarcomas, histiocytic sarcomas, osteomas and osteosarcomas, and chondromas and condrosarcomas. The benign tumors grow slowly, are localized, and are noninfiltrative. The malignant counterparts grow more rapidly, infiltrate surrounding tissue, and may metastasize.

Fibromas arise as firm fibrous lumps attached to the skin, subcutaneous tissues, muscles, and occasionally other organs; fibrosarcomas are of a softer consistency. In the skin, they may ulcerate. Myxomas and myxosarcomas are softer and contain tenacious slimy material: They occur mainly in the skin and muscles. Histiocytic sarcomas are firm, fleshy tumors occurring mainly in the viscera. Osteomas and osteosarcomas are uncommon and occur as hard tumors that may arise from the periosteum of any bone. Chondromas and chondrosarcomas are rare. They occur where cartilage is present and sometimes within fibrosarcomas and myxosarcomas. Ganglioneurosarcoma was reported associated with subgroup J ALV infection (238).

Microscopic. Fibromas in their simplest forms consist of mature fibroblasts interspersed with collagen fibers arranged in wavy parallel bands or whorls. Slowly growing tumors are more differentiated and contain more collagen and fewer cells than those growing more rapidly. Some fibromas may have edematous areas and should not be confused with myxomas and myxosarcomas. If necrosis, ulceration, and secondary infection have occurred, various inflammatory and necrotic alterations may be observed in the tumor. Inflammatory changes may be so prominent that the tumor may be confused with a granuloma.

Aggressive and destructive growth, their cellular composition, and the immaturity of constituent cells (Fig. 15.42) characterize fibrosarcomas. Large irregular and hyperchromic fibroblasts are abundant, and mitosis is common. Tumors contain less collagen than fibromas, and this is concentrated in and near irregular septa that subdivide the tumor. Regions of necrosis often occur in rapidly growing tumors. Edema is sometimes present. Multiple undifferentiated pulmonary sarcomas associated with subgroup J ALV infection have been reported (248).

Myxomas consist of stellate or spindle-shaped cells surrounded by a homogeneous, slightly basophilic, mucinous matrix. In the malignant form (myxosarcoma), the mucinous matrix is less abundant, and fibroblasts are proportionally more numerous and immature than in myxomas (Fig. 15.43).

Histiocytic sarcomas are derived from cells of the monocyte and macrophage lineage, and the cellular constituents are highly variable both within a tumor and between tumors (Fig. 15.44). They have been reported associated with infection by subgroup J ALV (4, 247). The cells may be spindle-shaped, usually appearing in groups or bundles as in fibrosarcomas; stellate reticulum-producing elements; and/or large phagocytic cells or macrophages. Tumors apparently derived from stem cells of the myelomonocytic lineage may also be considered to be histiocytic sarcomas. The so-called endotheliomas induced by MH2 and MC29 may be tumors of this lineage (182). In primary tumors, spindle-shaped cells usually predominate; whereas in metastatic foci, primitive histiocytic forms are more numerous.

Osteomas are structurally similar to bone except that much of

15.42. Fibrosarcoma in musculature of breast. ×120. (Feldman and Olson)

the inner histologic details is lacking. They consist of a homogenous acidophilic matrix of osseomucin containing collections of osteoblasts at irregular intervals. Osteosarcomas are usually very cellular infiltrative growths that invade and destroy surrounding tissues. The cells are spindle-shaped, ovoid, or polyhedral, and many are in mitosis. Nuclei are prominent, and cytoplasm is basophilic. Multinucleated giant cells may be quite numerous. Although very cellular and rapid growing, some areas usually have sufficient differentiation for the production of osseomucin, which is usually sufficient to identify these tumors.

Chondromas have a typical and unique structure (i.e., groups of 2 or more chondrocytes lying in a matrix of chondromucin). In chondrosarcomas, considerable cellular variation exists, ranging from the most immature to the fully mature chondrocyte.

Ultrastructural. Only the sarcomas produced by RSV have been examined in detail. The morphology of fibroblasts, macrophage-like cells, and mast cells, found in Rous sarcomas, have been described (33, 249). Tumor cells are similar to the cells in culture after infection with RSV in showing numerous pseudopodia and pronounced cytoplasmic vacuolation, which may contain virus particles (249).

Pathogenesis. Induction of sarcomas and other connective tissue tumors in the field is likely to be by activation of a cellular oncogene by a slowly transforming ALV, occurring up to several months after infection. During this process, acutely transforming viruses that carry the oncogene may be generated. Viral oncogenes that have been associated with sarcoma induction include *src*, *fps*, *yes*, *ros*, *eyk*, *jun*, *qin*, *maf*, *crk*, *sea*, and *erb*B (105, 181, 535) (Table 15.6). Experimentally, viruses carrying such oncogenes can induce sarcomas within a few days. Whether these acutely transforming viruses contribute to sarcoma induction naturally in the field is not clear. Most virus strains that induce tumors of connective tissue, whether slowly or acutely transforming, are multipotent, inducing a variety of tumors. Multipotency may depend on infection of particular target cells or on multipotency of precursor cells. Recently, an ALV related to MAV-1 was isolated from a field outbreak of sarcomas in commercial layers; inoculation of susceptible white leghorn chickens with new isolate resulted in sarcomas and myelocytomas (576).

These viral oncogenes reflect the cellular oncogenes that are activated by insertional mutagenesis and that may undergo mutation. These cellular oncogenes control a variety of functions in the cell (their products are generally growth factors, growth factor receptors, signal transducers, or DNA transcription factors), and it is their altered expression that results in the loss of regulation of cell proliferation or differentiation that causes neoplasia.

Osteopetrosis

Gross. The first grossly visible changes occur in the diaphysis of the tibia and/or tarsometatarsus. Alterations soon are seen in other long bones and bones of the pelvis, shoulder girdle, and ribs but not the digits. Lesions are usually bilaterally symmetric; they first appear as distinct pale yellow foci against the gray-white translucent normal bone. The periosteum is thickened, and

15.45. Osteopetrosis. A 24-week-old chicken, injected with RPL12 at 1 day of age, with advanced osteopetrotic lesions of the shanks. (Sanger)

the abnormal bone is spongy and at first easily cut. The lesion is commonly circumferential and advances to the metaphysis, giving the bone a fusiform appearance (Figs. 15.45 and 15.46). Occasionally, the lesion remains focal or is eccentric. Severity of the lesion varies from a slight exostosis to a massive asymmetric enlargement with almost complete obliteration of the marrow cavity. In long-standing cases, the periosteum is not as thickened as it was earlier; when it is removed, the porous irregular surface of the very hard osteopetrotic bone is revealed.

Early in the disease, the spleen may be slightly enlarged. Later, severe splenic atrophy occurs as well as premature bursal and thymic atrophy. LL often occurs in individual birds with osteopetrosis.

Microscopic. The periosteum over the lesion is greatly thickened from an increase in number and size of basophilic osteoblasts. The number of osteoclasts per tibia increases, but the density of osteoclasts (i.e., the number per unit volume of bone) decreases (455). Affected bones differ from normal bones in the following ways. Spongy bone converges centripetally towards the center of the shaft (Fig. 15.47). An increase occurs in size and irregularity of the haversian canals, as well as an increase in number and size, and an alteration in position, of lacunae. Osteocytes are more numerous, large, and eosinophilic; the new bone is basophilic and fibrous.

15.46.   Osteopetrosis of tibia in 10-week-old chicken. A. Shorter length of bone is due to reduced growth. Lower tibia is from control bird of same age. B. Cross-section of middle of shaft of bones in A. (447)

The blood picture is ordinarily aleukemic, and a secondary anemia often exists. There may be active erythropoiesis in remaining bone marrow and sometimes in focal areas in the liver. Experimentally, viruses that cause osteopetrosis can induce an aplastic anemia and an increased corpuscular fragility (258, 406).

Ultrastructural. Virus particles bud transiently from osteoblasts and continuously from osteocytes and accumulate in the periosteocytic space. With calcification of the bone, the particles become incorporated in the bone trabeculae. No virus production is observed from osteoclasts (213).

Pathogenesis. Osteopetrosis is a polyclonal disease of the bone and is thought to be caused by high levels of virus infection perturbing the growth and differentiation of osteoblasts. Much higher levels of virus infection were found in diseased bones than in cultured osteoblasts infected with the Br21 strain of an osteopetrosis-inducing ALV (212). Severe cases of osteopetrosis contained 10 times more viral DNA, 30 times more gag precursor protein, and 2–3 times more env protein than the infected osteoblast cultures. Apparently, the infected cultures lacked aspects of the bone environment that support both the high levels of infection and the aberrant function of osteoblasts characteristic of ALV-induced osteopetrosis. The osteopetrotic lesion is basically proliferative or hypertrophic (87, 447) and may be neoplastic (54, 455). Lesions of the lymphoid organs and bone marrow are degenerative or anaplastic (258). The propensity for certain ALVs to induce osteopetrosis depends on sequences in the *gag-pol-5′env* region of the viral genome (458). Env proteins have also been implicated in osteopetrosis induction (280).

Other Tumors

Apart from renal tumors, epithelial tumors caused by ALV are uncommon. They mainly have been reported following experimental infections with acutely transforming viruses, although some have occurred in natural and experimental infections with
15.47.   Osteopetrosis. Cross-section of humerus from 8-week-old chicken. Six separate osteopetrotic foci are present, two of which extend from endosteum to periosteum. ×18. (447)

subgroup J ALV. Strains BAI-A (34) and HPRS-103 (383) of ALV have induced thecomas and granulosa cell tumors of the ovary. A seminoma in the testis occurred in a bird inoculated with strain MH2 (34) and possibly in birds inoculated with subgroup

J ALV isolates (394). Adenocarcinomas of the pancreas have been induced in chickens by strains MC29, MH2, and HPRS-103 of ALV (34, 339, 383). The Pts-56 strain of osteopetrosis virus produced pancreatic adenomas and adenocarcinomas and duodenal papillomas in guinea fowl (292, 294, 295). Squamous cell carcinomas have been observed in a few chicks with strains MC29 and MH2 (34). The MC29 and MH2 strains have induced hepatocarcinomas (34, 313). Other epithelial tumors induced by subgroup J ALV include cholangioma and ovarian carcinoma (383).

Strains MC29 (34) and HPRS-103 of ALV (383) have been shown to induce mesotheliomas.

Immunity
Active
Under natural conditions, most chicks become infected by exogenous ALV from penmates or their surroundings and, after a transient viremia, develop virus-neutralizing antibodies directed against virus envelope antigens that rise to a high titer and persist throughout the life of the bird (437, 481). The virus-neutralizing antibodies serve to restrict the amount of virus in the bird, which in turn, will limit neoplasia, but they generally are considered to have little direct influence on tumor growth. After inoculation of birds with ALV at 4 weeks of age or older, transient viremia was detectable at 1 week and was followed by antibodies at 3 weeks and later (324). In a study of birds naturally infected after hatching, antibodies were first detected at 9 weeks of age, with a marked increase in the proportion with antibodies between 14 and 18 weeks, when 80% were positive (437). The younger the bird at infection, the longer the duration of viremia and the greater the delay to antibody. Infection at 1 day old by inoculation may lead to a permanent viremia rather than antibody production.

Antibodies against gs-antigen may also occur in ALV-infected birds, but these apparently have no influence on tumor growth (430, 460). Antibodies against RT also have been detected in virus-infected and virus-free chickens (240).

Knowledge of the occurrence of, and the part played by, cell-mediated immunity in ALSV infections is still incomplete, but it is likely to be directed against both the virus infection and tumor formation. The presence of cytotoxic lymphocytes against viral envelope antigens has been shown in birds immunized with ALV or RSV (31, 32, 305), and cell-mediated immunity and the MHC complex are clearly implicated in the regression of Rous sarcomas (452, 453). Viral proteins expressed on the surface of tumor cells appear to be important targets for the cell-mediated immunity, and nonvirion transformation-specific cell surface antigens may also be implicated. Recently, Thacker and coworkers (511) have developed a new system for studying MHC-restricted cytotoxic lymphocyte responses to ALV infection, which should be of value in determining the role of this type of cell-mediated immunity in ALV infections. Whether cell-mediated immune responses are directed against tumor cells in lymphoid and other forms of leukosis has yet to be determined. Reviews of cell-mediated immune responses to ALSV infections have been provided by Wainberg and Halpern (538) and Schat (453).

Chickens that are infected congenitally by ALV do not develop immune responses to the virus. Instead, they become immunologically tolerant to the virus and develop a persistent viremia in the absence of neutralizing antibodies (332, 437). Inoculating chickens up to 2 weeks of age with ALV may also induce tolerant infection. Early infection with subgroup J ALV is particularly likely to induce a tolerant infection (206, 562, 564). Birds with a tolerant viremic infection are more likely to develop neoplasms than are immune-infected birds, because of the greater virus load in viremics.

Infection by ALV can depress primary and secondary antibody responses and cell-mediated immunity (439) to unrelated antigens, although these effects have been variable in different studies. Fadly et al. (200), in a study of congenital infection with an A subgroup ALV, RAV-1, failed to detect effects on B- and T-cell function during the early and late stages of infection, and they reported no histological damage to the bursa, thymus, or spleen. In contrast, subgroup B ALVs have been reported to induce a marked suppression of the humoral immune response to several antigens and decreased responsiveness to several mitogens (545). Evidence that subgroup J ALV is immunosuppressive appears to be equivocal at present (310, 493, 494, 574).

Passive
Serum antibodies, which are mainly in the IgG fraction (333), are passed on by the hen to her progeny via the egg yolk and provide a passive immunity that lasts 3–4 weeks. Passive antibody delays infection by ALV (565), reduces the incidence of viremia and shedding of ALV (188) and reduces the incidence of tumors (63). Level and persistence of antibody in the chick are related to the titer of antibody in the dam's serum.

Genetic Resistance
Two levels of genetic resistance to leukosis or sarcoma virus-induced tumors are recognized: cellular resistance to virus infection and resistance to tumor development (13, 27, 114, 399).

Inheritance of cellular resistance to infection is of a simple Mendelian type (Table 15.13). Independent autosomal loci control responses to infection by ALSVs of subgroups A, B, and C and are designated tva (tumor virus A subgroup), tvb, and tvc respectively (117). A new gene nomenclature system recently has been adopted by the Poultry Committee of the United States Department of Agriculture National Animal Genome Research Program. The new terminology is given alongside the old in Table 15.13. The tvb locus also controls responses to subgroup D virus (371), and linkage occurs between tva and tvc loci (174, 391). At each tv locus, alleles for susceptibility and resistance exist that are designated tva^s, tva^r; tvb^s, tvb^r; and tvc^s tvc^r, respectively, and the susceptibility alleles are dominant over the resistance alleles. These genes usually are abbreviated to a^s, a^r, etc. It is probable that multiple alleles occur at each locus, encoding different levels of susceptibility (173).

Inheritance of resistance to subgroup E ALV is more complex, with involvement and interaction of genes at 2 autosomal loci designated tve and i^e (392). A dominant resistance gene, I^e, acting epistatically, blocks susceptibility conferred by presence of e^s

Table 15.13.   Genes controlling cellular susceptability to leukosis and sarcoma viruses.

| Virus subgroup | Locus | | Alleles | | Dominant trait |
	Old	New	Old	New	
A	*tva*	*TVA*	*tva*^{s} *tva*^{r}	TVA*S TVA*R	Susceptibility
B and D	*tvb*	*TBV*	*tvb*^{s1},*tvb*^{r}	TVS*S1, S3 TVB*R	Susceptibility
C	*tvc*	*TVC*	*tvc*^{s} *tvc*^{r}	TVC*S TVC*R	susceptibility
E	*tved*	*TVE*	*tve*^{s} *tve*^{r}	TVE*S TVC*R	Susceptibility
	ie		*I*^{e} i^e		Resistance

Note: The locus designation is adapted from Crittenden (117). The new locus designation is that agreed by the Poultry Committee of the USDA National Animal Genome Research Program, 1994. The allele previously designated *tvb*^{S2} now is considered to be identical to *tvb*^{S1}. The existence of a *tve* locus is not settled. The *i*^{e} locus is now considered to be an *ev* locus, with blocking of the subgroup E virus receptor by endogenous virus ENV glycoprotein expression.

allele. It has been reported, however, that susceptibility alleles at the *tvb* locus are required for susceptibility to E subgroup virus, and until recently it was not clear whether a separate *tve* locus exists (136, 369, 370). Recent studies indicated that mutations in the *tvb* receptor gene could explain some of the reasons for the resistance to subgroups B, D or E infections (27, 296, 298). Studies suggest that the *i*^{e} locus is, in fact, an *ev* locus, the ENV glycoproteins of which block the E subgroup receptor (425). Genetic resistance to infection by subgroup J virus has not been recognized in chickens, although a number of other avian species are resistant (381, 389). Recently the specific cell receptor for ALV subgroup J was shown to be the Na+/H+ exchange type I molecule (91). Susceptibility genes such as *a*^{s} code for the presence of subgroup-specific virus receptor sites on the cell surface, which interact with viral envelope glycoprotein and allow viral penetration and infection of the cell (547). Progress is being made in identifying the nature of such receptors (see "Virus Replication"). Cells resistant by virtue of the presence of a resistance gene such as *a*^{r} in the homozygous state are believed to lack the specific receptor sites necessary for infection to occur, although nonspecific adsorption of virus to such cells can occur, but without infection being established.

Cellular susceptibility phenotypes associated with these genes are designated according to a convention that recognizes the virus subgroups to which the chicken (C) cell is resistant (/) (e.g., C/AE denotes a cell resistant to A and E subgroups but susceptible to B, C, D, and J subgroups); C/0 denotes a cell resistant to no subgroup (i.e., susceptible to A, B, C, D, E, and J).

Resistance or susceptibility conferred by these genes is expressed by all cells, whether by cells cultured *in vitro*, such as chicken embryo fibroblasts; by chicken embryo cells, such as those of the CAM; or by chickens after hatching. These responses are applicable to ALSVs sharing the same envelope glycoproteins, and, thus, viral subgroup, but most genetic studies are undertaken with appropriate subgroups of RSV, because infection of the cell is expressed within a few days by visible growth of tumor cells. Thus, the phenotype of an individual may be determined by inoculation of a standard dose of RSV into chicken embryo fibroblasts in culture, with the production of foci of trans-

formed cells in susceptible embryo cells but not in resistant cells (434). Similarly, RSV can be inoculated onto the CAM of the chicken embryo, with or without the production of tumor pocks (129) or intracranially into day-old chicks, with death or survival as the response criterion (544) (see "Prevention and Control Procedures"). The phenotype of individual birds may be determined by culturing fibroblasts from plucked pin feather pulp and by challenging these cultures with RSV (135, 388, 487).

Genetically resistant chicks are resistant to infection and tumor induction by ALSVs of the subgroups concerned, and they usually fail to develop antibodies (118, 128). Genetic resistance to tumor development has been studied mainly with the Rous sarcoma (505), regression of which is determined by a dominant gene, *R-RS-1*, that lies within the major histocompatibility complex (MHC locus) of the chicken and located in the BBL region (107, 229, 405, 454). Conserved peptide motifs of the RSV proteins that bind to the MHC have been identified and shown to be immunoprotective against Rous sarcoma growth in chickens with class I allele B-F12 (259), and peptide motifs of the single dominantly expressed class I molecule explain the MHC-determined responses to RSV (540). The MHC (*Ea-B*) locus also influences incidence of erythroblastosis and, to a lesser extent, LL (18). Some influence of the lymphocyte antigen *Bu-1* locus on Rous sarcoma regression and of the *Th-1* locus on LL is reported (14).

Genetic resistance to LL tumor development, such as in RPL line 6, is conferred by bursal cells, not by other cellular elements of the immune system, such as thymic or thymus-derived cells or nonlymphocytes. It appears as though the intrinsic inability of the bursal target cell to become infected or transformed is the major factor in resistance (413). No obvious difference in the pattern of bursal infection in tumor-susceptible and -resistant lines was detected by Baba and Humphries (9).

Diagnosis

Isolation and Identification of Causative Agent

Because ALV is widespread among chickens, virus isolation and the demonstration of antigen or antibody have limited or no value in diagnosing field cases of lymphomas. However, assays for the

detection of ALV are very useful in identification and classification of new isolates, safety testing of vaccines, and in testing pathogen-free and other breeder flocks for freedom from virus infection. Samples most commonly used for detection of ALV include blood, plasma, serum, meconium, cloacal and vaginal swabs, oral washings, albumen of eggs, embryos and tumors (132, 193, 202, 208, 486). Virus also can be isolated from albumen of newly laid eggs or the 10-day-old embryo of eggs laid by hens that are transmitting virus vertically (483), from feather pulp (490), and from semen (456). All ALSVs are very thermolabile and can be preserved for long periods only at temperatures below −60°C. Thus, materials used for biological assays for infectious virus should be collected and placed on melting ice or stored at −70°C until assayed. In contrast, samples for detection of ALV gs antigens by direct assays can be stored at −20°C; see review by Fadly and Witter (208).

Because most strains of ALV produce no visible morphologic changes in cell culture, assays for ALV are based on the following: a) detection of specific proteins or glycoproteins coded for by 1 or more of the 3 major genes of ALV, namely *gag*, *pol*, and *env* genes (Fig. 15.22), or b) detection of specific proviral DNA or viral RNA sequences of ALV by the polymerase chain reaction (PCR) and reverse transcription (RT)-PCR, respectively.

The presence of virus is determined by the detection of ALV p27 by indirect biologic assays, such as complement fixation (CF) for avian leukosis (COFAL) (208), ELISA for ALV (125, 208), phenotypic mixing (363), resistance-inducing factor (359), and non-producer cell activation (422). Of all such assays, ELISA-ALV is the most commonly used test. All these biological assays require the use of chicken embryo fibroblasts (CEFs) with specific host range. The phenotype of CEFs most commonly used for the detection of ALV is shown in Table 5.10. Furthermore, Crittenden *et al.* (120) described the use of a Japanese quail cell line transformed by the envelope-defective Brian high titer strain of RSV [R(-)Q] for assay of exogenous and endogenous ALV. CEFs that are resistant to infection with endogenous ALV (C/E) are desirable to use in tests for detection and isolation of exogenous ALV. Other cells, such as those resistant to subgroup A (C/A) and resistant to subgroup J ALV (C/J) (265), can also be used to confirm the subgroup of isolated ALV. Testing samples on CEFs that are susceptible to all subgroups of ALV (C/O) and those that are resistant to subgroup E (C/E) can be used in differentiating exogenous and endogenous ALV. If a positive test is obtained from using C/O but not C/E CEFs, the sample is positive for endogenous ALV. Positive tests using both C/E and C/O indicate the presence of exogenous ALV. Recently, a flow cytometry method using a highly specific alloantibody termed R2 has been described for detection of endogenous ALV envelope in chicken plasma (12, 17). It should be noted that some tests such as CF and ELISA and possibly non-producer NP, PM, R(-)Q cell, and FA can be suitable for all leukosis and sarcoma viruses. The resistance-inducing factor (RIF) test can be performed only on ALVs that are not rapidly cytopathogenic. Other tests are specific for certain virus strains. Rapid transformation of fibroblast cultures is produced only by certain RSV and of hematopoietic cell cultures only by defective ALV. The test for

adenosine triphosphatase activity is specific for avian myeloblastosis virus. The procedures that are most widely used have been reviewed (193, 208).

Resistance-Inducing Factor Test

In general, most ALVs do not induce alterations in cultured cells except after prolonged passage. When CEFs are infected with an ALV, however, they become resistant to superinfection by a sarcoma virus of the same subgroup. Only viruses of the same subgroup interfere with one another in this way. The property of interference has been used for assay of ALVs by the RIF test (433) and also in delineating virus subgroups (536). In the RIF test, known susceptible chicken embryo fibroblast cultures are inoculated with material suspected of containing an ALV. Cells are subcultured at least 3 times at 3–4-day intervals, and at each passage, a sample of the cells is tested for susceptibility to RSVs of different subgroups. Alternatively, supernatant fluids may be transferred to new cell cultures every 4 days. In this case, cells may be challenged without subculture 4–6 days postinoculation. Control cultures infected with known ALVs and uninfected cultures are always included to establish validity of the tests. Presence of ALV in a cell culture is indicated by a 10-fold or greater reduction in number of foci produced by a standard stock of RSV when compared with the number of foci on similarly challenged control cells. Several different challenge viruses, one for each subgroup, must be used to detect ALVs belonging to different subgroups; each requires a separate cell culture plate for testing.

Tests for Viral-Internal, Group-Specific Antigens

Detection of the major antigen (p27) present in the core of ALSVs forms the basis of several diagnostic tests for virus.

The COFAL test can be used to detect the gs antigen in cultures of fibroblasts that have been inoculated with virus (449). Cells must be susceptible to infection with the virus sought; to obtain a suitable antigen from low-titer inoculate, inoculated fibroblasts must be cultivated for 14 days before they are harvested. The harvested cells are adjusted to a standard concentration, frozen, thawed, and then used as antigen in the test. Various controls are necessary, including uninoculated fibroblasts, because these may contain gs antigen derived from endogenous ALV. Titration of complement-fixing activity of extracts of the control and inoculated cultures allows differentiation between endogenous and exogenous viral antigen, because the titer of the latter is much higher. If available, fibroblasts that do not express endogenous antigen may be used.

Because of the difficulty in distinguishing between gs antigens of endogenous and exogenous viruses, direct CF tests of infected materials, without tissue culture passage, are of limited value. Nevertheless, direct tests may be done in certain circumstances (e.g., on egg albumen) (see "Eradication").

Complement-fixing antiserum against gs antigen can be obtained from hamsters bearing sarcomas induced by RSV (the Schmidt-Ruppin strain usually is used) (449). Rabbit and other mammalian antiserums prepared against purified gs antigens de-

rived from avian myeloblastosis virus can also be used (465, 497, 498). Antiserums have also been raised in pigeons bearing RSV-induced tumors (448, 451).

Highly sensitive radioimmunoassay (184, 446) and ELISA tests (102, 467) for gs antigens have been developed. They may be used directly for the assay of test material or indirectly using cell cultures inoculated with test material. These antigens may also be detected in cells by FA techniques (288, 373). Using indirect FA tests, monoclonal antibodies to ALV-J proved useful in the detection of ALV-J infected cell cultures (205, 417, 529). A variety of samples can be tested by ELISA for the presence of ALV; however, serum has been shown to be unsuitable for the detection of exogenous ALV by direct ELISA (385). For the detection of exogenous ALV, samples are inoculated on CEFs that are genetically resistant to subgroup E ALV. Seven to nine days later, cell lysates are tested for the presence of ALV gs antigen by ELISA (194, 208, 467). Rabbit anti-p27 antibody, which is used to coat ELISA plates, and rabbit anti-p27 conjugate, as well as complete kits for running ELISA for detection of ALV gs antigen, are available commercially.

Tests Based on Phenotypic Mixing of Viruses

CEFs can be infected with envelope-defective strains of RSV (e.g., BH-RSV) to produce transformed cells that are non-producers of infectious RSV of subgroups A, B, and D. Super-infection of a culture of NP cells by a leukosis helper virus results in production of infectious RSV, which is detectable in supernatant fluid by assays in susceptible CEF cultures and forms the basis of the NP cell activation test (421). Several variants of the test are described. Non-producer cell activation is an example of phenotypic mixing of viruses (see "Etiology"). Non-producer cells from embryos with endogenous subgroup E ALV may spontaneously produce a subgroup E RSV from complementation of the defective RSV by subgroup E envelope. In assaying for RSV production following activation, it is then necessary to use fibroblast cultures resistant to subgroup E but susceptible to subgroups A, B, C, D, and J (C/E cells).

A useful modified NP cell activation test uses Japanese quail cells that have been transformed with envelope-defective BH-RSV. Those nonproducing R(-)Q cells can be activated to produce infectious RSV by cocultivation with C/E cells infected with the exogenous ALV under test, thus providing the R(-)Q cell test (120).

Another variant of the NP cell test is the PM test (363, 411), for which cultures of C/O fibroblasts (i.e., cells susceptible to all virus subgroups) pretreated with DEAE dextran are infected heavily with subgroup E RSV(RAV-0), producing RSV-transformed cells. About 24 hours later, the supernatant fluid is discarded, and cultures are infected with test material. Cultures are incubated for 7 days, and the culture fluid is harvested, frozen, thawed, centrifuged, and assayed for infectious RSV on C/E fibroblasts. Because E subgroup RSV is excluded, the presence of RSV foci indicates presence of exogenous ALV in the test material. Various controls must be included in the test.

Variants of these tests have also been developed to detect infectious endogenous ALV, as well as expression in chick cells of subgroup E envelope glycoprotein termed chick helper factor (chf) encoded by the endogenous viral genome (120).

Comparison of Tests

In vivo and *in vitro* cell culture tests for detection or assay of exogenous ALVs are compared in Table 15.14.

All five *in vitro* tests require a standard source of chicken embryos free from exogenous ALSVs and of known phenotype for use in cell culture. The following reagents are also required: for the RIF test, stocks of challenge RSV of each subgroup; for the COFAL and ELISA tests, specific antiserum; for the NP test, quantities of NP cells; and for the PM test, stocks of RSV with endogenous helper, RSV(RAV-0). Cells obtained from embryos of unknown genetic origin should not be used in RIF, COFAL, and indirect ELISA tests because the results may be confused by genetic resistance. Both COFAL and indirect ELISA tests require either prolonged maintenance of culture or several subcultures to propagate the virus sufficiently; therefore, much more work is involved than in the NP or PM tests.

The indicator systems are different in the 5 tests. In the RIF test, the number and appearance of RSV foci after challenge are highly dependent on the physiologic condition of the cells. Thus, when cell cultures are not in optimal condition, a RIF test cannot be performed. A cell extract is used in the COFAL and ELISA tests, however, and it can be stored frozen and tested on more than one occasion if necessary. Similarly, in the NP and PM tests, the supernatant fluid of cell cultures can be stored and tested for virus by the cell culture technique. Results are usually more clear-cut in the NP and PM tests than in the RIF, COFAL, or ELISA tests. ALV infectivity and titer could be determined by ELISA within 7 days after cultivation, but after 19 days and 3 subcultures by the RIF test (522).

The subgroup of an infecting ALV can be determined by any of the tests. In the RIF test, only RSV belonging to the same subgroup as the ALV is subjected to interference. In COFAL and ELISA tests, genetically resistant cells can be used; thus, an ALV of subgroup A will not produce CF antigens in cells of the C/A phenotype (resistant to subgroup A viruses). In the NP test, genetically resistant NP cells can be prepared, and in the PM test, genetically resistant cells can be used in the mixing phase. In NP and PM tests, supernatant from the activation or mixing phase, which contains RSV of the same subgroup as the ALV, can be placed on genetically resistant cells or embryos or used in an interference test with an ALV of known subgroup.

Immunohistochemical Tests

Direct (288) and indirect (373) FA tests as well as flow cytometry (264, 265) have been used to detect viral antigen in CEF cultures; flow cytometry has also been shown to be a very useful tool in identifying the subgroup of ALV strains contaminating commercial Marek's disease vaccines (187).

When mammalian gs antiserums are used and cells are fixed in acetone, the test becomes analogous to the COFAL test. Avian serums are subgroup specific or even type specific (373). Other immunohistochemical techniques have also been described (166, 185, 233, 234).

Table 15.14. Comparison of methods for assaying exogenous avian leukosis viruses.

Method	Requirements	Response measured	Additional requirements for subgroup determination	Time required (days)[c]
In vivo				
Chick inoc 1 day IA	LL susceptible[a]	LL	Genetically resistant chickens	270
Chick inoc 1 day IA	Erythro susceptible[b]	Erythro	Genetically resistant chickens	63
Embryo inoc 11 days IV	Erythro susceptible	Erythro	Genetically resistant chickens	43
Cell culture RIF	RSV pseudotypes, C/E cells	Resistance to formation of RSV foci in CC[d]	Challenge virus of known subgroup	12 + 6
COFAL	Hamster antiserum, C/E cells	Complement fixation	Genetically resistant cells	14 + 1
ELISA	Enzyme-linked antisera C/E cells	Color change of substrate	Genetically resistant cells	14 + 1
NP	NP cells (chicken or quail)	RSV foci in CC	Genetically resistant cells of RIF test with leukosis virus of known subgroup	8 + 6
PM	RSV (RAV-0), C/O, and C/E cells	RSV foci in CC	Genetically resistant cells of RIF test with leukosis virus of known subgroup	5 + 6

Note: C/E, cells, genetically resistent to infection with viruses of E subgroup, but susceptible to viruses of other subgroups; C/O, cells phenotypically susceptible to infection by viruses of all subgroups; COFAL, complement fixation for avian leukosis viruses; CC, cell culture; ELISA, enzyme-linked immunoabsorbent assay; erythro, erythroblastosis; IA, intraabdominal; IV, intravenous; LL, lymphoid leukosis; NP, nonproducer; RIF, resistance-inducing factor; RSV, Rous sarcoma virus; RSV (RAV-0), Rous sarcoma virus with endogenous helper.

[a] Chickens susceptible to LL tumor formation (e.g., line 15I chickens).

[b] Chickens susceptible to virus infection and to development of erythroblastosis (or myeloblastosis).

[c] Approximate number of days necessary to cultivate the virus plus the number of days to indicate the presence of virus.

[d] Cell culture.

Enzyme Assays

Avian myeloblastosis virus has on its surface an enzyme (ATPase) that dephosphorylates adenosine triphosphate. This activity can be used as a quantitative assay to determine the amount of virus present in the plasma of infected chickens or in supernatants of myeloblast cultures (38).

Assays for RT activities have been used for the detection of oncogenic RNA viruses including all ALSVs (507). Detection of this enzyme, either directly when the correct template is used (287, 510) or indirectly when the radioimmunoassay is used (368), is an indication of presence of virus. Most recently, a highly sensitive PCR-based RT assay has been used to screen human vaccines that are produced in CEF or embryonated eggs for freedom from avian retroviruses (267, 519). In all tests for detection of ALV by RT assay, control tests must be conducted to rule out the presence of RT and of other retroviruses.

Detection of Viral Nucleic Acids

Blot-hybridization analysis of viral DNA or RNA in cell extracts is used increasingly for the detection of virus in avian tumor virus research (553, 554). The PCR is the most common DNA-based test used for detection and identification of ALV including subgroup E viruses (Fig. 15.48). RT-PCR has also been used to detect several subgroups of ALV (254). Most sequences used for developing primers are located in the env and LTR regions (see previous discussion). A specific PCR for ALV subgroup A can be used to detect proviral DNA and viral RNA in various tissues from ALV-infected chickens (526). Reverse transcriptase nested PCR (RT-nested PCR) test that amplifies a fragment of the LTR of exogenous ALV subgroups A, B, C, D and J, but not endogenous retroviral sequences has been described (225). Several primers specific for the detection of the most commonly isolated ALVs, particularly subgroup A (322), and the new subgroup ALV-J (462, 476, 477) have been developed. Other primers specific for endogenous, subgroup E ALV can also be used to detect cell culture infected with endogenous ALV-E, but not those infected with exogenous ALV of subgroups A, B, C, D, and J (208). PCR tests have been used to detect and characterize ALV strains contaminating Marek's disease vaccines (187, 573).

Hematopoietic Transformation

Avian myeloblastosis virus, an acutely transforming strain of ALV, harboring an oncogene, can infect and transform cultures of avian myeloblasts. Assays usually are based on a quantal response in which individual cultures are scored as positive or negative (23, 341). Focus assays for myeloblastosis, erythroblastosis, and other defective ALVs have been developed (241, 243, 343). Cultured chicken bone-marrow cells and blood monocytes are useful in isolation and propagation of acutely transforming viruses recovered from cases of myeloid leukosis induced by strain HPRS-103 ALV-J (384).

Transformation of Fibroblasts and Cytopathology

Avian sarcoma viruses transform spindle-shaped flat CEFs into spherical and refractile foci (414, 508) that can be seen microscopically after 4–5 days (Fig. 15.26). Genetically susceptible
15.48. PCR analysis of DNA isolated from line 0 CEF uninfected and infected with RAV-1 (ALV-A), RAV-2 (ALV-B), RAV-49 (ALV-C), RAV-50 (ALV-D), ADOL-HC-1 (ALV-J), and ADOL-R5-4 (ALV-J), and 15B1 cells uninfected and infected with RAV-0 (ALV-E) and EV21 (ALV-E). A. PCR analysis using primers specific for ALV-A-E (H5/AD1; reference 400). B. PCR analysis using primers specific for ALV-E (H5/DSW7.3; reference 400; reference 257). C. PCR analysis using primers specific for ALV-J (6J/S2; reference 385; reference 399). Lanes: M, 1 Kb plus DNA ladder; 1, RAV-1; 2, RAV-2; 3, RAV-49; 4, RAV-50; 5, RAV-0; 6, EV21; 7, ADOL-HC-1; 8, ADOL-R5-4; 9 line 0 CEF; 10, 15B1 CEF. (Lupiani)

cultures are inoculated with test material. The next day, medium is decanted and is replaced with an agar overlay (208). Inoculated cultures should be examined daily for RSV-induced foci, which usually develop within 4–7 days PI.

Sarcoma viruses also activate NP cells, produce the complement-fixing gs antigen, and can be detected by the FA technique. A number of defective acute ALVs can also transform CEFs (243). ALVs of subgroups B and D induce cytopathic effects in cell culture (242, 286). Because this property is restricted to a few viruses, it cannot be used as an assay for field viruses.

Serology
Plasma, serum, or egg yolk are suitable samples for the detection of antibodies to ALSVs.

Tests
Antibody to ALV can be measured by its reaction with RSV or ALV; a virus of one subgroup will not be neutralized by antibodies provoked by a virus of a different subgroup (536). Usually, a 1:5 dilution of heat-inactivated (56°C for 30 minutes) serum is mixed with an equal quantity of a standard preparation of RSV of a known pseudotype; after incubation, the residual virus is quantitated by any one of many procedures, the cell culture assay being most commonly used (437). A microneutralization test to assay for residual virus can be used for detection of ALV antibody (208). The test can be conducted in 96-well microtiter plates, and the neutralization of the virus is determined by an ELISA on culture fluids (199).

An indirect immunoperoxidase absorbance test (335, 336), ELISA tests (337, 472, 520, 523), and flow cytometry (264, 265) have been described for the detection of antibodies. ELISA kits for the detection of antibodies to ALV subgroups A and B are available commercially. Also, molecularly cloned, baculovirus-expressed envelope glycoproteins of ALV-J now are being used in commercial ELISA kits specific for the detection of antibody to ALV-J (314, 529).

Serotypes
Based on host range, interference spectrum, and viral envelope antigens, viruses of L/S group occurring in chickens are divided into 6 subgroups (A, B, C, D, E, and J) (378).

Viruses of different subgroups can be distinguished by the ability of monovalent antiserums to neutralize them. However, even though some cross-neutralization usually exists between viruses belonging to the same subgroup, the kinetics of neutralization vary, and slopes of curves for heterologous systems differ from those of homologous systems. No common neutralization antigens are among the viruses of different subgroups, except for a relationship between subgroups B and D. The diagnosis of infection by serologic means requires that representatives of all serotypes be employed. ALVs themselves may be used, but more commonly, RSV pseudotypes are employed in the neutralization tests (208).

Differential Diagnosis
Lymphoid Leukosis
Differential diagnosis of lymphomas in chickens can be difficult (189, 190, 196, 539). The 2 most common lymphoid neoplasms, namely Marek's disease (MD) and LL, are particularly confusing (567). Lymphoid tumors observed in REV-infected chickens, although only infrequently in cases of use of REV-contaminated vaccines, or under experimental conditions (see "Reticuloendo-

theliosis"), may also add to the confusion. LL cannot be differentiated from REV-induced bursal lymphomas on the basis of pathology, immunohistochemistry, and molecular changes in the c-*myc* region. Virologic, serologic, or PCR tests may be helpful in establishing infection for 1 virus and exclusion for the other. However, such assays are not particularly helpful in the diagnosis of virus-induced lymphomas of chickens including LL, as avian oncogenic viruses are widespread, and infection in the absence of tumor formation is common. Detection of proviral DNA (143, 189, 190) and integration junctions (96, 237) by PCR assays has been shown to be useful for tumor diagnosis.

Because LL tumors should contain ALV proviral DNA sequences inserted near the c-*myc* gene, differentiation between LL and REV-induced bursal lymphomas can be made by Southern blots and hybridization analysis of tumor DNA for clonal insertion of ALV (see previous discussion).

Lymphomas in which bursal tumors are lacking or in which the latent period is too short for that of LL can be confused primarily with MD; however, under certain circumstances, REV-induced lymphoma should also be ruled out (see "Reticuloendotheliosis"). In cases in which bursal tumors are lacking, LL and MD can be differentiated only with difficulty, because similar lymphoid tumors may occur in both diseases in the same visceral organs during the same age period. Visceral lesions of these 2 diseases cannot be distinguished by gross examination. Diagnosis is possible in most instances on careful microscopic examination; however, considerable experience is necessary. In coming to a decision, history, signs, gross and microscopic lesions, and cytology should all be considered. This section describes the points that should receive special attention (189–191, 416, 539).

Ordinarily, LL does not occur before 14 weeks of age, and most of the mortality occurs between 24 and 40 weeks. MD, however, may occur as early as 4 weeks, and the mortality peak varies from 10–20 weeks. Occasionally, losses continue and may reach a peak after 20 weeks.

Nodular tumors of the bursa can often be palpated through the cloaca in birds infected with ALV. Paralysis associated with gross lesions in autonomic and peripheral nervous systems and gross lesions of the iris ("gray eye") are specific for MD.

As stated previously, the bursa of Fabricius plays a central role in development of LL. When distinct focal or nodular lymphoid tumors are present in the bursa, a diagnosis of LL can be made; however, REV-induced bursal lymphomas must be ruled out. Such tumors are sometimes quite small and may be overlooked. In some birds, MD induces a premature atrophy of the bursa. In others, the bursa may be tumorous, in which case the walls and the plica may be thickened from interfollicular infiltration with pleomorphic lymphocytes. In contrast, intrafollicular tumors of the bursa consisting of uniform large lymphocytes are usual with LL.

Microscopic lymphoid infiltration in nerves, cuffing around small arterioles in the white matter of the cerebellum, and the feather follicular pattern of lymphoid cell infiltration in the skin, which are characteristic of MD, are not seen with LL.

Cytologically, LL tumors generally are composed of a homogeneous population of lymphoblasts (see Fig. 15.30). In contrast,

tumors of MD usually contain lymphoid cells varying in size and maturity from lymphoblasts to small lymphocytes, and plasma cells may also be present. Special stains such as methyl green pyronin are helpful for cytology. Immature lymphoblasts characteristic of LL tumors are highly pyroninophilic; whereas the medium and small lymphocytes that predominate in tumors of MD do not stain with pyronin.

LL tumors are composed almost entirely of B cells and have surface IgM markers; whereas 60–90% of MD tumor cells are T cells that lack IgM markers and only about 3–25% are B cells. In addition, from 0.5–35% of MD tumor cells have a tumor-associated cell surface antigen (MATSA), which is absent from LL tumor cells (168, 355, 356, 404). Recently, Witter *et al.* (567) introduced a diagnostic strategy for the differential diagnosis of viral lymphomas in chickens.

Other diseases that may be confused with LL are erythroblastosis, myeloblastosis, myelocytomatosis, pullorum disease, tuberculosis, enterohepatitis, Hjarre's disease, and fatty degeneration of the liver.

Erythroblastosis

Although gross lesions of liver, spleen, and bone marrow provide the basis for a presumptive diagnosis, a firm diagnosis must be based on finding large numbers of erythroblasts by microscopic examination of a blood smear and sections or smears of liver and bone marrow. Chickens in early stages of disease or without obvious signs may be missed easily unless microscopic examination is made.

Erythroblastosis with concurrent anemia is often difficult to differentiate from anemia resulting from non-neoplastic causes. In erythroblastosis, there is usually a defect in maturation of erythroblasts, resulting in the presence of large numbers of them and very few polychrome erythrocytes. In anemia, the reverse usually occurs. Extramedullary erythropoiesis and stasis of erythroblasts in the sinusoids are usually more prominent in erythroblastosis than in anemia.

Erythroblastosis can be distinguished from myeloblastosis on the following grounds. In myeloblastosis, the liver is usually pale red and the marrow is whitish; whereas in erythroblastosis, the liver and marrow are usually cherry red (see Fig. 15.33B,C). In myeloblastosis, the cells accumulate intravascularly and extravascularly, whereas in erythroblastosis they are always intravascular. The erythroblast and myeloblast may be difficult to distinguish. Erythroblasts have a basophilic cytoplasm and perinuclear halo; myeloblasts often have some granules (see Fig. 15.33D,E).

Erythroblasts are cells of the erythropoietic system and can be differentiated from cells of the myelopoietic system on the basis of the presence of certain markers. Thus, erythroblasts have erythroid markers including hemoglobin, chicken erythrocyte-specific histone H5 and chicken erythrocyte-specific cell surface antigens detected by immunofluorescence. Myeloblasts and myelocytes have myeloid markers including adherence and phagocytic capacity, Fc receptors as determined by rosette formation, macrophage- and granulocyte-specific cell surface antigen as detected by immunofluorescence, and dependence of colony formation on colony-stimulating factor (243, 344).

Erythroblastosis can be distinguished from LL by the nature and distribution of lesions. Microscopically, the cytoplasm of lymphoblasts is somewhat less basophilic than that of erythroblasts, and there is also a larger nuclear-cytoplasmic ratio than in the latter cells. Lymphoblasts are more variable in size and shape than erythroblasts, but they are all at the same primitive developmental stage. Lymphoblasts tend to have an ovoid rather than spherical nucleus and a finer, more delicate-looking chromatin network.

Myelocytomas are distinguished easily from erythroblastosis.

Myeloblastosis

As in erythroblastosis, a tentative diagnosis may be based on gross lesions; however, these are often so similar to those of LL that specific diagnosis cannot be made without examination of a blood smear. Examination of liver or bone marrow sections is helpful when identity of the cell type is in doubt. The myeloblast is, on the average, smaller than the erythroblast or lymphoblast; its cytoplasm is more acidophilic and is polygonal or angular. The nucleus is less vesicular; the nucleolus, while present, is not nearly so frequently seen or conspicuous as in the other two leukoses. Myeloblasts also have physiologic markers that identify them as members of the myeloid series (see the previous discussion).

Myelocytomatosis

The distinctive character and location of tumor (see the previous discussion) provide the basis for diagnosis, which can be verified by examination of a stained smear or tumor section. Gross tumors must be differentiated from myeloblastosis, LL, osteopetrosis, and necrotic and/or purulent processes occurring in tuberculosis, pullorum disease, and mycotic infections. In recent outbreaks of ALV-J induced tumors, myelocytomatosis was diagnosed primarily on the basis of presence of characteristic microscopic feature of tumor cells (206, 381, 383, 394).

Hemangioma

Hemangiomas on the skin should be differentiated from wounds, bleeding feather follicles, and cannibalism. Those in the visceral organs should be differentiated from hemorrhages and sarcomas.

Renal Tumors

Renal tumors should be suspected when tumor nodules or large masses are found only in the kidney or are encountered suspended from the lumbar region. Diagnosis can be verified by microscopic examination. Tumors should be differentiated from other causes of kidney enlargement including hematomata, LL, and accumulation of urates.

Osteopetrosis

Bone lesions of advanced cases are sufficiently distinctive to present no difficulty in diagnosis. Cross and longitudinal sectioning of long bones is helpful in detecting slight exostoses and endostoses, particularly in early stages.

Among other osteopathies (407), rickets and osteoporosis can be differentiated from osteopetrosis by their epiphyseal formation of osteoid or porous bone. In perosis, there is twisting and flattening of the shank while the bone structure itself remains normal.

Connective Tissue Tumors

These tumors are usually easy to distinguish from the leukoses. They should not be confused with granulomas (Hjarre's disease, tuberculosis, pullorum disease), results of trauma, myelocytomas, or leiomyomas.

Intervention Strategies

Vaccination

No commercial vaccine is available for the protection of chickens from infection with ALV. However, the idea of using vaccines to increase host resistance to ALV infection is very attractive (443). In a series of attempts to inactivate ALV by various means, however, Burmester (67) demonstrated that ability of these virus preparations to induce antibody was destroyed almost concurrently with inactivation. Attempts to produce attenuated strains of ALV that do not induce disease have also failed (364). Results of experimental vaccination with live ALV on shedding and congenital transmission of the virus are equivocal. Some success has been obtained in attempts to increase the resistance of the host to RSV by immunization with viral or cellular antigens (40, 379). The use of experimental recombinant ALSVs as vaccines may prove to be a valuable adjunct to current programs for reduction or eradication of ALV infection. Recombinant ALVs expressing subgroup A (93, 192, 329, 568) and ALV-J (314, 529) envelope glycoproteins have been produced that could have potential as vaccines to protect against horizontal transmission. It is worth noting that congenitally infected chicks are immunologically tolerant and, thus, cannot be immunized even if a suitable vaccine was available. These chickens constitute the major source of ALV transmission and are the most likely to develop neoplasms.

Treatment

No practical measures have been found for treatment of the various forms of the avian leukosis complex. In general, all attempts to treat virus-induced neoplasia have resulted in negative or non-reproducible results.

Prevention and Control Procedures

Eradication

Eradication of ALV from primary breeding stocks is the most effective means for controlling ALV infection in chickens. Primary breeding companies of layer-type and meat-type stock have made significant progress in reducing or eradicating ALV of subgroups A, B, and J from their elite breeding lines.

Until 1977, eradication was only applicable to experimental or special SPF flocks because methods used were long, complicated, and expensive. Since then, eradication from commercial flocks has become feasible (92, 387, 390, 483, 566) using the techniques described by Spencer *et al.* (486).

Programs for eradication of ALV infection depends on breaking the vertical transmission of virus from dam to progeny.

Breeder hens are tested by various methods for the presence of ALV, and those that test positive are discarded. In order to establish an ALV-free flock, it is necessary to hatch, rear, and maintain in isolation a group of chickens free from congenital infection. To achieve this, embryos must be obtained from dams that are not transmitting virus to their progeny. In earlier work on development of ALV-free flocks, several methods for selecting dams were used or recommended. The dams selected to produce the next generation and hoped to be a virus-free generation were (1) immune, nonvirus shedders. Hens with antibody were selected on the assumption that they were less likely than hens without antibody to shed virus. Chicks were hatched from those that did not transmit virus to their embryos, based on tests on at least 3 embryos per hen (261). (2) Nonimmune, nonvirus shedders. Hens without antibody were selected on the assumption that they had not ever been infected and were less likely than hens with antibody to become intermittent shedders (317). (3) Nonviremic hens regardless of immune status. These were identified and used to provide replacements; however, up to 4 generations of testing were needed before flocks were free of viremics, and infection of nonviremics was not ruled out (572).

Application of eradication programs of ALV to commercial flocks has depended on associations between virus infections in hens, eggs, embryos, and chicks (486): (1) Egg albumen may contain exogenous ALV and gs antigen, and both are usually present together. (2) A strong association exists between ALV or gs antigen in egg albumen and ALV in vaginal swabs. (3) An association exists between ALV in vaginal swabs or egg albumen and ALV in chicken embryos and newly hatched chicks. Consequently, hens with a low probability of producing infected embryos are hens negative for virus (or gs antigen) by the vaginal swab test, or hens that produce eggs with albumen free from virus or gs antigen. Commonly, virus in vaginal or cloacal swabs may be detected by ELISA, NP, or PM tests and in egg albumen by ELISA or direct COFAL tests. It is unlikely that a single test will detect all potential shedder hens. A problem that arises in applying the ELISA test to albumen or swabs is the need to differentiate positive reactions due to the presence of gs antigen derived from endogenous ALV or loci from the reactions due to the presence of exogenous ALV infection (269). Reactions due to the latter are usually markedly higher, but the setting of the boundary between endogenous and exogenous virus infections is sometimes difficult and somewhat arbitrary. High reactions due to exogenous virus are clearer with albumen samples than with swabs (132). There is a prospect that monoclonal antibodies developed against p27 protein will be used in ELISAs to differentiate between endogenous and exogenous infections (315); also, PCR assays using primers based on the proviral LTR will be useful.

A procedure for eradication of ALV involves (1) selection of fertile eggs from hens negative in the egg albumen or vaginal swab test (134, 202, 360, 386); (2) hatching of chicks in isolation in small groups (25–50) in wire-floored cages, avoidance of manual vent sexing (203), and of vaccination with a common needle (147) to prevent mechanical spread of any residual infection; (3) testing of chicks for ALV by a biologic assay or PCR on blood, discarding reactors and contact chicks (202, 203, 360); and (4)

rearing ALV-free groups in isolation (203, 566). In practice, selection of hens with a low shedding rate is a simpler requirement to fulfill than the subsequent chick testing and isolation rearing needed to achieve complete eradication. Consequently, some commercial breeder organizations are concentrating only on reduction of infection rate by hen testing. Progress in reducing shedding rates was reported for many lines, although some responded poorly (201, 362). Poor response to selection was not inherent in the lines but appeared to be related to environmental factors (201). For a review of these and other control methods, see Spencer (484, 487), de Boer (144), Payne and Howes (387), and Payne and Venugopal (394). Small group hatching and rearing procedures allowed identification and removal of groups containing chickens infected prior to hatching and prevented horizontal transmission of ALV-A in egg-type chickens (203) and ALV-J in meat-type chickens (566).

Chicks are most susceptible to contact infection by ALVs during the period immediately after hatching. Although congenitally infected hatchmates are likely to be the main source of such infection, several procedures can reduce or eliminate infection remaining from previous populations. Incubators, hatchers, brooding houses, and all equipment should be thoroughly cleaned and disinfected between each use. Chick boxes should not be reused, and each farm ideally should have only one age group of chickens. The danger of introducing strains of virus not already present in the population can be eliminated if eggs or chicks from different sources are not mixed, and if chicks are reared under isolation conditions that will prevent cross-contamination of flocks.

Experimental vaccination of chickens with virulent ALV at 8 weeks of age is reported to prevent virus shedding to eggs and to facilitate eradication of ALVs (420), but this could not be confirmed by Okazaki *et al.* (361). Chicks vaccinated at 8 weeks of age or older do not usually shed virus to their eggs, they may harbor it, particularly in white blood cells and the spleen (324).

Selection for Genetic Resistance

The frequencies of the alleles that encode cellular susceptibility and resistance to infection by exogenous ALSVs (see "Genetic Resistance") vary greatly among commercial lines of chickens (126, 345). In some lines, high frequencies of a resistant allele may be found naturally. In others, frequencies of the resistant alleles can be increased by artificial selection. In practice, emphasis is placed on resistance to the predominating A subgroup ALV and sometimes to B subgroup also. With the emergence of ALV-J infection in meat-type chickens, the value of developing lines that are resistance to ALV-J should be determined.

In artificial selection, genotypes of unknown parents may be determined in a progeny test by mating them to recessive tester birds of the subgroup in question (e.g., $a^r a^r$ for A subgroup virus) (372). Depending on the segregation of susceptible and resistant progeny in a particular mating, the genotype of the unknown parent may be determined. The phenotypic identification of progeny in the test may be determined by inoculation of RSV onto the CAM, the embryo being scored as susceptible or resistant on the basis of pock count (129) or intracranial inoculation of RSV into hatched chicks,

chicks being scored on the basis of death or survival (442). The former method is preferable and has many advantages.

Crittenden (115, 118) discussed some of the problems raised by this approach. Mutant viruses are more likely to overcome resistance from a single gene than that related to a multiple gene effect, and mutant subgroups then may be favored. In a host population resistant to virus penetration, there can be no effective selection for resistance to the development of neoplasms; for this reason, mutant viruses may take over. It is probable that past selection for host viability has increased the resistance of infected birds to the development of neoplasms. This type of resistance is poorly defined but may be controlled by a number of genes and is, consequently, more difficult to overcome by viral mutation. A prospect suggests that it will become possible to control ALV infections by the development of resistant stock by transgenesis (117). Recent methods of developing commercial chicken strains free of endogenous retroviruses (15) and the new methodologies of transgenesis using genetically modified primordial germ cells (524, 525) point towards the feasibility of using these approaches for generating resistant stock.

Reticuloendotheliosis

Aly M. Fadly, Guillermo Zavala and Richard L. Witter

Introduction

Definition

Reticuloendotheliosis (RE) designates a group of pathologic syndromes in several avian species caused by retroviruses of the reticuloendotheliosis virus (REV) group. The disease syndromes include 1) a *runting disease* syndrome, 2) *chronic neoplasia* of lymphoid and other tissues, and 3) *acute reticulum cell neoplasia*. Disease manifestations are not common although infection appears to be widespread.

The laboratory-derived strain T is defective for replication in chicken fibroblast tissue cultures and possesses a unique oncogene of cellular origin (v-*rel*) that is responsible for its acute oncogenicity (101, 102). Stocks of strain T also contain a nondefective helper REV that replicates in chicken fibroblast cultures but lacks acute oncogenic properties (101). The helper virus has been variously designated as *REV-A* (101) or as *nondefective strain T* (268). The REV group now includes strain T, *chick syncytial virus* (51), *duck infectious anemia virus* (138), *spleen necrosis virus* (238). Many other nondefective strains have been isolated from a variety of avian species including turkeys, chickens, ducks, pheasants, geese and prairie chickens (259). Nondefective strains are a single serotype, but have been differentiated into 3 antigenic subtypes (45).

The nondefective REVs are responsible for the runting disease

and the chronic neoplastic disease, both of which occur in nature. The acute reticulum cell neoplasia is induced only by strain T and is not known to occur in nature.

Economic Significance

Dramatic economic loss from runting syndrome or chronic neoplasia can occur when REV-contaminated vaccines are administered to very young chickens (83, 113, 128). However, such events are rare and on the basis of reported clinical disease, the economic importance of RE in turkeys and chickens is minor. Progeny of seropositive flocks are prohibited from export to certain countries, however, causing economic loss to certain breeders. Significant costs are also incurred by vaccine companies and producers of specific-pathogen-free flocks who must routinely monitor their products for REV contamination. Potential problems such as the possibility of immunodepressive disease from environmental exposure or contaminated vaccines, or of infection becoming endemic in valuable breeding stock have raised the level of concern (257).

Public Health Significance

The extended host range of REVs, which includes certain mammalian cells (1, 250) and other characteristics that suggest an evolutionary linkage with mammalian retroviruses (14, 127, 192), raised the possibility of human infection (114). Johnson and colleagues reported the detection of antibodies against REV antigens in human sera by ELISA and Western blot assays (115, 116), but titers were low and most of the reactivity could be removed by absorption with normal chicken tissue. However, other workers have considered the evidence for human infection with REV as insufficient to warrant concern (66, 68, 93).

Scientific Significance

RE has received uncommon attention by researchers. The acute and chronic neoplastic diseases represent (with Marek's disease and lymphoid leukosis) a third etiologically distinct group of avian viral neoplasms. The virus has a wider host range than other avian tumor viruses and can infect or transform a variety of cell types (1, 14, 251). The various REV-induced neoplastic syndromes in chickens resemble both lymphoid leukosis and Marek's disease and RE is a model for the study of immunosuppression in chickens. REV has become a frequently used model system in comparative retrovirology. REV can integrate into the genome of large DNA viruses, including Marek's disease and fowl pox (100, 110). REVs have been used as expression vectors to insert foreign genes into chicken and mammalian cells; such vectors may have diverse uses from production of transgenic chickens (28) to gene therapy in humans (69).

History

The initial REV isolate, strain T, was obtained in 1957 from a turkey with visceral lymphomas and was serially passaged over 300 times in turkeys and chickens by Twiehaus and colleagues at Kansas State University with cellular and cell-free inocula. Although these authors obtained considerable experimental data on this virus during the period 1958–60, publication was delayed (195). In the meantime, Sevoian obtained the isolate from Twiehaus and found it acutely oncogenic, causing death of young chicks 6–21 days after inoculation (210). Theilen *et al.* confirmed the acute oncogenicity of strain T for young chickens, turkeys and Japanese quail; these authors were the first to designate the disease as a *reticuloendotheliosis* on the basis of the prominent cell in the neoplastic lesion which he called reticuloendotheliosis (234), now termed acute reticulum cell neoplasia. Subsequently, Bose and coworkers designated the strain T virus as reticuloendotheliosis virus (27).

Purchase (183) recognized the antigenic relationships between strain T and the previously-characterized but nononcogenic chick syncytial spleen necrosis and duck infectious anemia viruses, thus establishing the concept of a reticuloendotheliosis virus group where the member strains have diverse biological properties. Thus, nomenclature for the disease and the virus originated from the atypical pathology induced by the defective strain T and was extended to all viruses in the group, even though reticuloendotheilal cell lesions are rarely, if ever, induced by infection with nondefective strains.

The literature on REV is substantial and other reviews may be consulted for additional details (11, 26, 68, 146, 154, 178, 184, 255, 259).

Etiology

Classification

REVs are retroviruses immunologically, morphologically, and structurally distinct from the leukosis/sarcoma group of avian retroviruses (see review (184). The International Committee on Taxonomy of Viruses has recently classified REVs within the family *Retroviridae*, subfamily *Orthoretrovirinae*, genus *Gammaretrovirus* (30). REVs were formerly classified within the genus *mammalian C-type*, whereas the avian leukosis viruses are classified in a separate genus (48). The phylogenetic relationship with mammalian C-type retroviruses is supported on the basis of morphology, nucleic acid sequences, amino acid sequences of major polypeptides, and immunologic determinants (see review (153) and receptor interference patterns (123).

Morphology

Viral particles are typical of retroviruses; they are about 100 nm in diameter (277), and are covered with surface projections about 6 nm long and 10 nm in diameter (118). Virions have a density of 1.16–1.18 g/ml in sucrose density gradients (20), but can be differentiated from avian leukosis/sarcoma viruses by morphology in thin sections (152, 277). The morphology of the viral particles is shown in Figure 15.49.

Chemical Composition

Nucleic Acid

Genomic single stranded RNA of REVs consists of a 60–70 S complex containing two 30–40 S RNA subunits, each having a size of about 3.9×10^6 d (22, 142) . The nondefective REV has a genome of about 9.0 kb, while the replication-defective strain T genome is only about 5.7 kb due principally to a large deletion
15.49. Electron micrographs of thin sections of chicken embryo fibroblasts infected with REV. A. Typical virus particles in the extracellular spaces. ×40,000. B. REV particles budding from the plasma membrane of infected cells (arrow). ×60,000. (Nazerian)

in the *gag-pol* region and a smaller deletion in the *env* region (49). Moreover, the replication-defective strain T genome contains a substitution of 0.8–1.5 kb in the *env* region that represents the transforming gene, identified as v-*rel* (44, 50, 269). The v-*rel* is not present in nondefective REVs or other avian or mammalian retroviruses. Related sequences (c-*rel*) are present in the DNA of normal avian cells, including turkey cells from whence the oncogene was most likely transduced (44, 254). No endogenous REV sequences in host DNA have been recognized. The long terminal repeats (LTRs), 569 base-pairs in length (213) are efficient promoters in a variety of cell types (193). The complete genome sequence of two field isolates of REV from China and the United States has recently been published (GenBank accessions NC006934 and DQ387450, respectively).

Oncogene

The v-*rel* oncogene is transcribed in strain T-transformed lymphoid cells and produces a phosphoprotein product identified as pp59$^{v\text{-}rel}$. The v-*rel* protein is a member of the rel/dorsal family of proteins, which are related to nuclear factor kappa B and function as DNA-binding transcription factors (25, 198). It differs from the c-*rel* protein both in structure and transforming ability (see (95) and, unlike most other oncogene products, can be detected in both the cytoplasm and nucleus of transformed cells (see (26). The v-*rel* protein is usually complexed with cellular proteins (125, 136, 222). This protein is responsible for the acute oncogenicity of replication-defective strain T (26).

In several cases, REV isolates other than strain T have induced neoplastic disease within very short latent periods (70, 71, 185, 186). Examination of such strains for viral oncogenes of cellular origin may be of interest.

Proteins

Like other retroviruses, REV genes express structural proteins, an envelope protein and a polymerase. The protein encoded by the v-*rel* gene is described above. The RNA-directed DNA polymerase (reverse transcriptase) differs structurally and immunologically from the comparable enzyme of leukosis/sarcoma viruses (19, 152). The preference of the REV polymerase for Mn^{2+} ions is a characteristic by which it can be differentiated from enzymes of other avian retroviruses (152, 205, 272).

A variety of polypeptides have been isolated from REV. The envelope protein is composed of two peptides, the gp90 surface unit (SU) and the gp20 transmembrane unit (TU) (239, 241). There are five *gag* gene-encoded structural proteins, p12, pp18, pp20, p30, and p10 (240). The C-terminal epitope of gp90 is located on the surface of infected cells (241). The gp90 protein is considered the immunodominant protein of the virus (62). The receptor binding regions have been mapped and structural differences compared to other retroviruses were noted (143). The 30-kD (p30) protein constitutes the major group-specific antigen that plays a role in viral particle assembly (252). Mosser *et al.* (157) located the two glycoproteins and two other proteins on the surface of the virions. Antiserum to p30 cross-reacted with p30 of several other REVs, thus establishing this protein as group specific (141).

Replication

Nondefective Strains

The cycle of replication *in vitro* is similar to that of other retroviruses and has been reviewed by Dornburg (68). Virus entry involves binding of the envelope glycoprotein to a specific receptor on the cell surface that has not yet been identified. Receptor
15.50. Acute (cytopathic) and chronic (noncytopathic) infection of chicken embryo fibroblasts inoculated with nondefective REV, strain T. A. Mild cytopathic changes 13 days after infection. Unstained, ×55. B. Cytopathic changes and viral antigens 13 days after infection demonstrated by indirect immunofluorescent staining. C. binding results in interference with superinfection (85). Entry of virions into cells is probably accomplished by direct membrane fusion. Integration of the DNA provirus proceeds by different mechanisms in chicken and D17 cells. Viral RNA transcription and translation are initiated through promoter and enhancer sequences in the LTR. Two polyproteins are encoded, *gag-pol* and *env*; the *gag* precursor protein is myristylated. The encapsidation sequence is located in the *gag* gene. The final stage is budding of viral particles from the plasma membrane. Virus particle production was first noted at 24 hr (118), and maximum virus production occurred 2–4 days after infection in chicken cells (27, 88, 231).

Defective Strain
The replication-defective strain T virus requires a nondefective RE helper virus for replication (101). Oncogenicity of this strain is maintained during passage *in vivo* (195) or during culture of infected hematopoietic cells (101), but is rapidly lost during passage in chicken fibroblast cultures (234, 265) and dog thymus cells (1). Breitman *et al.* (29) showed this apparent attenuation in chick embryo fibroblast cultures to be due to the loss of the replication-defective, acutely oncogenic virus, which was completely absent after three passages; however, the nondefective helper REV continued to replicate.

Cytopathology
Replication of REV in avian fibroblast cultures is accompanied, in some but not all cases (234), by subtle cytopathic changes.

Syncytial cell formation has been reported in infected cultures (51) but degenerative changes are more commonly seen (231). Temin *et al.* (232) proposed the following model: Infected cells synthesize unintegrated viral DNA, a part of which is integrated at multiple sites in the cellular genome. Progeny virus then superinfects the already infected cells, leading to an accumulation of unintegrated viral DNA. Cells with large amounts of unintegrated DNA die, while those cells able to prevent early superinfection have few copies of unintegrated viral DNA and survive.

The acute phase of cell killing (Fig. 15.50 A,B) lasts 2–10 days after infection and is followed by a state of chronic infection characterized by the disappearance of cytopathology and continued virus production (Fig. 15.50 C) (230, 231). This cytopathic effect is the basis of a plaque assay (36, 156, 231), but the method has not been widely used, perhaps because the cytopathology is somewhat inconsistent. Cho (46, 47) described a plaque assay in the QT35 line of chemically transformed Japanese quail fibroblasts.

Host Range
Cultured avian cells from many species, but especially chicken embryo fibroblasts, are susceptible to infection. However, certain mammalian cells support at least limited viral replication. Nondefective REV has been grown in D17 dog sarcoma cells (14, 250), Cf2th dog thymus cells (1, 214), normal rat kidney cells (122), mink lung cells (1), and bovine cells (13). D17 cells are susceptible and constitute a useful host system for virus propagation (250, 251), although REVs require some adaptation be-

fore high titers are obtained. Rat and mouse cells were only semi-permissive for replication of REV, with blocks at different replication steps (73, 74). Chimeric vector particles containing the REV-A matrix protein infected mammalian cells more efficiently than those containing the matrix protein of spleen necrosis virus strain (43). A wide range of avian species support REV replication *in vivo* but there is little evidence for *in vivo* replication of REV in nonavian species. Johnson *et al.* (116) reported the presence of antibodies in humans, monkeys, horses and goats but this report requires confirmation. Although Koo *et al.* (126) reported that REV-A-based vectors could infect human cells, recent evidence indicates that REVs do not infected human cells due to the inability to bind to a cell surface receptor (93). Further, some batches of a commonly used D17.2G packaging cell line appear to be contaminated with murine retroviruses that produce, when infected with REV, pseudotyped virions that can infect human cells (93).

Pseudotypes

The envelope component of nondefective REV forms pseudotypes with Rous sarcoma virus (201, 242) and with vesicular stomatitis virus (119). The pseudotype virus can be neutralized by antiserum to REV; Crittenden *et al.* (55) has used this principle to detect REV antibodies in test sera.

Insertional Mutagenesis

Like other retroviruses, replication of REV requires integration of proviral DNA into the host cell genome. However, REV proviral DNA also can integrate into the genomes of large DNA viruses including Marek's disease virus (110) and fowl poxvirus (100). Insertions apparently result from co-infections of REV and a recipient DNA virus, and occur both *in vitro* and *in vivo* (59). Most insertions consist of a solitary LTR, sometimes with partial deletions, (117, 155). However, full-length, infectious REV genomes have been detected in turkey herpesvirus (111). In fowl poxvirus, a nearly full-length, infectious REV provirus has been detected in certain strains (90, 100, 124, 215). Such proviral insertions have been detected in fowl poxvirus stocks lyophilized for over 50 years (124). This phenomenon could be important because of the potential for REV insertions to change the biological properties of the recipient organism and because infectious clones of REV packaged in other viruses may provide a novel and important mechanism for transfer of infection (see section on horizontal transmission).

Strain Classification

The different isolates of REV are remarkably uniform in antigenicity (32, 183, 265) and, except for defective strain T, have similar structural and chemical properties (19, 120). Although REVs belong to a single serotype (45), three subtypes were identified on the basis of neutralization tests and differential reactivity with monoclonal antibodies (45, 56). Viruses of subtype 1 and 2 could not be differentiated by receptor interference (85), thus confirming the absence of major differences between subtypes. REV isolates differ also in certain biologic properties, including pathogenicity (184) and replication *in vivo* (2), but such differences have not been the basis for strain classification.

Laboratory Host Systems
Cell Cultures

Fibroblasts from several avian species and certain cell lines, such as QT35 quail sarcoma cells (47, 53) and D17 dog osteosarcoma cells (14, 250), are susceptible to infection with nondefective REVs. In infected cultures, antigens (Fig. 15.50B,C), virus particles, proviral DNA, cytopathology, and reverse transcriptase may be detected and serve as criteria for virus assay. When the cultures are grown under agar, foci of cells containing immunofluorescent antigens can be localized and used as the basis for a quantitative fluorescent focus assay (183). Duck embryo fibroblasts may be preferred for demonstration of cytopathic effects (12). However, chicken bone marrow-derived macrophages appear resistant to infection (33).

Embryos and Birds

Other laboratory host systems for REV include chicken embryos (2, 211) and a variety of avian species including young chickens, Japanese quail, ducks, geese, turkeys, pheasants, and guinea fowl (15, 185, 234). Embryos and animals may respond to infection by development of specific lesions, viremia, or antibodies.

Cell Lines

Hematopoietic cells transformed *in vivo* or *in vitro* by the replication-defective REV have been developed into continuous cell lines; the cell types and surface markers vary based on the strain of helper virus and whether transformation occurred *in vivo* or *in vitro* (see 26, 105). A line of transformed chicken embryo fibroblasts has also been developed (87). Nonproducer clones can be isolated that produce pseudotypes when infected with nondefective REV strains (102). The cells possess surface viral antigens that co-cap with antigens of the major histocompatibility complex (140). Cell lines have also been derived from chronic lymphomas induced by nondefective strains of REV (169, 186). Cell lines induced by *in vitro* transformation of spleen cells with defective REV can serve as useful expression systems for transfected foreign genes (182, 204) or as substrates for the propagation of other viruses (188). Some of these transformed cell lines elaborate growth factors or cytokines (67, 91, 94).

Pathobiology and Epidemiology

Incidence and Distribution

REV infection is common, but not ubiquitous, in flocks of turkeys, ducks, chickens and certain other avian species throughout the world. The prevalence of seropositive flocks and the proportion of seropositive birds in an infected flock both increase with the age of the flock. Aulisio and Shelokov (6) found nearly half of 92 chicken flocks in the United States were seropositive. Subsequent studies, reviewed by Bagust (12), have established the presence of REV antibodies (or virus) in a number of countries. Infection appears to have been endemic in Japan as early as 1964 (244, 270). Recent surveys showed antibodies in 34–75% of chicken flocks in Korea (209) and Egypt (3). Seropositive chicken flocks are still common in the United States (Witter, unpublished).

In contrast, the incidence of REV-associated clinical disease in commercial poultry varies from sporadic to negligible. Acute reticulum cell neoplasia is not seen in the field. The runting disease syndrome has been primarily seen following vaccination of young chickens with REV-contaminated vaccines (113, 121, 273), although REV has been demonstrated in flocks with a naturally-occurring immunodepressive disease in Korea (209). In vaccine-induced outbreaks, a high proportion of chickens are typically affected.

Chronic neoplasia associated with REV infection is also rare. Field cases of lymphomas in turkeys have been described in the United States (54, 176, 221, 261, 266), England (145), and Israel (107). Losses from mortality and condemnation at slaughter in affected flocks could be as high as 16–20% (145, 176). Lymphomas associated with REV infection have also been reported in wild turkeys (99, 134). REV-associated lymphomas in chickens have also been reported (60, 107, 149, 173, 174) but are rare. Chronic neoplasia associated with REV has also been occasionally observed in ducks (97, 177, 179), quail (39, 203, 243), pheasants (71), geese (70), peafowl (151) and prairie chickens (72, 78, 276).

Administration of REV-contaminated vaccines to chickens may also induce chronic lymphomas (12, 83, 187).

Natural and Experimental Hosts

Natural hosts for REV infection include turkeys, chickens, ducks, geese, pheasants, Japanese quail, peafowl, and prairie chickens. Experimental hosts include all of the above species, as well as guinea fowl. Chickens and turkeys have been most frequently employed as experimental hosts.

Transmission, Vectors, and Carriers

Horizontal Transmission

Experimentally, REV can be transmitted by direct physical contact with infected chickens, turkeys and ducks (132, 160, 175). Horizontal transmission may be influenced by the host species (183) and the virus strain (262, 274), and was not detected when chickens were separated by wire mesh (10).

In nature, many flocks develop REV infection at older ages (262) where direct contact with infected birds can be excluded. Environmental sources of infection may include contaminated poultry houses, insects and other biological reservoirs. Poultry house environments can become contaminated with virus shed by infected birds since REV has been detected in feces and cloacal swabs (8, 180, 268, 274), other body fluids (10), and litter (249). Virus present in poultry house environments, if transported on fomites or insufficiently disinfected, could potentially serve as a source of infection for other flocks. However, this does not seem to explain the high rates of flock infection because, in flocks infected at later ages, virus is difficult to isolate (262) and the quantity of shed virus is probably limited. Furthermore, REVs, like all retroviruses, are quickly degraded outside the host at ambient temperatures (38).

Insect transmission is another possible source of horizontal transmission of REV. Virus could be recovered for brief periods in *Triatoma infestans* and *Ornithodoros moubata* after feeding on infected chickens (235, 236) but attempts to propagate REV in cultures of *Aedes albopictus* were unsuccessful (190). Motha *et al.* (166) isolated virus from 7 of 39 batches of mosquitoes (*Culex annulirostris*) in contact with viremic chickens and demonstrated apparent mechanical transmission of the infection to recipient chickens exposed to infected mosquitoes. Davidson and Malkinson (62) found that mosquitoes fed on infected blood for 96 hr retained infectious virus for an additional 5 hr but no transmission studies were conducted. Mosquito transmission has been proposed to explain why flocks seroconvert more commonly during summer months (61, 166) and why there is a high prevalence of infection in Southern states (262, 264). However, if insects are to be an important mode of infection for older poultry flocks, an ample reservoir of infected donor animals would be required, but the proportion of viremic chickens in field flocks at any given time appears too low to constitute the necessary biological reservoir. Novel viral reservoirs such as fowl poxvirus that may contain infectious clones of REV (90, 100, 215) and is also transmitted by mosquitoes could also be considered. Thus, mechanisms for horizontal transmission among commercial flocks and the identity of biological reservoirs of infection are poorly understood and further study is needed.

Vertical Transmission

Chickens, turkeys and ducks with persistent viremias may transmit infectious REV to progeny, although usually at low frequency (compared to avian leukosis virus). McDougall *et al.* (147) isolated virus from 2 of 25 embryos from tolerantly infected turkey hens. Similar low rates of viral shedding and transmission were documented for tolerantly infected chickens (8, 10, 245, 268), although Motha and Egerton (165) reported transmission to over 50% of chicks in an experiment in which eggs were incubated within 24 hr of lay. Albumen samples from tolerantly infected hens frequently contained RE viral gs antigen, although at low levels; infectious virus was rarely isolated (268). Vertical transmission may occur at higher rates in ducks, since virus was isolated from 87% of embryos derived from tolerantly infected females in one trial (160). Vertical transmission from nontolerantly infected chickens is even less common, but one exceptional antibody-positive, virus-positive turkey hen transmitted virus to 6 of 21 progeny (266).

Although semen from tolerantly infected turkeys contains infectious virus (148, 266), the role of the tom in vertical transmission is not clear. McDougall *et al.* (147) found that previously nonexposed turkey hens inseminated with infected semen produced infected progeny, but, in contrast, Witter and Salter (266) found the frequency of vertical transmission was no greater from hens mated with viremic males than with hens mated with nonviremic males. Furthermore, they found no evidence in turkey breeders or congenitally infected progeny of clonal insertions of proviral DNA that would be indicative of genetic transmission (266). Male transmission has received less attention in chickens, but Salter *et al.* (199) found RE proviral DNA in 10 of 820 chicks from matings of viremic males and nonviremic females. Clearly, a role for the male in vertical transmission of REV has not been excluded and needs further study.

The possibility that congenitally transmitted virus could be transferred by the sequential use of needles during the administration of Marek's disease vaccines to embryos or newly hatched chickens should also be considered (12).

Contaminated Biological Materials
Accidental contamination of virus and vaccine stocks with REV has been observed on a variety of occasions. The use of REV-contaminated fowl pox (23, 83) or Marek's disease (113, 274) vaccines has been documented, sometimes resulting in major economic consequences. Certain stocks of avian myeloblastosis virus, for many years distributed as a source of reverse transcriptase for biochemical purposes, contained a low level of REV (264). Quality control procedures to exclude REV from licensed poultry biologics are not uniformly effective (75). Standard assays may not detect REV contamination in vaccines such as fowl pox (75, 80). REV continues to be found in some (65, 90, 100, 215), but not all (155), fowl pox virus vaccines. REV has also been detected in stocks of *Plasmodium lophurae*, which was serially passed in ducks (138, 238). The occurrence of such problems points to further mechanism for increasing the distribution of this virus in nature.

Incubation Period
The runting disease syndrome includes a number of nonneoplastic disease processes that are not coordinately expressed and vary depending on virus strain and several other factors. Atrophic changes in the bursa and thymus can be seen as early as 3 days after infection (167). Weight depression in infected chicks can be detected as early as 6 days of age (158) and persists for life. By the second week postinoculation, chickens developed microscopic nerve lesions (265) and had depressed immune responses (263).

Chronic neoplastic responses occur after moderate or long incubation periods. Chickens developed bursal-derived B-cell lymphomas 17–43 wk after inoculation (268). Chronic nonbursal lymphomas with latent periods as short as 6 wk have been described in line 6_3 and line 0 chickens following experimental infection with the spleen necrosis or chick syncytial strains of nondefective REV (267). REV-associated lymphomas in turkeys occurred between 15 and 20 wk of age (145, 176). In transmission studies, lymphomas were induced after 8–11 wk (175) or 11–12 wk (145). Chronic lymphomas occur between 20 and 30 wk in the domestic goose (70), at 4–24 wk in ducks (97, 177, 179). Experimental inoculation of newly hatched ducks induced lymphomas and other neoplasms between 8 and 30 wk (135, 160).

For acute reticulum cell neoplasia, the incubation period can be as short as 3 days, but death occurs more commonly 6–21 days after inoculation (210). Because of the short latent period and high mortality, Bose has referred to defective REV strain T as the most virulent of all retroviruses (26).

Clinical Signs
Chickens with runting disease syndrome may be notably stunted and pale (167). Weights of infected chickens may be 20–50% lower than controls by 3–5 wk after infection (263, 265). Weight depression has also been seen in infected ducks (183). Some chickens may have abnormal feather development, termed *Nakanuke*, i.e., wing feathers with adhesion of the barbs to a localized section of the shaft (131). Lameness or paralysis is rare even in birds with gross nerve lesions. Mortality is rare in chickens (263) but affected birds in commercial flocks are usually culled prior to death; a culling loss of over 50% between 5 and 8 wk was described in one flock (227).

Birds developing chronic lymphomas become depressed prior to death but show few specific clinical signs. Similarly, newly hatched chickens or turkeys that develop acute reticulum cell neoplasia following inoculation with defective strain T show few clinical signs due to the rapid onset of the disease, and mortality rates often reach 100% (211, 234).

Pathology
Runting Disease Syndrome
In chickens, the principal lesions include runting (167, 265), atrophy of the thymus and bursa of Fabricius (167), enlarged peripheral nerves (265), abnormal feather development (129, 130), abnormal proventriculitis (113), enteritis (145), anemia (121, 138), and necrosis of the liver and spleen (184, 238). These are often accompanied by depression of cellular and humoral immune responses (32, 40, 107, 121, 263). The acute hemorrhagic or chronic ulcerative proventriculitis observed in field cases (113) could not be reproduced by Bagust *et al.* (9) with a similar isolate.

It is unclear whether the proliferative lesions in enlarged peripheral nerves are neoplastic or inflammatory; however, nerve lesions often occur in the absence of other neoplasms (265). Grossly, nerves are only modestly enlarged—up to 2× the diameter of controls. The infiltrating cells, which include lymphocytes and plasma cells, are shown in Figure 15.51.

At least parts of the runting disease syndrome occurs in ducks inoculated with the spleen necrosis or duck infectious anemia strains of REV (138, 238). Hematocrit values in ducks inoculated with spleen necrosis strain can be as low as 20%, compared to 35% for control ducks (238). Enlarged nerves (175, 176) or enteritis (145) have been observed in turkeys with RE-related chronic lymphomas.

Genetic differences in susceptibility have not yet been described; chicks from lines of different susceptibility to Marek's disease were equally susceptible to the development of nerve lesions following inoculation with REV (265). Most nondefective REV strains, when inoculated at hatch, induce high frequencies of gross lesions (183, 263) but others, such as chick syncytial strain, may induce few, if any, lesions (263).

Chicken Bursal Lymphoma
Chickens inoculated with the nondefective chick syncytial or T strains developed B-cell lymphomas, involving principally the liver and bursa of Fabricius (258, 268). The gross lesions were nodular or diffuse lymphoid lesions in the liver and other visceral organs, including nodular lesions in the bursa of Fabricius, which were indistinguishable from lymphoid leukosis (Fig. 15.52). A few birds may develop sarcomas or adenocarcinomas. The frequency of lymphomas was influenced by virus strain and whether a tolerant infection had been induced (268). Interestingly, coin-
15.51. Microscopic lesions in a peripheral nerve of a chicken inoculated with nondefective strain T REV. Infiltrating cells consist of mature and immature lymphocytes and plasma cells.

fection of chickens with serotype 2 Marek's disease virus enhanced the incidence of REV bursal lymphomas (5) as had also been reported for lymphoid leukosis (7).

The tumor cells, which appeared histologically as uniform populations of lymphoblasts, were identified as B cells by IgM and other B-cell specific markers (169, 268). The bursal dependency of this tumor was confirmed by the finding that chemically or surgically bursectomized chickens were refractory to tumor development (82). Bursal lymphomas may not always be present in field cases. Grimes *et al.* (96) observed what may be similar lymphomas in two chickens at 22 and 24 wk after inoculation with a field strain of REV, but no bursal involvement was reported. However, typical bursal lymphomas were observed in two chicken flocks following administration of a REV-contaminated fowl pox vaccine (83).

Chicken Nonbursal Lymphoma
Chronic nonbursal lymphomas have been described in certain lines of chickens following experimental infection with the spleen necrosis or chick syncytial strains of nondefective REV (267). Grossly, these lymphomas appear as focal or diffuse lymphoid infiltrations, usually producing enlargements of the thymus, liver, and spleen or focal lesions of the myocardium (see Fig. 15.53). The bursa of Fabricius is not involved. Nerve enlargements, probably from concomitant expression of the runting disease syndrome, may be seen. Histologically, the tumors appear to be a uniform, immature lymphoreticular cell that lacked B-cell markers and did not express MATSA, a cellular antigen associated with Marek's disease tumors (267) and also expressed on activated T lymphocytes (144). The principal tumor cell type is a CD8+ T cell but Ia antigens are not expressed (52). Only certain chicken lines, especially line 6_3, are susceptible (267). Thusfar, T-cell lymphomas have not been documented in the field.
15.52. Bursal lymphoma in a chicken. Note gross lymphomas in the liver and bursa of a chicken 25 weeks after inoculation with the nondefective chick syncytial strain of REV.

15.53. Nonbursal lymphoma in a chicken 48 days postinoculation with the nondefective spleen necrosis strain of REV. Note enlargement of spleen, nodular lymphomas on heart, and bursal atrophy of infected chicken (top row). Organs from age-matched control chicken are shown in the bottom row. (267).

Turkey Lymphoma

Chronic lymphomas in turkeys are characterized by gross lymphoid infiltrations in the liver, intestine, spleen, and other visceral organs. Paul *et al.* (175) and McDougall *et al.* (145) both described lymphomatous lesions in the bursa, but this lesion was not common. Grossly, livers were enlarged up to 3–4× normal size. Some spleens were enlarged while others showed little enlargment but focal lesions were present. Intestines were thickened and some showed annular lesions. Histologically, the lesions were composed of uniform populations of lymphoreticular cells (145). Crespo *et al.* (54) described T-cell lymphomas associated with an outbreak of reticuloendotheliosis in turkeys.

Lymphomas of Other Species

Various other species develop chronic lymphomatous lesions associated with REV infections. Gross lesions are not greatly different for those described for chickens and turkeys. Lesions reported in ducks include enlarged livers and spleens with diffuse or focal involvement, intestinal lesions, and infiltrations in skeletal muscle, pancreas, kidneys, heart and other tissues (97, 135, 160). Perk *et al.* (179) described an outbreak in ducks characterized by generalized leukemia in addition to visceral lymphomas. Similar tumors were described in geese, and included also occasional lymphoproliferative lesions in the bursa of Fabricius (70). Outbreaks in both pheasants and prairie chickens were characterized by cutaneous lesions on the head and mouth in addition to nodular lymphomas in visceral organs (71, 72, 276). Outbreaks in quail, attributed to REV, were characterized by liver and spleen enlargements (203) or intestinal lesions (39). Histologically, tumors from all these species generally resembled those described for chickens and turkeys; the identify of the target cell has not been determined.

Acute Reticulum Cell Neoplasia

The pathology of the acute reticulum cell neoplasia has been well described (195, 211, 234). The affected birds develop large livers and spleens with infiltrative focal or diffuse lesions. Lesions are also common in the pancreas, gonads, heart, and kidney. The blood shows a decrease in heterophils and an increase in lymphocytes (228), leading to a frank leukemia a few hours before death (212). The serum transferrin level is elevated (237) and Shen (212) reported elevated globulin and decreased albumin concentrations.

Histologic changes are generally characterized by the infiltration and proliferation of large vesicular cells, variously described as mononuclear cells of the reticuloendothelial system (234) or primitive mesenchymal cells (195, 211). Some lesions are composed almost solely of such cells, whereas others include also a moderate to heavy population of smaller lymphoid elements, probably indicating a host immunologic response to the primary lesion. Areas of necrosis in association with the neoplastic lesions are also frequent. A typical liver lesion is shown in Figure 15.54.

Multiple Syndromes

Lesions of the different types can be observed in the same experiment, or even in the same bird. Nondefective REV strains may

first induce lesions of the runting disease syndrome and lymphomas may occur later in the survivors, sometimes accompanied by nerve enlargements. Chickens inoculated with replication-defective, acutely transforming strain T, especially those surviving the acute disease, may develop lesions associated with the nondefective strain T helper virus.

Pathogenesis

Virus Infection

Once REV infection is established in a susceptible host animal, it proceeds in one of two paths, which to a large extent determine pathologic outcomes.

Tolerant infection, i.e., persistent viremia in the absence of antibody, is induced readily in chickens by embryo inoculation (107, 268) and by vertical transmission of virus from infected dams (10). Persistent infections occur rarely following inoculation at hatching (8, 147, 268) depending on the strain of chicken (81); and are unlikely to occur if exposure occurs at later ages. Persistent infections also occur in turkeys (147, 266). Some birds with persistent infections develop antibody responses. Tolerant infection is associated with higher rates of vertical transmission and tumor development, and birds are typically stunted and immunodepressed.

In birds exposed at hatching or later, however, a transient viremia followed by the development of antibodies is the most common consequence of infection (8, 263). Bagust and Grimes (8) described the persistence of noninfectious RE viral antigens in the blood for several weeks following the disappearance of infectious virus. Transient infection only rarely results in vertical transmission, immunosuppression, or tumor development. Infection of older birds rarely results in clinical disease (180, 183, 262, 274) except, perhaps, in turkeys in which lymphomas have been observed following contact exposure (147, 148, 175).

Various other factors influence susceptibility of avian hosts to infection or disease. No genetic cellular resistance has been recognized. However, some differences in the pathologic response of lines or families has been recognized in chickens (81, 207, 212, 267) and quail (233). However, differences were not apparent when two chicken lines were challenged with serial dilutions of the replication-defective strain T (210). Although endogenous leukosis virus genes had no influence on tumor induction or antibody response following exposure of chickens to REV, virus was isolated more frequently from chickens with *ev*2 than from chickens lacking this gene (55). A cellular resistance (interference) due to viral envelope gene expression has been described in cultured D17 cells (64) (85). Maternal antibodies appear to limit susceptibility to infection (218).

Runting Disease Syndrome

The pathogenesis of the various lesions associated with the runting disease syndrome has not been elucidated. Stunted chickens did not consume less food, but had marked reduction of phosphoenolpyruvate carboxykinase, a key gluconeogenic enzyme in the liver (92). The adherence of feather barbules to the shaft (Nakanuke) is apparently due to REV-induced necrosis of feather-forming cells early after inoculation (225). Mussman and Twiehaus considered the microscopic lesions of chicks with runting syndrome to resemble a graft-versus-host reaction (167), but a specific autoimmune component has not been identified.

Chronic Lymphomas

Noori-Daloii *et al.* (172) found in REV-induced bursal lymphomas that the DNA proviral genome of REV was integrated adjacent to c-*myc*, a cellular oncogene important in the induction of lymphoid leukosis by avian leukosis virus. The molecular mechanism by which c-*myc* is activated by insertion of REV proviral DNA has been described (89, 194, 224). The proviral insert often contains major deletions that prevent the expression of infectious virus (223). Based on pathology, proviral insertional activation of c-*myc*, and enhancement by serotype 2 Marek's disease virus, bursal lymphomas induced by REV and avian leukosis virus appear indistinguishable—a rare case in which the same disease is caused by two unrelated viruses. However, some subtle differences have been noted. For example, chickens of lines resistant and susceptible to lymphoid leukosis were uniformly less susceptible to lymphoma induction by REV than by avian leukosis virus (81), and the REV lymphomas usually require longer latent periods than those induced by avian leukosis virus.

For nonbursal lymphomas, the molecular mechanism of oncogenesis also involves insertional activation of c-*myc*, but differs from that in bursal lymphomas; the strong tendency for the provirus to be oriented in the same direction as c-*myc* in bursal lymphomas was not observed in nonbursal lymphomas (112).

Critical comparisons between chronic lymphomas in turkeys and chickens have not been made and there is no evidence that a common mechanism of oncogenesis exists. In ducks, the frequency of experimentally induced REV lymphomas was not affected by embryonal bursectomy (135), indicating that these tumors may not be of B-cell origin.

Acute Reticulum Cell Neoplasia

The target cell transformed *in vivo* by replication-defective strain T (with REV-A helper virus) expresses T lymphoid and myeloid markers (16). These cells also express surface MHC class I and II antigens, as well as interleukin-2 receptor (103), and are immunoglobulin M (IgM) negative but vary in expression of CT3 (16). Similar tumors were induced in chemically bursectomized chickens (16). Inoculation directly into the thymus induced thymomas composed of T and B cells (26). On the other hand, defective strain T, when associated with chick syncytial virus helper virus instead of REV-A, induces IgM-positive B-cell lymphomas with rearrangements of the heavy- and light-chain immunoglobulin loci (17, 18). Thus, cell tropism appears to be determined, in part, by differential effects of the helper viruses on lymphoid populations.

Neoplastic transformation in acute reticulum cell neoplasia is mediated by the oncogene, v-*rel*, contained within the replication-defective strain T virus. Transformation does not require the presence of a helper virus (133). Lymphoid cells transformed by strain T *in vitro*, but which produce no infectious virus, will produce typical RE when transplanted into syngeneic recipients (133, 197).

Immunity
Humoral Responses

Birds with nontolerant infections develop robust antibody responses. Antibodies have been detected as early as 16–21 days after inoculation in chickens (32, 161), but 6–10 wk may be required in contact-exposed birds (107, 132, 147). Antibody titers may decline with age (8, 32, 268), but McDougall *et al.* (147) detected neutralizing antibodies at high frequency in experimentally infected turkeys through 40 wk. Most birds that develop tolerant infections do not develop humoral immune responses, although a few tolerantly infected chickens ultimately develop antibodies (158). The presence of antibodies may influence tumor susceptibility as chemically bursectomized quail were more susceptible than controls to inoculation with a field isolate (185).

Cellular Responses

Major histocompatibility complex (MHC)-restricted cytotoxicity against lymphoblastoid cell lines transformed with defective REV has been described in chickens within 7 days after inoculation with defective or nondefective RE viral strains (139, 253). This response appears to be mediated by activated (MHC class II+) CD8+ T cells (127). However, NK cells were not activated (202). The induction of cytotoxic T cells by REV has been used as a general indicator of immune response in the study of other avian viruses (188).

Immunodepression

Humoral and cellular immune responses are frequently depressed in chickens infected with nondefective REV strains. Depressed antibody responses to Marek's disease virus and turkey herpesvirus (32, 121), Newcastle disease virus (107, 273), as well as to sheep erythrocytes and *Brucella abortus* (263) are documented. The magnitude of antibody depression is influenced by

the dose and strain of virus, and primary responses are more se-verely affected than secondary (263). Barth and Humphries (17) found that different strains of nondefective REV varied in ability to induce bursal atrophy and in suppression of B-cell populations available for transformation by v-*rel*. Studies on chimeric viruses derived from REV-A and chick syncytial virus showed that regions in both *gag* and *env* genes were associated with the strong immunodepressive ability of REV-A (86).

Spleen cells from chickens infected with replication-defective strain T were suppressed in their ability to respond to the mito-gen, phytohemagglutinin (40, 206). This effect is associated with the nondefective helper virus in strain T stocks (42) and is medi-ated through a population of suppressor cells (41, 196). The suppressor cells could be demonstrated only through the third week after infection (197). Other cellular immune responses inhibited by REV infection include mixed lymphocyte reaction and allo-graft rejection (248).

Witter *et al.* (263, 268) found depression of humoral responses and mitogen responsiveness was transient following infection with the chick syncytial strain, but persisted through 10–19 wk in chickens tolerantly infected with nondefective strain T. Infected chickens were more susceptible to the development of a Marek's disease tumor transplant (35), to reactions from infectious laryn-gotracheitis vaccine (161, 217), to natural fowl pox virus infec-tion (164), to infectious bronchitis virus (217), and to mortality induced by *Eimeria tenella* (163) and *Salmonella typhimurium* (162). No increase in susceptibility to Marek's disease virus was noted (31), but Witter *et al.* (263) demonstrated interference by REV infection with immunity induced by turkey herpesvirus against Marek's disease in chickens. Humoral immunodepression was also seen in ducks infected with a field isolate of REV (135). In the field, immunodepression is probably the most important consequence of embryo- or vaccine-derived REV infections but is less likely to result from contact infection (262) and has not commonly been associated with seropositive flocks. REV-induced immunosuppression has recently been reviewed by Zavala (275).

Tumor Immunity

A protective immune response against the acute neoplasia in-duced by strain T has been described. Regression of strain T-in-duced wing-web tumors was partially abrogated by bursectomy, thymectomy, and bursectomy-thymectomy (137). Serum from hyperimmunized chickens was protective against tumor develop-ment even after absorption to remove antiviral antibodies (104), thus suggesting the existence of tumor-specific transplantation antigens on RE tumor cells. Chickens immunized with purified or inactivated preparations of nondefective strain T helper virus were resistant to challenge with acutely transforming strain T preparations (21). However, immunization with empty virions (150) did not provide protection.

Diagnosis

A diagnosis of RE requires not only the presence of typical gross and microscopic lesions, but also the demonstration of REV.

Because REV, unlike avian leukosis and Marek's disease viruses, is not yet as ubiquitous, the demonstration of infectious virus, viral antigens, and proviral DNA in tumor cells has diagnostic value. Diagnostic techniques have been reviewed by Fadly *et al.* (84).

Isolation and Identification

Viremia with REV is typically low titered and transient, except following congenital transmission or embryo inoculation that leads to tolerant infection. Birds with lesions are normally a good source of virus. Virus may be isolated by inoculation of suscep-tible tissue cultures with tissue suspensions, whole blood, plasma, or other inocula. In general, cellular inocula are pre-ferred over cell-free inocula, since the former usually contain higher titers of virus than the latter. Because cytopathic effects in cell cultures may not be seen on primary isolation, cultures should be maintained through at least two blind 7-day passages. The presence of REV is confirmed by the demonstration of viral antigen in infected cell culture using polyclonal or monoclonal antibodies (56), by immunofluorescence (265), immunoperoxi-dase staining (36), complement fixation (219), or enzyme im-munoassay (57, 109). In comparative studies, enzyme im-munoassays were more sensitive than complement fixation tests (57) and indirect immunofluorescence was more sensitive than indirect immunoperoxidase or immunoelectron microscopy (171). A convenient and sensitive indirect immunofluorescent assay conducted in 96-well plates (45) has been used for virus isolation from field samples (266).

Virus isolated by this procedure may be identified by repro-duction of the typical disease in experimental animals and by fur-ther neutralization tests. Virus isolates may be assigned to anti-genic subtypes by the differential reactivity of monoclonal antibodies in immunofluorescent assays (45). Subtyping of iso-lates may have value for epidemiologic studies.

Detection of proviral DNA by polymerase chain reaction (PCR) assays that amplifies the 291 base pairs product of REV LTR (Fig. 15.55) has been shown to be a sensitive and specific method for detection of various strains of REV in infected chicken embryo fibroblasts as well as in blood and tumors of in-fected chickens (4, 209). This procedure appears useful for tumor diagnosis (58, 60, 61, 63) and the evaluation of vaccines for possible REV contamination (80, 83, 100, 191, 226, 229). Garcia *et al.* (90) found that assays amplifying REV envelope and REV 3′ LTR sequences provided a more accurate assessment of REV provirus than PCR assays that amplify the REV 5′ LTR region. Although PCR assay can be used in lieu of antigen detec-tion assays for demonstration of infection in inoculated cell cul-tures or directly in tissue samples it may not be as well suited as enzyme immunoassay for large-scale testing.

Serology

Confirmation of REV infection by serologic procedures involves the detection of antibodies in sera from chickens inoculated with suspect isolates or from affected chickens. Antibodies are in-duced with various frequencies and persist for varied periods. The most sensitive test for detection of antibodies to REV is
15.55.   PCR analysis of DNA isolated from chicken lymphomas using primers specific for REV. Lanes: M, 100 bp ladder; 1, experimentally induced REV lymphoma (positive control); 2, unknown lymphoma (test sample); 3, uninfected chicken embryo fibroblasts. The expected 291 bp PCR product (arrow) is indicated. (Lupiani)

virus neutralization; briefly, samples of plasma or serum are reacted with REV and the neutralization of REV is determined by assay for residual virus using enzyme immunoassay or immunofluorescence. Immunoperoxidase plaque assay (36) has also been shown to be a sensitive and reliable method for detection of REV antibody. Specific antibody may be detected in the serum or egg yolk from exposed birds by indirect immunofluorescence (6, 265), virus neutralization (147, 183), agar gel precipitin (106, 159), enzyme immunoassay (34, 170, 220, 271) and pseudotype neutralization (55) tests. Enzyme immunoassay kits for antibody detection are commercially available. The agar gel precipitin test may detect viral antigen as well as antibody in sera (106, 107). Antibody tests are particularly useful in ascertaining the absence of viral exposure in specific-pathogen-free breeder flocks or flocks producing progeny for export.

Differential Diagnosis

The pathology of REV-induced tumors, particularly those of lymphoproliferative nature, can be confused with that of tumors seen in Marek's disease and lymphoid leukosis (76, 79, 246). Because avian tumor viruses are widespread and infection in the absence of tumor formation is common, in most cases virologic and serologic criteria rarely provide a definitive diagnosis. However, as previously stated, diagnoses of RE should be sup-

ported by virologic evidence of REV infection, as REV is not as ubiquitous as Marek's disease and avian leukosis viruses. Techniques based on immunocytochemistry with monoclonal antibodies to cellular, tumor and viral antigens, or molecular hybridization can be used in the differential diagnosis of avian viral lymphomas including RE.

Avian retroviral lymphomas in chickens originate from either B cells (RE, lymphoid leukosis) or T cells (RE), whereas Marek's disease lymphomas are of T-cell origin (see subchapters on Marek's disease and Leukosis/Sarcoma Group). The characteristics of target cells provide the basis for tests that distinguish among B- and T-cell lymphomas using monoclonal antibodies specific for cell surface antigens of B- and T-lymphocytes. Nondefective strains of REV have been shown to transform chicken B or T cells by integration within a cellular (c) *onc* gene such as c-*myc* resulting in the enhanced expression of such gene and thereby initiating the lymphomagenic process (112, 224). These molecular changes are the bases for testing tumor DNA for the definitive diagnosis of REV-induced lymphomas.

The PCR assays for RE (see "Isolation and Identification"), Marek's disease (see subchapter, Marek's Disease) and exogenous avian leukosis virus (see subchapter, Leukosis/Sarcoma Group) can be helpful in the differential diagnosis of RE. For instance, because Marek's disease lymphomas should contain a significant proportion of Marek's disease virus-infected cells, compared to latently infected tissues, Marek's disease lymphomas should have more infected cells, each with greater number of viral copies thus resulting in higher total estimates of viral load by PCR analysis. Quantitative PCR analysis may be conducted by at least two methods, a quantitative-competitive method (189) and real-time PCR. Nonquantitative PCR assays are probably of little value for diagnosis of Marek's disease because of the potential to detect MDV DNA in the absence of lymphomas. Also, PCR has been shown to detect REV-LTR sequences from lymphomas and brains of REV-infected chickens, but not from DNA from Marek's disease or lymphoid leukosis lymphomas (4). However, diagnosticians should always keep in mind that PCR assays demonstrate the presence or absence of the respective virus and thus posess the same limitations for tumor diagnosis as virus isolation.

Chronic neoplasia in the chicken where the tumors are of bursal origin cannot usually be differentiated from lymphoid leukosis on pathologic criteria (258); virologic, serologic, or PCR tests providing infection can be established for one virus and excluded for the other. In addition, RE or lymphoid leukosis tumors should contain proviral DNA sequences of the respective virus inserted near the c-*myc* gene, a characteristic that could permit differentiation of lymphomas by molecular hybridization. Using appropriate REV probes such as pSNV, or c-*myc probes*, Southern blots and hybridization analysis of tumor DNA is used to detect insertion of REV provirus and alteration in c-*myc*, respectively.

Chronic neoplasia in the chicken in which bursal tumors are lacking or in which the latent period is too short for that of lymphoid leukosis must be differentiated from Marek's disease. Here too, pathologic criteria are insufficient and virologic assays (including PCR) may be helpful. The pp38 antigen of Marek's dis-

ease virus, occasionally expressed in Marek's disease lymphomas (see subchapter, Marek's Disease), is not present in RE lymphomas. Also, MHC class II (Ia) antigens are reported to be present on Marek's disease lymphoma cells (202) but absent on RE nonbursal lymphoma cells (52). Recently, Witter *et al.* (260) introduced a diagnostic strategy for the differential diagnosis of virus-induced lymphomas in chickens.

The acute reticulum cell neoplasia syndrome is not known to occur in the field and is unlikely to require differential diagnosis when experimentally reproduced in the laboratory. A new syndrome of broiler chickens characterized by reticuloendothelial proliferation in the spleen and liver, and resulting in condemnation loss at processing, has been confused with RE (98, 247), but can be distinguished by the absence of RE antigens and proviral DNA in the lesions (256). Virus detection tests including PCR have been used to confirm the diagnosis of REV-induced orbital lymphosarcoma in an Indian peafowl (151) and lymphomas in captive greater and Attwater's prairie chickens (72, 78, 276).

The runting disease syndrome must be distinguished from Marek's disease in the chicken, especially when nerve lesions are also present. Differences between REV-induced and Marek's disease virus-induced nerve lesions have been discussed (263, 265), but are not consistent. Both types of nerve lesions must be distinguished from spontaneous neuropathy, a probable autoimmune lesion of peripheral nerves (24). Other immunodepressive diseases such as infectious bursal disease and infection with chicken anemia virus may also resemble the runting disease syndrome.

Chronic RE neoplasia in the turkey must be differentiated from lesions of lymphoproliferative disease of turkeys (108); differences in pathology and in properties of the viral reverse transcriptase can be helpful (205, 272). The PCR assays for lymphoproliferative disease (200) and RE (above) should also aid the differentiation of these diseases. Marek's disease has recently been diagnosed in turkeys in France, Israel, Germany and Ukraine (see subchapter on Marek's disease) and should be ruled out in the differential diagnosis of RE in turkeys.

In summary, naturally occurring RE lesions can be confused in the chicken with Marek's disease, lymphoid leukosis, and various other lymphoproliferative or immunodepressive conditions, and in the turkey, with lymphoproliferative disease virus-induced neoplasms and Marek's disease. An increasing awareness of REV-related syndromes, the increasing prevalence of REV infection, and the availability of improved diagnostic techniques should facilitate the inclusion of RE in the differential diagnosis of avian neoplasms.

Intervention Strategies

Vaccination
Although vaccines have not been seriously proposed for control of RE, some candidate vaccines have been described. Vaccination of chickens with a recombinant fowl pox virus expressing the *env* gene of REV (37, 168, 216), or empty REV particles produced by transfected QT35 quail cells (150), provided some protection against REV infection. Use of defective REV particles produced by infection of the D17 transformed canine cell line

(250) has also been shown to induce neutralizing antibody in inoculated chickens (77). A baculovirus construct expressing the env gene of REV has also induced REV antibody in inoculated chickens (249).

Treatment
No treatment for RE is known. Since immune responses are mounted to infection, it is possible that some affected birds may recover.

Prevention and Control Procedures
Prevention of RE is currently accomplished through quality assurance of poultry biologics and, in SPF flocks, by strict biosecurity (257). Although it is desirable to prevent environmental exposure and seroconversion of breeder flocks where progeny are destined for export, this is difficult to accomplish because knowledge of the important natural reservoirs of infection is incomplete. Control of insect vectors and virulent fowl pox virus infections could be important in prevention programs (257).

Procedures for the control of RE have rarely been applied in commercial practice, mainly because the disease has been sporadic and self-limiting, but also because the necessary techniques and knowledge have not been available. Studies by Witter and Salter (266) on a flock of naturally infected breeder turkeys showed that REV has the potential to be a major economic problem, and provided an evaluation of some techniques for identification of shedder hens. Enzyme immunoassay to detect RE viral antigen in albumen samples seems to be the procedure of choice (109, 266). Presumably, it would be necessary to eliminate vertical transmission through removal of potential transmitter hens, and to rear progeny under isolated conditions whereby horizontal infection could be precluded. Many of these principles have successfully been applied to the control of avian leukosis virus in chickens. Such control procedures could be considered if REV infection becomes endemic in especially valuable breeding stock, as is the case with the endangered Attwater's prairie chickens (72, 78, 181, 257).

Dermal Squamous Cell Carcinoma
Scott Hafner and Mark A. Goodwin

Introduction and History

There have been sporadic reports of squamous cell carcinomas in the skin, tongue, pharynx, crop, and esophagus of aged chickens worldwide since the 1800s. Squamous cell carcinomas in older chickens are rarely metastatic (1), but often are locally invasive (3,

7, 8, 14, 15, 18, 25, 27). In contrast, the term "dermal squamous cell carcinoma" (DSCC) has been used to denote lesions usually found in the skin of young broiler chicken carcasses at slaughter. This condition predominantly affects only the dermis, and there are no reports of metastasis (5, 6, 12, 13, 19, 20, 24, 26, 28).

In the past, DSCC has been accepted as being the appropriate name for these lesions in young broiler chickens (5,6,16,26); however, more recently authors have preferred to use either avian keratoacanthoma or keratoacanthoma (12,13,19,20). This is because keratoacanthomas are regressing tumors of humans that resemble squamous cell carcinomas both grossly and microscopically (2, 17), and naturally occurring DSCCs in live broiler chickens have also been found to regress (12).

Economic Significance

Carcasses with extensive lesions of dermal squamous cell carcinoma (avian keratoacanthoma) are condemned at slaughter, while less affected birds undergo trimming. Condemnations of whole carcasses represent a significant economic loss (11).

Public Health Significance

There is no known public health significance, although birds with extensive lesions may be septicemic due to secondary bacterial infections.

Incidence and Distribution

These skin lesions are most commonly found in broiler chicken carcasses, but similar tumors are also occasionally present in the carcasses of older chickens (12). In broilers, the prevalence of carcasses with multiple lesions averages from 0.01% to 0.05%, but may be 0.09% or higher in individual flocks (13, 16, 26, 28). Flocks of chickens slaughtered at less than 48 days had an increased prevalence of these skin lesions in one study (13) and in some investigations tumor prevalence was cyclic, lowest in summer months (13, 28). In some surveys, high condemnation rates were associated with dusty houses, birds placed in new houses, or with certain producers (11).

Etiology, Epidemiology, and Pathogenesis

The etiology of the natural condition is unknown. Applications of methylcholanthrene to chickens that were also chronically infected with fowlpox resulted in the formation of papillomas and squamous cell carcinomas; however, these tumors either regressed or resolved to cutaneous horns after applications of the carcinogen were discontinued. A few metastatic squamous cell carcinomas originated from residual lesions after several years had passed (9). In later work, repeated topical applications of methylcholanthrene produced regressing lesions that were originally diagnosed as squamous cell carcinomas (22), then as squamous cell carcinomatoid tumors (23), and finally as keratoacanthomas (21). More recently, DSCC developed in two young chickens that had been injected with strains of avian leukosis virus, but other similarly treated chickens did not develop these lesions (4). DNA sequences specific for fowlpox virus were detected by a nested PCR nearly as frequently in DSCC lesions as these sequences were detected in fowlpox lesions and much more frequently than these sequences were detected in normal skin or skin affected by dermatitis. However, no evidence of infectious poxvirus was identified (10).
15.56.   Typical carcass lesions are craterous ulcers within feather tracts.

Gross Lesions

Carcasses most commonly exhibit crater-shaped ulcers with raised margins that occur in feather tracts (Fig. 15.56). Smaller ulcers average 5 mm in diameter and are circular, but large irregular, coalescing ulcers are present on some carcasses (13). These ulcerated lesions may either form aggregates within feather tracts, or they may be found scattered throughout the tracts. In one study (13), lesions occurred most frequently in dorsopelvic, femoral, and pectoral tracts, but some surveys have found no apparent site predilection (26). In live chickens, these ulcers are filled with keratin and cell debris (Fig. 15.57). Small (average 3 mm) nodular lesions often accompany ulcers and appear grossly as enlarged feather follicles (Fig. 15.58). In live young broiler chickens, these nodular lesions progressed to ulcers, and all lesions eventually regressed (12).

Histopathology

Nodular lesions appear microscopically either as proliferative outgrowths of feather follicle epithelium (Fig. 15.59), cysts that originate from dysplastic feather follicle epithelium, or hyperplastic feather follicles that contain hyperkeratotic feathers (13, 24). The cytokeratin profiles of tumor cells also suggest that tumors originate from the feather follicle epithelium rather than the surface epidermis (24). Ulcers are composed of a central cup-shaped cavity lined by epithelium and filled with keratin, bacteria, sloughed epithelial cells, and inflammatory cells. Epithelial lips overhang the central keratin mass. The lining epithelium keratinizes toward the central cavity and extends thin strands of keratinocytes into the surrounding dermal fibroplasia (Fig. 15.60). The peripheral fibroplasia contains isolated keratinocytes, het-

15.57. In live chickens, ulcers contain central masses that are mixtures of keratin, cell debris, and bacteria.

15.59. Microscopically, nodular lesions are expansions of feather follicle epithelium. ×40

15.58. Early lesions in the skin of live chickens are nodules in the base of feather follicles.
15.60. A section through the epithelial lip of an ulcer from a live bird shows the centrally keratinizing and peripherally invasive lining epithelium (arrows) adjacent to the central keratin and cell debris. ×100

erophils, scattered macrophages, and perivascular lymphocyte aggregates. Carcass lesions are often extensively altered by defeathering with loss of the central keratin core and much of the lining epithelium (12, 13).

Ultrastructurally, desmosomes interconnect keratinocytes that contain tonofibrils or keratohyalin granules. In some studies, viral particles were not seen (5, 12). However, in one study type C retroviruses were identified (24).

Pathogenesis

The complete pathogenesis of DSCC is unknown, however, lesions appear to begin at the margin of hyperplastic feather follicles. The peripheral follicular epithelium either infiltrates the adjacent dermis or expands into small cysts with irregular peripheral margins of invading keratinocytes. The lesions are further surrounded by a zone of fibroplasia that contains numerous inflammatory cells. As the cysts enlarge, they become superficially ulcerated. Overlying epithelial lips at the margins of the ulcers restrain the central mass of keratin and bacteria. After the central keratin core is lost, there is rapid regression of the lesion to a dermal scar overlaid by re-epithelialization.

Diagnosis

Grossly and microscopically, the differential diagnosis is primarily an ulcerative dermatitis. Adequate examination of microscopic sections confirms the diagnosis.

Prevention and Control

There are no known methods of prevention and control.

Multicentric Histiocytosis
Scott Hafner and Mark A. Goodwin

Introduction

Multicentric histiocytosis is a condition of young broiler chickens that is characterized grossly by both splenomegaly and hepatomegaly with numerous small white masses in the spleen, liver, and kidneys. This condition has been noted since 1991 in the organs of young chickens presented for slaughter in the United States (4). Synonyms for this disease include "big spleen Marek's disease" and "reticuloendotheliosis-like syndrome." Similar diseases in other countries have been described as "histiocytic sarcomatosis" and "systemic spindle-cell proliferative disease" (1, 8, 9). It has not been determined whether these lesions are true neoplasms or a marked proliferative response (2, 4, 5, 6).

Public Health Significance

There is no known public health significance.

Etiology

No definitive etiologic agent has been identified. In some examinations, the DNA extracted from lesions of naturally diseased broiler chickens did not contain sequences specific for reticuloendotheliosis viruses, Marek's disease virus, or exogenous leukosis-sarcoma viruses (4, 10), but subgroup J viruses may not have been detected by the primers used in PCR amplification of tumor cell DNA (1). Serum samples from naturally diseased flocks have not implicated Marek's herpesvirus, infectious bursal disease virus, or reoviruses (7). Broiler and SPF leghorn chickens injected with tissues from field cases have developed characteristic gross and microscopic lesions (3). In these birds, antibodies to REV or ALV did not develop and REV were not isolated, but six ALVs were isolated and grown in CEF resistant to ALV bearing the subgroup A envelope. However, only one of these isolates was identified by PCR of the CEF culture DNA as a subgroup J ALV. In a British study rare lesions termed "histiocytic sarcomatosis" were detected in meat-type chickens experimentally infected with HPRS-103 or related strains of subgroup J ALV at 1–2 days of age, but not in similarly infected leghorn chickens. Lesions were determined to be composed of a mixture of macrophages, dendritic cells, and lymphocytes (1). In Japan, broiler chicken carcasses condemned for suspicion of Marek's disease were determined after microscopic examination to contain multiple organs affected by proliferative lesions composed of spindle cells. Avian leukosis virus antigens were detected in these spindle cells and evidence of subgroup J ALV infection was detected by PCR (8, 9).

Gross Lesions

Spleens are enlarged 2–4 times normal and livers are enlarged (2×) normal size. Miliary (0.5–2 mm) white-to-yellow nodules are present throughout the spleen and liver. Similar 1–5 mm nodules are often visible in the kidney, but gross changes are rarely identified in the other organs. Some diseased birds are pale and are smaller than their flock mates (2, 4, 5, 6). Lesions are not accompanied by myeloid leukosis (myelocytomatosis) (3).

Histopathology

In the spleen, circular nodules of spindle-shaped cells diffusely expand periarteriolar lymphoid sheaths (Fig. 15.61). These histiocytic cells (denoting cells with abundant eosinophilic cytoplasm) contain elongated oval, fusiform, or more bizarrely configured nuclei (Fig. 15.62). Mitotic figures and individually necrotic cells are common in these nodules. The exact lineage of these cells has not been identified by specific markers although cells resemble fixed macrophages or dendritic cells. Multinucleated cells are not present. A few plasma cells, small lymphocytes, scattered lymphoblasts, and germinal centers are often present within nodules. Similar but often more heterogenous nodules diffusely stipple the liver, primarily replacing periportal hepatocytes and bulging into portal veins. Nodules also partially replace the bone marrow, kidneys, pancreas, proventricular glands, and lungs. There are diffuse accumulations of histiocytic cells under the mucosal epithelium of the proventriculus and in
15.61.   Nodules diffusely expand the splenic periarteriolar lymphoid sheaths. ×20
15.62.   Histiocytic spindle-shaped cells contain elongated and pleomorphic nuclei. ×200

the enteric mucosal lamina propria. In the duodenum these cells fill the lamina propria and may expand deep into the muscularis. Occasionally perivascular aggregates of lymphoblasts are present in the musculature of the ventriculus and in cardiac and skeletal muscle (4).

Diagnosis

Histopathology is currently the only method of diagnosis. Nodules are characteristic and are consistently found within specific locations in multiple organs (4).

Other Tumors of Unknown Etiology
Rodney L. Reece

Introduction

Standard veterinary texts dealing with general pathology or neoplasia rarely mention tumors of poultry, and the most comprehensive description of tumors of the domestic fowl remains that of Campbell (25), even though it is out of print. The purpose of this chapter is to provide an outline of the more commonly encountered tumors of unknown etiology of poultry. In this respect, much is owed to accounts by other veterinary pathologists (48, 63, 66, 81, 93, 106). Where relevant, reference is made to tumors in other avian species because their pathogenesis is expected to be similar to that of equivalent tumors in poultry, and there is a good morphological correspondence between many avian and mammalian tumors thus allowing some extrapolation of observations on mammalian tumors. As with mammalian species, the histologic appearance of avian tumors allows most to be classified according to their cell of origin. Detailed studies involving tinctorial charateristics with special stains, cytogenetics, immunohistochemistry, and electron microscopy are useful for more accurate classification, but such techniques are rarely applied to poultry tumors because of the lack of incentive and resources to investigate what are deemed to be incidental conditions discovered during investigations of flock problems.

Prognosis and treatment are not discussed in this chapter. In human and companion animal pathology immunoreactivity of tumors to various markers of cell type and function are undertaken as prognostic indicators and guides to appropriate therapeutic interventions. In avian medicine and particularly with regards to commercial poultry such studies are rare, but they are becoming more prevalent in companion bird medicine where there is a high individual monetary and emotional value, and a relatively long life for animals in good health. Specific staining reactivity with many monoclonal antibodies decreases significantly if tissue is held in fixative for more than 48 hours. Samples several days in transit to the laboratory and archival materials can yield uninterpretable, rather than negative, results. Additionally caution needs to be exercised in the interpretation of immunohistochemistry in avian species using antibody raised against mammalian proteins, and different antibody preparations intrinsically may have very different reactivities. Some tumors may lose specific immunostaining capacity due to anaplasia. In any test schedule appropriate positive and negative controls are necessary.

Some studies have successfully utilized antibodies to identify tissues in avian species, both neoplastic and normal: vimentin is found in most mesenchymal cells (11), desmin occurs in smooth and striated muscle fibers (11), cytokeratin, of which there are many types, in epithelial cells (99), actin in muscle fibers (110), neurone-specific enolase in neuroepithelial cells (79), anti-neurofilament-200 in nerve fibers (140), anti-myelin basic protein in Schwann cells (19), and in situ detection of hormones such as growth hormone (140). The S-100 protein family contains a number of related calcium-binding proteins and they are found in variety of tissues. Mammalian cutaneous melanocytes contain a large amount of S-100-A and S-100-B, and thus immunoreactivity is used as a marker of melanoma. In lower vertebrates the melanocytes appear not to contain epitopes recognized by some antibodies raised against mammalian S-100 (89). Additionally the range of tissues staining in avian species with antibody derived from mammalian S-100 appears to vary: antibody to S-100 protein did not stain nerve elements in white Pekin ducks (142) but did so in other avian species (89, 140).

The proliferative activity of a tumor may be defined by the number of mitotic figures per high power field in densely cellu-

lar types of tumors. More quantitative assessments can be made by other methods including immunohistochemistry using cell cycle specific monoclonal antibodies such as against proliferating cell nuclear antigen (PCNA). The amount of PCNA rises during the S-phase of cell division but the half-life of PCNA is shorter in cells that cycle compared to those that move into a quiescent state and interpretation needs to take that into account. A few studies of avian neoplasms have utilized PCNA (for example 99).

One of the best characterized tumor suppressor genes is p53. This gene encodes a nuclear phosphoprotein that regulates the movement of the cell through the cell cycle. Mutation of the p53 tumor suppressor gene is a common genetic alteration in human and other mammalian tumors. The monoclonal antibody PAb-240, which is specific for both mutant and wild types of mouse p53, cross-reacts with chicken p53 and has been shown to have over expression in virus-induced lymphomas in chickens (59). The role of p53 in other avian tumors has yet to be determined.

In the study of avian tumors, attention has been focused on those of viral etiology, both from the standpoint of their economic importance and as potential models applicable to tumors in humans (21). Tumors of the reproductive tract of laying hens, keratoacanthomas of broiler chickens, and amputation neuromas have been studied to some extent, but little research has been directed to the other neoplastic diseases of unknown etiology in poultry. The recognition of avian leukosis virus serotype J infection (see "Leucosis/Sarcoma") as a cause of what were traditionally considered non-virally induced tumors such as granulosa cell tumors, mesothelioma and pancreatic adenocarcinoma (111) may yet help to provide a greater understanding of tumor pathogenesis.

The incidence of non-virally induced tumors appears to be low, but properly constructed surveys are needed to clarify the situation. In a report of cage layers inspected at Irish abattoirs, the condemnation rate was 1.4%, of which one-fifth (0.3%) was due to nodules; 90% of the nodules were tumors and 70% (<0.2%) of these were adenocarcinomas, probably derived from the reproductive tract (145). A histological study of skin lesions in downgraded broiler carcasses concluded that accurate data required histological examination because changes observed grossly were not necessarily specific (46). Caution needs to be exercised in interpreting results of such surveys because early or small tumors are unlikely to be detected, organs such as the brain and the oviduct lumen are not routinely examined, and histological examination of the skin is rendered difficult because of processes at the abattoirs.

Official animal health surveillance in many countries has become more focused on early identification of notifiable diseases, detection of new and emerging diseases of possible animal and human health significance, identification of diseases or problems likely to compromise animal welfare, and monitoring of changes in selected endemic diseases which could effect efficiency and/or productivity of livestock. Combined with a move towards cost recovery, there has therefore arisen a significant disincentive to submit routine diagnostic material to government veterinary pathology laboratories. In the six months following the outbreak of high pathogenicity avian influenza in New South Wales, Australia 1997, many poultry were necropsied to determine the cause of death or respiratory distress. Three cases of oropharyngeal squamous cell carcinoma and one case of gizzard adenocarcinoma were observed (122). These birds were all noncommercial adults more than a year old from unrelated flocks and of different breeds. In the surveillance following the outbreak of virulent neurotrophic Newcastle disease virus in New South Wales, Australia, 1998–2000, the brains and tracheas of many poultry exhibiting nervous signs or found dead were examined histologically. These birds were predominately broilers and therefore of a relatively young age. A single slightly off mid-sagittal section of the brain and brain stem, and a single transverse section of the upper trachea, were histologically examined. Some of the samples submitted were of poor quality but were adequate for exclusion of Newcastle disease. Brain tumors were not observed. One enterprising veterinarian included a subcutaneous nodule from an unspecified site of a 5-week-old broiler that was diagnosed as a schwannona, and an unrelated 6-week-old broiler had a tracheal leiomyoma (122). In addition, two cases of cystadenoma involving the infra-orbital sinus were found in adult noncommercial poultry, one hen and one cockerel. These tumor types had not been observed previously at this laboratory, nor by the author elsewhere, nor since. As these types of tumors were present in the population but not previously detected, it would appear that the incidence of tumors of unknown etiology in the wider poultry population cannot be ascertained with any confidence by examination of records from passive surveillance.

The life span of commercially raised chickens and turkeys is generally short and may be less than that required for development of some non-virally induced tumors. The restricted information available on tumor incidence in older birds (the potential life span of chickens is generally considered to be around 15 yr but may be up to 35 yr) comes from several sources. The first is represented by long-term studies of flocks of aged chickens (51). The second is from diagnostic reports by veterinary pathologists, particularly of poultry maintained for periods of time longer than those of poultry kept under intensive conditions (134, 135). The third comes from necropsy reports from zoos where various species of birds often are maintained for natural life spans and are usually necropsied at death (30, 43, 78, 96, 98, 102, 118), and also from studies on other captive and wild birds (17, 34, 119, 125, 132). Reports of neoplastic diseases in the latter category have provided useful information, albeit not directly applicable to poultry. In particular, captive budgerigars (*Melopsittacus undulatus*) have a high incidence of tumors, although there is some evidence of retrovirus infection in this species, which could be partly responsible (64). The incidence of tumors in wild budgerigars is not known.

This chapter includes personal observations of spontaneous neoplasms in a U.S.A. flock of 466 specific pathogen free (S.P.F.) white leghorn hens, many of which were allowed to live out their natural life span (51); moribund and dead birds from an Australian S.P.F. flock; and field cases submitted for necropsy. The U.S.A. S.P.F. flock was free of clinical Marek's disease and exogenous avian leukosis virus, and the following tumors were diagnosed: 142 ovarian tumors (adenocarcinomas, granulosa cell tumors, and ovarian Sertoli cell tumors), 40 oviductal tumors

(adenocarcinomas and leiomyomas), seven pancreatic adenocarcinomas, and one case each of parabronchial adenocarcinoma, proventricular adenocarcinoma, hepatocellular carcinoma, cholangiocellular carcinoma, and mesothelioma (52). It is not certain, however, how applicable these rates of spontaneous neoplasms are to other breeds and strains of chickens, since this strain had a high incidence of genital tumors for which there is some genetic predisposition (see "Reproductive System"). The Australian S.P.F. flock was free of Marek's disease virus, exogenous avian leukosis virus, and reticuloendotheliosis virus and the following tumors were identified: two cases each of lymphomas, fibrosarcomas, and metastatic abdominal adenocarcinomas, and one case each of myelocytoma, reticulum cell sarcoma, histiocytic sarcoma, abdominal liposarcoma, subcutaneous lipoma, renal adenocarcinoma, granulosa cell tumor, and adrenocortical adenoma (121). In neither flock were these tumors associated with known oncogenic viruses.

There are reports of lymphoid tumors in S.P.F. chickens (37, 121), which indicates that on occasions, such tumors may be induced by factors besides known transforming viruses. Additionally, lymphomas are a common diagnosis in other avian species (97, 119, 150) and on occasions they have been inappropriately described as Marek's disease or lymphoid leukosis without direct evidence of involvement of transforming viruses. It would be preferable for such cases to be described in morphologic terms (for example lymphosarcoma or mixed cell lymphoma) rather than ascribing them a name denoting etiology. The older surveys and reports of poultry tumors cited in this review (22, 63, 81, 106) were published prior to the implementation of control programs for Marek's disease and lymphoid leukosis. After allowing for cases likely to have a viral etiology, the prevalence of other tumors was low, with the overwhelming majority being derived from the reproductive tract of adult hens. That situation still appears to prevail.

Public Health Significance

The tumors described in this section mostly occur at extremely low prevalence. The only exception is tumors of the female reproductive tract of adult hens and there is evidence that this may be related to selection for mature body weight and egg production (3): it is not related to use of female hormones. Contrary to the common urban myth commercial poultry are not treated with growth inducing or gender associated hormones and therefore there is no potential public health risk related to that. Tumors of the female reproductive tract are not present in commercially killed broiler chickens because of their young age. Advanced cases in spent layers and breeders are unlikely to enter the human food chain as the affected birds are not suitable for killing in abattoirs and/or the carcasses will be condemned. Hens with oviductal adenocarcinomas cease laying eggs.

Reproductive System

Ovary

The classification of gonadal tumors of poultry is complex and controversial. It is somewhat complicated because of a tendency for investigators to apply to avian species terms used in the description of mammalian, and particularly human, ovarian tumors. This ignores the dissimilarity between mammalian and avian ovaries in terms of histology, endocrinology, and physiology. Some authors have argued that avian gonadal tumors should be defined no further than gonadal tumors (for example 17) until a great deal more is known about them. This would solve some problems but create others. It is sometimes useful to consider ovarian tumors as being derived from surface mesothelium (adenocarcinomas); sex cord (granulosa-theca cell tumors and arrhenomas); germ cell (dysgerminomas and teratomas); or arising from connective tissue elements, other supportive tissues or as metastases from other sites or tissues (fibrosarcomas and lymphosarcomas). It should be noted that myxomas and fibromas of the ovary may, on gross examination, be mistaken for adenocarcinomas, and both fibrosarcomas and myxosarcomas can occur as metastatic abdominal tumors requiring histologic study to differentiate them from metastatic abdominal adenocarcinomas. Ovarian tumors have been described in turkeys (151), budgerigars (8) and other avian species (119). In hens, ovarian tumors are usually observed in birds more than 1 year old.

Adenocarcinoma

Early tumors are small, round, white, and firm nodules on the ovarian surface, which may be mistaken for atretic follicles. In advanced cases, these coalesce into a gray-white, firm cauliflower-like mass. Numerous transcoelomic implants are common at this stage, varying from small pearl-like growths to massive nodular tumors on serosal surfaces of the pancreas, oviduct, mesentery, and intestines. Ascites usually develops when such tumorous growth is extensive. The walls of affected intestines are thickened and adhered together, and the intestinal lumina become constricted. Metastatic abdominal adenocarcinomas may originate from either the ovary or the oviduct, and differentiation can be difficult, as in either case the ovary and the oviduct may be involved. Many cases of metastatic abdominal adenocarcinomas are described as ovarian adenocarcinomas without any serious attempt to determine their origin. Failure to detect tumor growth in the mucosal lining of the oviduct indicates that the tumor was not of oviductal origin and, therefore, probably arose from the ovary. For confirmation, frozen tissues can be stained immunohistologically for ovalbumin, which is only present in tumors arising from the magnum of the oviduct (72). Terminally hens are extremely thin and assume an upright, penguin-like position. Usually there are no maturing follicles in advanced cases, and the oviducts are inactive.

The cell of origin of these tumors remains to be identified but is frequently assumed to be the overlying mesothelium (so-called germinal epithelium) of the ovary or its invaginations into the ovarian cortex; alternatively they may be derived from thecal glands, interstitial cells, remnants of embryonic sex cords, or the mesonephros. The tumor may start in the theca externa of smaller follicles (Fig. 15.63), in the interfollicular stroma or occasionally fairly deep in the ovarian stalk. They often are multifocal in origin, but growth is fairly slow over a period of months. Ovarian adenocarcinomas are not associated with excess production of steroidal hormones (51).
15.63. Ovarian adenocarcinoma in the theca region demonstrating delicate trabeculae and round nuclei; note the granulosa cells and yolk of the developing ova (top). H & E, ×360.

15.64. Acinar structures, typical of ovarian adenocarcinoma filled with eosinophilic material and lined by cuboidal cells containing round nuclei with condensed chromatin and sparse eosinophilic cytoplasm. H & E, ×600.

15.65. Ovarian adenocarcinoma with papillary structures projecting into dilated acini. H & E, ×160.

15.66. Another form of ovarian adenocarcinoma with dense bands of stromal cells enclosing clusters of neoplastic acinar cells with intensely basophilic nuclei. H & E, ×160.

Histologically, the commonest structures comprising the ovarian adenocarcinoma are acini formed by a single layer of low columnar or cuboidal non-ciliated epithelium. These eosinophilic cells with basal, round nuclei are oriented around a lumen of variable size and shape, sometimes containing an intensely eosinophilic, homogeneous material that is periodic acid-Schiff (PAS)-positive and mucicarmine-negative (Fig. 15.64). Other tumors are more densely cellular, with the acinar structures compressed to give the appearance of islands or sheets of tumor cells, while in another variant, the lumen may be enlarged with infolding of the neoplastic lining forming papillary structures (Fig. 15.65).

The prevalence of mitotic figures varies from scant to abundant, although in most cases they are not prominent. Division of ovarian adenocarcinomas into medullary or scirrhous forms appears unwarranted, as size determines morphology; the acini of large tumors are interlaced with dense fibrous tissue (Fig. 15.66), whereas smaller tumors have a lesser component of fibrous tissue. Serosal implants may induce a proliferative response of smooth muscle in the underlying muscularis, but the extent of this varies (104). Ovarian adenocarcinomas similar to those seen in the chicken have been described in mature turkey hens (151).

Occasionally ovarian adenocarcinomas are found in ovaries covered with grape-like clusters of follicles filled with yellow fluid. Some of these are cystadenocarcinomas comparable to ovarian cystadenocarcinomas of mammals. In others the cystic spaces are lined by flattened stromal lacunae cells. In this context it is relevant to remember that the avian ovary has a well-developed anastomosing stromal lacunae system, the lining cells of which have phagocytic properties and resemble peritoneal lining mesothelial cells. These lacunae are not directly connected to the vascular or lymphatic systems but are actively involved in removal of burst ovarian follicle yolk and other fluid and thus may become involved in adenocarcinomas. Cystic ovarian follicles occur in other avian species and are not related to neoplasia (75). Large cystic acini lined by low cuboidal to squamous epithelium may be found in some cases of metastatic abdominal adenocarcinomas, and their lumina contain a PAS-positive mucinous secretion similar to that described above (25, 121). Ovarian myxomas occur and they may present with tenacious mucinous material exuding from the cut surface, but histologically they are quite distinctive.

Granulosa-Theca Cell Tumor

This tumor is yellow, round, and lobulated with an extremely friable consistency very different from the firm, cauliflower-like adenocarcinoma. Granulosa-theca cell tumors are encapsulated within a smooth, glistening membrane, and larger tumors have extensive areas of necrosis and hemorrhage. Tumors that are attached to the ovary only by a thin stalk may grow to enormous size, and metastasis to adjacent viscera occurs occasionally. Histologically these tumors are composed of pale, eosinophilic, polyhedral to fusiform cells with some cytoplasmic vacuolation (Fig. 15.67). The arrangement of these cells can be very variable even within a single tumor. They may form tubular, or less frequently, follicular structures (Fig. 15.68), separated by a delicate vascular stroma. In some cases there may be elaborate cylindriform or gyriform arrangements (Fig. 15.69), or typical rosettes of groups of a dozen or so epithelial cells clustered radially around small central spaces (Fig. 15.70). In others the stroma may be prominent. The proportion of mitotic figures varies but tends to be low, and the tumor appears to grow at a slow rate.

The tumor cells have been confirmed as granulosa cells because they have an ultrastructural component known as the transosome, which has been identified solely in avian follicular granulosa cells (77). Greatly elevated plasma concentrations of estrogen are found in hens with large granulosa-theca cell tumors (51). It is known that granulosa cells from mature follicles normally produce progesterone, whereas theca cells produce estrogen (112). This, coupled with the observation of numerous theca glands in granulosa cell tumors, justifies the binomial descriptor granulosa-theca cell tumor. The high concentrations of circulating estrogen result in the oviducts being similar in size to those of laying hens. Comb development is as for hens in lay, but eggs are not produced. The existence of separate ovarian thecal cell tumors such as those described by Campbell (25) still awaits further study. The presence of highly vacuolated theca-like cells may lead to the tumor being designated as luteinized and if this is excessive, the tumor may be referred to as a luteoma.

15.68.   Granulosa-theca cell tumor composed of a uniform population of tightly packed tumor cells with plentiful, pale eosinophilic cytoplasm and uniform, round vesicular nuclei. Note the mitotic figure (arrow). H & E, ×600.

Arrhenoma and Arrhenoblastoma

The terms arrhenoma and arrhenoblastoma may be applied in a morphologic sense to ovarian tumors with testicular elements, or in a functional sense, to encompass a diverse group of virilizing ovarian tumors. Sex reversal (virilism) in domestic fowls has been recognized since ancient times (50), but very few of such cases are due to ovarian tumors (25). It must be remembered that in avian species, contrary to the situation in mammals, the male
15.69. Gyriform arrangements of cells in one area of an ovary with a granulosa-theca cell tumor. H & E, ×90. (Courtesy of *Avian Pathology*)

15.70. Granulosa-theca cell tumor showing tubular arrangements and rosettes formed by clusters of cells radiating out from small central lumina. H & E, ×365. (Courtesy of *Avian Pathology*)

is the neutral sex and the female chick is demasculinized by her ovarian hormones (107). In the hen only the left ovary normally develops, but rudimentary male medullary tissue and primordial cells are present in the normal ovary (57). Surgical removal of the functional ovary leads to hypertrophy of the vestigial right gonad into an organ resembling an ovo-testis or testis, depending upon the age at treatment. The ovo-testis so formed has some areas of immature seminiferous tubules, but spermatogenesis is not normally a feature (20). Destruction of the left ovary by a non-steroid-producing tumor or other pathologic processes may result in the formation of a right ovo-testis. In studies of sex reversal in the fowl there is one well-documented case of an adult hen that laid eggs but subsequently developed ovarian pathology, underwent sex reversal, and was able to successfully fertilize eggs. However this was a case of tubercular oophoritis, not neoplasia (49). The opposite situation of feminization is very poorly documented (see "Sertoli Cell Tumor").

In this chapter the terms arrhenoma and arrhenoblastoma are reserved for those cases in which there is an ovarian tumor associated with some evidence of sex reversal (virilism). There are no reports on hormone production of these tumors in poultry, so it is not known if sex reversal is due to a lack of estrogens or the production of androgens. Arrhenomas are characterized by growth of seminiferous tubules within the ovarian stroma and appear as white, solid, lobulated masses within atrophic ovaries. They are of uncertain histogenesis and histologically are extremely variable. In the most differentiated form they are composed of branching cords of columnar epithelium, often two cell layers deep, which resemble immature seminiferous tubules. Spermatogenesis tends to be absent or poor. A loose or compact network of fusiform and epithelial cells arranged as cords, nests, rosettes, or incomplete tubules may be observed in less well-developed forms (Fig. 15.71). The interstitium may be prominent and contain nests of polyhedral lipoid-rich cells resembling Leydig cells. The seminiferous-like tubules can be filled with vacuolated cells (68). In large tumors there may be cystic cavitation and hemorrhage. Experimental induction of masculinizing arrhenoblastomas by injection of radioactive isotopes into the left ovary has been described (152). Arrhenomas may be mistaken for adenocarcinomas.

Gynandroblastomas are mixed steroid-producing tumors with estrogens produced by granulosa-theca cell components and androgens produced by arrhenomatous tissue.

Ovarian Sertoli Cell Tumors

In the five cases of ovarian Sertoli cell tumors reported by Fredrickson (51), obvious sex reversal was not apparent, and circulating hormone concentrations were comparable to those of non-laying hens. Compact masses of tubules developing multifocally under the ovarian capsule were seen histologically. Interstitial cells were variably present, and the well-defined tubules lined by a single layer of columnar epithelial cells with basal nu-

clei were considered to be Sertoli cells (Fig. 15.72). Some ovarian Sertoli cell tumors appeared to develop within granulosa-theca cell tumors.

Dysgerminoma

Wight (155, 156) detected four ovarian tumors in pseudohermaphrodites, and three of these were designated as dysgerminomas, the equivalent of ovarian seminomas. These were not associated with sex reversal, but rather with loss of external morphologic features of hens and acquisition of some male characteristics such as enlarged combs and male-type saddle feathers. These tumors are considered to originate from seminiferous elements within the left ovary or vestigial right gonad. Histologically they consist of elaborate fibrous trabeculae surrounding cords or groups of round or polygonal cells, and occasional syncytia.

Mesosalpinx

Leiomyoma

Leiomyoma of the mesosalpinx is a common tumor in hens. They are usually located centrally in the ventral ligament of the oviduct, an area normally rich in smooth muscle. Occasionally, leiomyomas may be found on the peritoneal surface of the oviduct or growing in the mesentery. They vary from small white nodules to large gray heavily vascularized masses several centimeters in diameter. This tumor is usually a single, sharply cir-

cumscribed, encapsulated, solid, round mass with a characteristic white, glistening appearance on the cut surface. They are benign and composed of interlacing bundles of smooth muscle separated into fasciculi by a variable component of fibrous tissue (Fig. 15.73). These tumors may be referred to as leiomyofibromas or fibroleiomyomas, depending upon which tissue predominates. Mitotic figures are rare. They appear to have little effect on the oviduct or its function, although they may predispose to ova escaping into the abdominal cavity. The prevalence of this tumor in different strains of S.P.F. and commercial hens varied from 0–60% at the end of their first year of lay (5). Affected hens had elevated concentrations of circulating 17-ß-estradiol (4) and a high incidence of these tumors was induced in a commercial white leghorn strain by treatment with both diethyl-stilbestrol and progesterone, thus confirming a role for these steroid hormones in tumorigenesis (5).

Oviduct

Adenocarcinoma

Most adenocarcinomas of the oviduct originate in the upper magnal portion of the oviduct, with occasional cases occurring in the infundibulum or uterus (shell-gland). Large focal and abdominal metastatic tumors are usually detected in hens more than 1 year of age. In a survey published in 1969 (60), the prevalence of oviductal adenocarcinomas in end-of-lay hens, determined by examining the mucosa of oviducts, varied from 5 to 81%. A positive correlation was found between tumor incidence, and mature body weight and egg weight (3). This indicates the possibility of an association with selection for egg laying, but properly constructed surveys need to be carried out. Metastatic abdominal adenocarcinomas observed at necropsy or abattoir inspection are but a small proportion of actual cases of oviductal adenomas and adenocarcinomas, and some such adenocarcinomas may be of ovarian origin. If the organ of origin is not readily determined, it would be preferable to refer to them as metastatic abdominal adenocarcinomas of unknown origin.

Studies of adenomas and adenocarcinomas of the magnum of the oviduct in domestic fowls and turkeys revealed a progression from focal dysplasia through sessile clusters to polypoid masses. The earliest lesions are small (2–10 mm in diameter) nodules on the ridges of the glands and may be found in laying hens at 30 wk of age. They are easily overlooked (143). Histologically these early nodules are composed of closely packed columnar cells with secretory granules in the apical cytoplasm and pale nuclei. The cells are oriented concentrically rather than toward the lumen (Fig. 15.74). These lesions are probably pre-neoplastic. Their incidence in commercial poultry is not known.

Individual or clustered sessile adenocarcinomas are gray and firm. They tend to coalesce into large, irregularly shaped tumors protruding into the oviductal lumen. Early lesions are found in hens with active ovaries, whereas abdominal metastases are associated with ascites and loss of bodily condition. In the primary tumor in the magnum there is generally a distinct boundary between neoplastic and normal glandular epithelial cells (Fig. 15.75). Malignant cells vary in the degree they maintain the normal glandular architecture of the magnum and amount of acidophilic secretory granules within their cytoplasm. Implants of acinar tissue are generally well-encapsulated (Fig. 15.76). In some cases cells are agranular and grow in solid sheets. However cytologic differences are not reflective of tumor invasiveness, since implants may be found that are composed of well-differentiated cells. The ultrastructural details of these tumors have been described (80).

Adenocarcinomas of the magnum are extremely malignant. Even when the primary tumor is quite small it may penetrate through the muscularis and spread through the abdominal cavity via tunnels between the celomic membranes to implant on the intestinal serosa, especially the pancreas and duodenum, because they lie deep in the ventral abdominal cavity (84). The muscularis underlying implants on the oviductal or intestinal serosa becomes hyperplastic and hypertrophied. Implants on the intestinal serosa are generally composed of small islands or acini of fairly anaplastic tumor cells encased in dense fibrous tissue (Fig. 15.77).
15.74. Dysplastic adenomatous focus in a fold in the magnum showing clear demarcation from surrounding normal glands. The columnar epithelial cells are densely packed and oriented concentrically. H & E, ×175. (Courtesy of *Avian Pathology*)
15.75. Magnal adenocarcinoma showing the well-defined margin between normal secretory tissue with cellular cytoplasm containing eosinophilic granules of ovalbumin (above) and very lightly granular tumor cells (below). H & E, ×600.

These are similar, both grossly and histologically, to those produced by ovarian adenocarcinomas, and the ovary itself is a frequent site of implantation. Sometimes metastases may be found quite deep in the ovary. Implants on the oviduct serosa frequently
15.76. Implant of magnal adenocarcinoma deep in the ovary showing capsule around adenocarcinomatous cells. Despite the apparent aggressiveness of this tumor, mitotic figures are not prominent. H & E, ×200.

lack intense cirrhosis (Fig. 15.78). Metastasis to the lungs and other viscera occurs via hematogenous emboli (84).

Immunohistochemical studies showed that these tumor cells contained ovalbumin (72) and retained their receptors for estrogen and progesterone (4). Adenocarcinomas of the magnum were estrogen responsive; their growth was maintained by potent estrogens and suppressed by anti-estrogens (3). Oviductal tumors similar to those found in chickens also have been described in turkeys (14) and metastatic abdominal adenocarcinomas, probably of oviductal origin, have been reported from many other avian species (119).

Testis

Teratoma
Teratomas are tumors containing multiple cell types arising from more than one embryonic layer. Involvement of the testes appears to be more common than that of the ovary (25, 76), despite more hens than cockerels being kept to sexual maturity. Teratomas also have been found in a number of other sites including the ovary, kidney, adrenal gland, spinal cord, pineal body, and eye (26, 66). They are generally round, yellow to white, encapsulated firm masses that sometimes contain cysts. Several types of teratomas are recognized. One type is composed of bone, cartilage, smooth muscle, nerves, fat, and/or melanocytes. In other types cysts are lined with columnar ciliated epithelium which, along with cartilage and smooth muscle, may form tracheal ring-like structures; additional structures and epithelial pearls formed by squamous

epithelium may also be seen. Another type of teratoma presents as a sac dilated with fluid and containing fully formed feathers (26). Teratomas that are attached to the spinal column in the lumbar area resemble dermoid cysts of mammals except for the formation of feathers rather than hair. Histologically the sac wall is lined by thin keratinized epithelium and fully formed feather follicles; there are erector pili muscles and nerves in the surrounding tissue. Spontaneous teratomas have been reported in waterfowl (18, 123) and may be induced experimentally by injection of metallic ions into the testes of young adult cockerels (69).

Sertoli Cell Tumor
Sertoli cell tumors have been described in the testes of Japanese quail (62) and budgerigars (119), but they appear to be rare in chickens (25). Grossly they appear as firm, nodular masses with varying degrees of necrosis, hemorrhage, and cyst formation. Histologically well-defined tumors are characterized by Sertoli-like epithelial cells with a large dense basally situated nucleus and basophilic cytoplasm, arranged in a palisading manner around the central lumina of tubules (Fig. 15.79). In other cases the tumor cells are arranged as lobules and sheets separated by delicate stromata. Mitotic figures are common. The number of interstitial cells between these tubules and islands is variable, and in some cases such cells may be vacuolated. In mammals Sertoli cell tumors may be associated with estrogen production and feminization. A case of feminization has been described in an incompletely surgically castrated cockerel wherein a Sertoli cell tumor arose from the gonadal remnants (133); and several examples of

demasculinization have been reported in budgerigars with Sertoli cell tumors (12). Feminization in avian species requires demasculinization by female hormones but hormonal studies in affected poultry have not been reported.

Seminoma
Seminomas are large unilateral tumors with a well-defined capsule and histologically are composed of loose sheets or compact cords interspersed with a delicate stroma (Fig. 15.80). The cells are large and round, containing a round-to-oval nucleus with prominent nucleoli (24). Occasional syncytia are noted and mitotic figures are numerous. Seminomas have also been reported in ducks, quail, and budgerigars (12, 53, 119).

Leydig Cell Tumors
Neoplastic Leydig cells may be a component of a seminoma. Leydig cell tumors are composed of large polygonal cells with eccentrically placed vesicular nuclei and granular acidophilic, sometimes vacuolated, cytoplasm arranged in irregular acini.

Digestive System
Alimentary Tract
Pharyngeal and esophageal squamous cell carcinomas in chickens have been described (1, 30, 122). A high incidence of this
15.81. Oro-pharyngeal squamous cell carcinoma in an adult non-commercial chicken. Cords and islands of epithelial cells with some central keratin pearls (arrow). Mucosal gland is shown at top left. H & E, ×200.

tumor has been reported in chickens from northern China, and humans in the same area also have a high incidence of esophageal carcinoma (27, 114, 131). In southern China a relatively high incidence of a homogenous group of squamous cell-derived carcinomas of the nose, mouth and pharynx of humans is associated with Epstein-Barr virus (109), but it has been proposed that there may also be a significant contribution of genetic predisposition, and environmental or ingested chemicals. Perhaps some similar factors are operative in the oro-pharyngeal squamous cell carcinoma of chickens. These tumors were composed of cords or islands of epithelial cells in the lamina propria and deeper tissues, with formation of some central keratin pearls. Superficial ulceration and infection was common (Fig. 15.81).

Papillomatous-like growths in the esophagus and crop of chickens have been reported, but their etiology and pathogenesis are not known (106). Internal papillomatous disease of psittacines, particularly macaws and Amazon parrots, often affects the cloaca. The lesions vary from irregular hyperplastic epithelial cells supported on a fibrovascular stalk extending from the lamina propria to poorly differentiated cords of adencarcinomatous tissue. A study in neotropical parrots revealed all cloacal papillomatoid lesions contained psittacine herpesvirus DNA but it was absent in the adjacent non-affected tissues: psittacine herpesvirus genotypes 1, 2 and 3 were identified in these lesions (139). Bile duct and pancreatic adenocarcinomas also tend to occur more frequently in psittacines with mucosal papillomas and similarly psittacine herpesvirus DNA was reported in these (138). No evidence was found of involvement of papillomaviruses in these cases. Herpes-like virus particles were observed in a cloacal papilloma of a conure (61). Cutaneous papillomatoid-like lesions in fish and marine reptiles are also associated with herpesvirus infections. Papillomatous nodules on the mucosa, skin and commisures of the beak associated with papillomaviruses occur in canaries (40), finches, African gray parrots and Cuban Amazon parrots (139). In such cases basophilic intranuclear inclusions may be noted in the hyperkeratotic proliferative epithelium. Small polypoid-like nodules are noted from time to time on the conjunctival mucosa of chickens and other birds, particularly towards the muco-cutaneous junction: they often overlie a prominent capillary bed and the epithelium is moderately hyperplastic and hypertrophied, and folded into small papillomatoid or polypoid nodules. The cases in poultry have not been studied in detail.
There have been several reports of adenomas of the crop, esophagus, proventriculus, and gizzard of birds (9, 26, 92, 119, 121). Adenocarcinoma of the gizzard has been observed in U.K. and U.S.A. broiler chickens (Fig. 15.82) (26), an adult hen (122) and other avian species (31). Guerin (66) described five epithelial tumors of the small intestine and one of the ileocecal junction, and cited several other reports of intestinal carcinomas in chickens. In these cases gross examination revealed papillary projections of tumor tissue into the lumen of the affected organ, sometimes with penetration of the muscularis by invading epithelial tissue, which formed acinar or cystic structures containing mucin. Solitary nodular adenocarcinomas of the intestinal mucosa of chickens also have been described (121, 147). Campbell (25) noted that reports of intestinal adenocarcinoma in the chicken should be viewed with caution, as such tumors can be difficult to differentiate from metastatic abdominal adenocarcinomas that arise from the reproductive tract and frequently implant on the intestinal serosa and infiltrate through the muscularis into the underlying mucosa and then proliferate there as a solid nodule.

Leiomyomas may be found in the muscularis of the gizzard or intestines (see "Musculoskeletal System"). In pheasants and peafowl pseudoneoplastic nodules of proliferating fibrous tissue in the cecal wall may be induced by larval stages of *Heterakis isolonche* (65). Enterogenous cysts derived from gastrointestinal tract mucosa have been described in chickens (87).
15.83. Hepatoma composed of large eosinophilic neoplastic cells, some in mitosis, forming irregular plates. H & E, ×600.

15.84. Cholangioma composed of dilated ducts in a loose fibrocytic stroma. H & E, ×75.

Liver

Hepatocellular Tumors

Spontaneous neoplasms of hepatocytes appear to be rare in chickens, and only occasional reports of either benign trabecular hepatocellular adenomas or anaplastic carcinomas have been published (25, 32, 106, 121). Typical hepatocellular adenomas grow in the hepatic parenchyma as a large, circumscribed, soft, yellow-gray mass. Histologically they are composed of polygonal eosinophilic cells about double the size of normal hepatocytes, forming thick, irregular cords lacking normal hepatic triad structures (Fig. 15.83). Mitotic figures are rare. Hepatocellular carcinomas are often multifocal nodules composed of sheets of basophilic neoplastic cells somewhat smaller than those in hepatomas and with numerous mitoses (115); metastasis to the lung may occur. Such tumors are similar to hepatocellular carcinomas induced with transforming avian retroviruses, most notably avian leukosis virus strain MC29 (13). A chicken hepatocellular carcinoma cell line was derived from a typical tumor induced by long-term parenteral treatment with diethyl-nitrosamine (85).

Hepatic tumors also have been reported in ducks (23) and appear to be inducible in this species with aflatoxin (29). Additionally hepatocellular carcinomas in ducks have been associated with duck hepatitis B virus (163). The incidence of hepatic tumors in Chinese ducks is high, ranging from 2 to 15%, with hepatocellular carcinomas being most common (95). The role of genetics, age, diet, and other environmental or virologic factors is not known. Hepatocellular tumors have been described in a variety of other avian species (119, 149).

Cholangiocellular Tumor

Tumors of the biliary system are not common in chickens. They are generally firm, demarcated from normal hepatic parenchyma, and yellow-gray in color. The histology varies according to the degree of malignancy. Cholangiomas are composed of clearly recognizable but enlarged tubules resembling distorted bile ducts, interspersed with fibrous connective tissue (26, 52, 121) (Fig. 15.84). In cholangiocarcinomas duct formation is irregular
15.85. Cholangiocarcinoma composed of small clusters of epithelial cells in a fibroblastic stroma. H & E, ×190.

and the connective tissue is fibroblastic (Fig. 15.85). Infiltration between hepatic cords is aggressive. These tumors of bile ducts need to be differentiated from chronic hepatotoxin induced bile duct proliferation that is often accompanied by fibrosis and distorsion of hepatic architecture. Cholangiocellular tumors have been described in pigeons (153) and other birds (113, 149).

Pancreas

Adenocarcinoma

Tumors of the pancreas are difficult to differentiate from metastatic abdominal adenocarcinomas derived from the ovary or oviduct, that frequently implant on the serosa of duodenal loop and pancreas and then invade the pancreas. There can be absolute
15.86. Pancreatic adenocarcinoma, probably of ductule cell origin, composed of columnar cells forming tubular structures among a few remnant acinar cells (arrow). ×160.

15.87. Pancreatic acinar cell adenocarcinoma with normal exocrine tissue (right) and agranular neoplastic cells (left). H & E, ×600.

15.88. Mesothelioma with prominent neoplastic epithelial cells supported on a delicate stalk. H & E, ×600.

certainty of a pancreatic primary tumor only in absence of ovarian or oviductal involvement, as in the case of the male Guinea fowl reported by Okoye and Ilochi (105). Extensive metastatic implants to the serosa of the duodenum and proventriculus, and the hepatic capsule can occur, but the ovary is not involved. Most pancreatic adenocarcinomas probably originate from ductal epithelium, not acini. They are composed of tubular structures lined by columnar epithelial cells with lightly basophilic cytoplasm (Fig. 15.86). The basal nuclei are round to oval, and mitotic figures are prevalent. In one case observed by Fredrickson and Helmboldt (52), the tumor appeared to arise from exocrine tissue, rather than ducts, because a clearly defined transitional zone between normal acini and tumor tissue could be distinguished. The large neoplastic cells had extremely vesicular, round nuclei, and cytoplasm contained a variable number of the same deeply eosinophilic granules typical of normal acinar cells (Fig. 15.87).

Peritoneum

Mesothelioma

Mesotheliomas have been reported in chickens (66, 106), ducks (94), a hawk (35), and ratites (119). In this tumor both the surface lining the mesothelial cell and the underlying connective tissue are involved. One case in a S.P.F. hen was described by Fredrickson and Helmboldt (52); the abdominal cavity contained about 200 mL of milky fluid and the serosal surfaces were covered by glistening, gray cystic structures. Histologically these were composed peritoneal cells supported by thick connective tissue stromata that formed the walls of the cysts and are projected into these papillary (Fig. 15.88). Mitotic figures were rare, but tumor growth was extensive.

Urinary System

Renal adenocarcinomas (nephromas) and nephroblastomas may occur as spontaneous neoplasms in chickens, but they are inducible with avian leukosis virus and are described elsewhere in this book (see "Leukosis/Sarcoma Group"). Renal adenocarcinomas are common in budgerigars (103), but their etiology is not known.

Respiratory System

Infra-orbital Sinus

Adenoma

A hen and a cockerel from unrelated noncommercial free-ranging poultry flocks were presented with single pea-sized cysts (single in the hen, two in the cockerel) underneath the eye. The cysts were well-encapsulated, extended into the infra-orbital sinus and exuded mucinous material when cut. They were composed of cuboidal epithelial cells arranged as acini with fluid filled lumina: mitotic figures were rare (122).
15.89. Adenocarcinoma of lung composed of papillary growth of epithelial cells that have replaced most of the normal lung. H & E, ×200.

Lung

Adenocarcinoma

Tumors of the respiratory tract of poultry are rare, with Campbell describing only three cases of pulmonary adenocarcinomas in domestic fowls (25). Ducks appear to be more prone than other avian species to pulmonary tumors, as there are several reports of naturally occurring pulmonary adenocarcinomas in ducks (96, 164) and a variety of lung tumors were induced in Pekin ducks given a chemical carcinogen intratracheally (124). Stewart (137) described 20 cases of pulmonary adenocarcinomas or adenomatosis in birds, including 11 in ducks. Most of these cases appeared to originate from the bronchial epithelium. Adenocarcinomas of magnum of the oviduct and other tumors (rhabdomyosarcomas, myxosarcomas, and fibrosarcomas) can metastasize to the lungs of domestic fowl (121), and such tumors need to be differentiated from adenocarcinomas arising from within the lungs. The case described by Fredrickson and Helmboldt (52) clearly arose multifocally from parabronchi and resembled papillary adenocarcinomas as described by others (6, 137). In that case cuboidal epithelium formed distorted bronchial-like tissue often containing eosinophilic material (Fig. 15.89). Widespread and distant metastases in the thorax and abdomen attested to the extreme malignancy of this tumor.

Nervous System

Central Nervous System

Astrocytoma

Sporadic cases of astrocytoma have been described (15, 82, 83, 121). Wight and Duff (158) investigated a small epizootic affecting 20 birds out of a flock of 1000, of which 13 were examined histologically. Adult birds are usually affected, and all five cases examined by the author (121) were in aged noncommercial hens. Clinical signs include transitory torticollis, retropulsion, and incoordination. Astrocytomas are frequently multiple, unencapsulated small nodules, usually located in the base of the cerebellum or underlying rostral brain stem. Although each tumor is small,
15.90. One of several clearly demarcated but unencapsulated astrocytomas composed of fibrillar astrocytes, in anterior brain stem. There is a significant lymphocytic infiltrate around the blood vessels within the tumor and the adjacent tissue. H & E, ×100. (Courtesy of *Avian Pathology*)

usually no larger than 5 mm in diameter, they may be seen without difficulty, especially in fixed tissues, as sharply delineated whitish masses. There is frequently a marked perivascular reaction of lymphocytes bordering the tumor, but no hemorrhage, giant cells, or areas of pressure necrosis (Fig. 15.90). The neoplastic cells vary considerably in morphology, but are mainly polygonal with extended cytoplasmic fibrillar processes (Fig. 15.91): these processes can be enhanced with phosphotungstic acid hematoxylin stain. Astrocytomas need to be differentiated from reactive gliosis induced by migrating parasites.

Wight and Campbell (157) reported finding an ependymoma and two meningiomas in chickens. The former was a growth in the lateral ventricles of palisaded or rosette-forming, vacuolated cells, while the meningiomas were of the angioblastic variety composed of vascular sinuses lined with plump endothelial cells associated with a dense network of reticulin. Several ependymomas and a choroid plexus papilloma were identified in the brains of budgerigars, and found to be S-100-protein positive (140).

Pineal Body Tumor

There are several reports of avian pineal body tumors (25, 119, 121, 144, 160). Swayne *et al.* (144) used several criteria to differ-
15.91.   Astrocytoma composed of uniform astrocytes with extended cytoplasmic processes. H & E, ×190.

15.92.   Lobules of a pineal body tumor separated by fine trabeculae. Palisaded low columnar epithelial cells with large vesicular nuclei are arranged around a small lumen, and these cells are surrounded by smaller parafollicular cells. H & E, ×200. (*Avian Pathology*)

entiate pineal body tumors from hyperplasia: in tumors, the pineal body was greatly enlarged, impinged on the adjacent cerebellum, and mitotic figures were present in the epithelial cells. There may be clinical signs such as fine tremors and head pressing, and a large encapsulated mass can be found between the cerebellum and the cerebrum, often impinging onto or even embedded into the cerebellum. The tumor is composed of lobules of epithelial cells comprising low columnar cells arranged in a palisading manner around a lumen, and there are abundant parafollicular cells with dense nuclei, separated by fine trabeculae (Fig. 15.92).

Peripheral Nerves

Schwannoma

Tumors of the Schwann cells or perineural cells of peripheral nerves are preferably called Schwannomas, although often they are designated as neurofibromas, neurilemmomas, or neurogenic sarcomas; differentiation between these is difficult and they are best considered together. Campbell and Appleby (26) reported 39 tumors of the nerve sheath in broiler chickens and reviewed 17 other cases, of which some were in adult birds. They are generally benign localized tumors forming white nodular or fusiform growths, most often in the region of the dorsal root ganglia. The tumor cells are spindle shaped with a small central nucleus, and usually they form concentric whorls reminiscent of nerve sheaths (Fig. 15.93). Multiple nodular tumors have been reported (2), including a congenital case (26). Tumors described as neurilemmomas had cells arranged in a palisading manner with occasional structures resembling Wagner-Meissner tactile corpuscles (25). Tumors resembling Schwannomas should only be so designated if the nerve of origin is identified or they can be confirmed as being of Schwann cell origin (19); otherwise they are best described as fibrosarcomas to avoid confusion. Some cases of Schwannomas resemble hemangiopericytomas.

Neuromas

Amputation of the tip of the beak of juvenile chickens, turkeys and other poultry, and partial amputation of the hallux of male broiler breeders, may result in the formation of neuromas (54, 55). In neuromas there is a nodular or diffuse thickening due to proliferating nerve bundles within a dense collagenous matrix. The pathogenesis is similar to post-traumatic neuromas of domestic mammals and humans where a regenerating nerve stump encounters an obstruction such as dense fibroblastic scar tissue and cannot re-innervate normal dermal tissue so it proliferates as a tangled mass of axons, Schwann cells and associated connective tissue (Fig. 15.94). The axons can be identified by staining with Holme's silver method, but they are thinly myelinated. Technically these are an abnormal regeneration rather than neoplasia. Partial beak amputation of the beak in young chicks results in loose dermal scar tissue and that is probably the reason they are not prone to neuroma formation (38). Compared with chickens, partial beak amputation of turkeys also appeared to be associated with less dense scar tissue and neuromas did not form (56).
Melanoma

Melanocytes are derived from the neural crest. Thus, melanomas are considered under tumors of neural tissue. Melanosis is common in many avian species, and breeds of chickens such as silkies
15.93. Schwannoma of the sciatic plexus showing concentric whorling pattern of spindle-shaped cells with central nuclei. Note the mitotic figure (arrow). H & E, ×400.

have numerous foci of melanocytes especially in gonads, peritoneum, perineurium, and periosteum. Campbell (25) reviewed a number of cases of melanoma and noted that malignant forms may arise in the ovary and metastasize throughout the abdominal cavity. The eye also can be a primary site of melanomas (42). Malignant melanomas have been observed in ducks (39, 58, 119), a cormorant (89), and budgerigars (128). Melanomas with varying degrees of melaninization occur in the subcutis of racing pigeons (117, 122), and multifocal melanomas have been observed, although rarely, in chickens (121): in such cases mitotic figures are infrequent. As in mammalian species the morphology of the cells in avian melanomas vary from fusiform to elongate and pleiomorphic, and they may be arranged as discrete foci, as infiltrates into the surrounding tissue, or as more superficial small islands of closely packed melanocytes reminiscent of epithelial tissue (Fig. 15.95). Excess melanin can be bleached from sections using various techniques, such as with H_2O_2, to reveal occasional multinucleated cells and numerous mitoses. Melanin granules may be sparse, and in such cases, the brown pigment can be enhanced with ammoniacal silver techniques such as modified Masson-Fontana stain. The D.O.P.A. (L-3,4-dihydroxyphenylalanine) test can be used on unfixed relatively amelanotic melanomas to detect the presence of tyrosinase, a necessary enzyme in the biosynthesis of melanin and other substances. The S-100-protein family contains a large number of related calcium binding proteins found in mammalian dermal melanocytes and other cells such as nervous, lymphoid and endothelial tissues. Therefore S-100-protein immunoreactivity is considered a useful marker of mammalian melanomas, however, limited studies have revealed that the range of tissues which reacted in avian species, represented by the duck, was somewhat different to that in mammalian species (142). A melanoma in a cormorant was S-100-protein negative but the adjacent peripheral nerve bundles were positive (89).

Special Senses

Eyes

Ocular tumors besides lymphomas and myelomas are rare in birds. The avian iris muscle is striated and intra-orbital rhabdomyosarcomas were detected in juvenile and subadult chickens (42). Cole (33) described a retinoblastoma. Melanomas and teratomas may also involve the eye. Osteosarcomas may originate in the orbit, but these need to be differentiated from intra-ocular ossification, a not unusual sequellae to progressive retinal degener-
15.95. Subcutaneous melanoma of the wing of a pigeon. There is melanin pigment in many polyhedral cells. Mitotic figures are rare. The cells are densely packed, clearly demarcated from the surrounding tissue, and penetrate between muscle fibers and adipocytes as shown at lower right. H & E, ×200.

ation (86) or chronic intra-ocular infections such as toxoplasmosis (148).

Endocrine System

Thymus

A few thymomas, as distinct from thymic lymphomas, have been reported in chickens (26, 47, 66, 106), a duck (162), a budgerigar (165), and a Java sparrow (99). They are characterized by replacement of the normal thymic architecture with sheets of large polyhedral epithelial cells interspersed with variable numbers of lymphoid cells. No structural pattern is obvious, although there may be poorly defined lobules. The vesicular nucleus and abundant pale-staining cytoplasm of the epithelial cells contrast with normal lymphocyte morphology. The borders of the neoplastic cells are indistinct but may show squamous differentiation. The epithelial origin of these cells was confirmed by immunostaining for cytokeratin (99). Aggregates of cells resembling Hassall's corpuscles are sometimes mixed among the tumor cells.

Pituitary Gland

Pituitary adenomas have been reported in budgerigars (10, 129, 140), and although frequently cited as common, the true incidence in this species is not known: the 50 cases described by Schlumberger were solicited from throughout U.S.A. by targeted advertisements (129). Campbell (25) reported two pituitary adenomas in domestic fowls. None were seen by Fredrickson and Helmboldt, although pituitary glands were examined in several hundred aged hens (52), nor were any seen in the brains of many chickens or other birds showing neurologic signs, which were examined histologically by the author (74, 120, 122).

Adrenal Gland

The avian adrenal gland has an intermingling of inter-renal (cortical) and enterochromaffin (medullary) tissues and tumors can arise from either. Campbell and Appleby (26) recorded a single case of an adenoma they considered was most likely derived from the adrenal gland, and an adenoma involving the adrenal gland was seen in an adult S.P.F. hen (121). These adrenal adenomas were composed of well-differentiated cells with abundant eosinophilic cytoplasm, but there were no particular histologic characteristics that would allow definitive confirmation that these tumors were derived from adrenal tissue. Similar tumors have been described in other avian species (119). An adrenal tumor in a budgerigar was studied ultrastructurally, and cytoplasmic granules consistent with those in adrenal medullary tissue were observed thus meriting the tumor's description as a pheochromocytoma (71).

Thyroid and Parathyroid Glands

Guerin (66) described an adenoma arising in the parathyroid gland of a chicken and pointed out that only one other case of parathyroid carcinoma had been reported in chickens. Tumors of the thyroid gland in poultry appear to be extremely rare (25, 106). Naturally occurring goiters have been reported in chickens (66), and were induced in chickens and quail by feeding rapeseed meals containing goitrogens (159). Goiters also occur in budgerigars, probably as a consequence of low iodine intake (16, 119). In budgerigars neoplasia of the thyroid gland may be difficult to differentiate from hyperplasia and dysplasia associated with goiter; however, in the thyroid adenomas reported by the author (119), there were discrete areas of neoplastic adenomatous tissue. A mixed cell tumor of the thyroid gland was composed of adenomatous tissue and islands of proliferating chondrocytes and fibroblasts.

Integument

Subcutis

Soft tissue tumors such as fibromas, fibrosarcomas, myxomas, and myxosarcomas are encountered in the subcutis of chickens and may be induced by avian leukosis virus (see "Leukosis/Sarcoma Group"). Occasional cases are reported in S.P.F. poultry and other species. Myxomas and fibromas were observed on the rostral extremity of the upper trimmed beaks of hens (121). The etiology of these was not determined but it was postulated that they may have resulted from retrovirus-induced transformation stimulated by local injury.

Hemangiopericytoma

A few hemangiopericytomas in the subcutaneous tissue of chickens have been described (52, 134). All of these were benign tumors occurring as subcutaneous nodules of variable size, usually in the cervical region. The nodules were dense, white, well-delineated, and firmly embedded in the subcutis. The histologic appearance was of uniform spindle-shaped cells possessing a fusiform nucleus with diffuse chromatin, and abundant cytoplasm but indistinct cell borders. They were arranged in a concentric manner around central blood vessels, and the intervening reticulin fibers could be readily demonstrated by a silver stain (Fig. 15.96).

15.96.   Hemangiopericytoma with concentric rings of pericytes clearly defined. Silver, ×90.

Lipoma and Liposarcoma

Subcutaneous lipomas in mammals often arise at sites of trauma, but they are not common in chickens (25). However subcutaneous and intra-abdominal lipomas are frequently encountered in other avian species, especially psittacines (90, 119). They are generally encapsulated, benign, delicately trabeculated tumors with variable degrees of necrosis and hemorrhage. They are composed of mature adipocytes with large cytoplasmic vacuoles and a displaced pale nucleus. Mitotic figures are rare. Malignant liposarcomas of chickens are rare and may be locally invasive or metastasize (101, 121). They may be similar in histologic appearance to fibrosarcomas except for intracytoplasmic fat vacuoles within tumor cells. In other cases the tumor may be composed of obviously immature adipocytes. Multifocal liposarcomas have been described in other avian species (41, 119).

In other avian species as well as in humans and other mammals a variation of lipoma known as myelolipoma or erythrolipoma is reported. This presents as a well-delineated benign mass with foci of myelopoietic and/or erythropoietic elements embedded in adipose tissue corresponding to bone marrow but in an abnormal location. They have been recorded in the subcutaneous tissue of the limbs or liver (91). They need to be differentiated from extramedullary erythropoiesis and/or myelopoiesis.

Cutis

Squamous Cell Carcinoma

The tumor of broiler chickens commonly referred to as dermal squamous cell carcinoma, in some aspects the avian equivalent of a keratoacanthoma, is dealt with elsewhere in this book. A true squamous cell carcinoma is a malignant tumor of keratinocytes and forms irregular masses or cords that proliferate downward and invade the dermis and subcutis. It is characterized by aberrantly located dermal epithelial cells with intercellular bridges resembling the stratum spinosum. There is no cushion of basal cells and the epithelial tumor cells lack orderly maturation, although some keratinization usually is found. These tumors are associated with an intense mononuclear inflammatory cell infiltrate and a reactive fibroplasia. Squamous cell carcinomas are locally invasive, but may be slow to metastasize. There are only a few reports of true dermal squamous cell carcinomas of chickens in the literature and most of these affected the scaly skin of the shanks and lower feet of adults (25, 28, 141). Several cases of squamous cell carcinoma involving the oropharynx of chickens have been reported (see above). In other avian species dermal squamous cell carcinoma may involve the uropygeal gland and these need to be differentiated from impaction, trauma and/or uropygeal adenocarcinomas (130).

Feather Folliculoma

Feather folliculomas are usually multiple cystic structures with central lumina containing keratinized debris and feather remnants. They are lined by cuboidal to squamous epithelial cells with abrupt keratinization, and areas of disorganized feather follicle epithelium. There is usually an intense inflammatory cell infiltration into the surrounding dermis and some fibrosis (Fig. 15.97). Feather folliculomas of chickens (121) and turkeys (36) have been described, and they are common in some caged birds such as Norwich canaries (108).

Intracutaneous Keratinizing Epithelioma

These are a benign cystic tumor of the facial skin of adult chickens. They present as multiple small well-encapsulated nodules with a central craterous pore (121). They are lined by well-developed stratified epithelium consisting of basal cells progressing to maturation with prominent intercellular bridges in the stratum spinosum. The lumina contain lamellated keratin but no feather remnants (Fig. 15.98). They are surrounded by a small amount of fibrous tissue and there is little inflammatory cell reaction unless there is rupture of the wall. These tumors are probably derived from keratogenous cysts and are distinct from both keratoacanthomas of broilers and feather folliculomas.

Other Tumors of the Cutis

Hard, horny, papillomatoid tumors of the scale-producing epithelium of the shanks, with heavily keratinized whorls, are acanthomas (25). Uropygeal adenomas may arise from the preen (uropygeal) gland situated dorsal to the base of the tail in the chicken. Papillomatous-like lesions on the footpads of French ducks were reported but not described in detail, and an association with papillomatous lesions in abattoir workers was postulated (67); their etiology was not determined. Acanthotic and hyperkeratotic lesions found on the footpad of a duck were associated with herpesviruses (161), but the relationship of that to other footpad neoplasms, such as those described elsewhere (see "Chondroma and Chondrosarcoma") is not known.

Xanthomas are yellow subcutaneous nodules sometimes found in gallinaceous and psittacine birds, often overlying lipomas. They are composed of lipid-laden macrophages, giant cells, free cholesterol and fibrous tissue: they are not true tumors. Multiple xanthomas were noted in chickens in the U.S.A. in the 1950s, possibly due to a reaction against feed contaminant metabolites accumulating in subcutaneous fat (126).

Multiple small firm white nodules in the skin of a hen were found to be cutaneous mast cell tumors. The round to oval cells, with hyperchromatic nuclei and a prominent chromatin ring, were arranged as sheets interspersed by dense collagen bundles. The cytoplasm contained distinct metachromatic granules that on ultrastructure were considered typical of avian mast cells. There were metastases to the lung (70).

A basal cell carcinoma in the neck of a parrot consisted of lobules and nests of polygonal cells lacking intercelluar bridges. There was a tendency at the edge of the nests to form a palisade-like pattern reminiscent of feather barbs (146).

Atypical pox lesions of the feathered areas of broiler chickens may mimic dermal squamous cell tumors (44), and some skin lesions may be a combination of both dermal squamous cell carcinoma and cutaneous pox (45). Note that in the older literature atypical pox referred to poxvirus infection of the larynx and trachea. Nodular cutaneous wart-like, papular or deep craterous nodular lesions of feathered regions have been observed in association with poxvirus in several avian species, including pigeons, canaries (73, 117, 122) and flamingos (7). In these lesions pox inclusions are abundant within the cytoplasm of the superficial epithelial cells of hypertrophied and hyperplastic adnexal structures such as feather follicles that are penetrating deep into the dermis. These lesions tend to persist for a long period and are frequently biopsied for investigation of suspect neoplasia.

Musculoskeletal System

Leiomyoma and Leiomyosarcoma

Leiomyomas of the ventral ligament of the oviduct are common in laying hens (see "Reproductive System"), and equivalent tumors in other sites are histomorphogically similar. Leiomyomas were observed by the author in the intestinal wall of a commer-
15.99.   Leiomyoma of the trachea of broiler chicken. Bundles and whorls of smooth muscle fibers in the lamina propria as shown in upper portion and penetrating between the cartilagenous rings and into the adjacent adventitia (lower right). H & E, ×100.

cial duck and a freckled duck (120), in the gizzard musculature of a chicken (121), in the tracheal ring of a broiler (122) (Fig. 15.99), and attached to the pancreas of pigeons (119). There are a few reports of leiomyosarcomas involving the intestinal wall (2), ovary (81), and tracheal muscle (26) of chickens. Leiomyomas and leiomyosarcomas are rare in other avian species (119, 127, 136).

Rhabdomyosarcoma

Rhabdomyosarcomas tend to be soft, poorly encapsulated and prone to necrosis and hemorrhage. The pectoral and sartorius-gracilus muscles were commonly involved, and also the heart (26). Metastases to the lung have been reported (88, 121). Histologically there are irregular bundles of interlacing cells, some of which exhibit a typical racquet or star shape, and multi-nucleated cells (Fig. 15.100). The cytoplasm is intensely eosino-philic, but cross striations are difficult to detect with either polar-ized light or phosphotungstic acid stain (25, 106). They also have been described in budgerigars (90, 119).

Osteoma and Osteosarcoma

Osteomas and osteosarcomas are uncommon tumors of poultry (25). Campbell and Appleby (26) described two osteomas, eight osteosarcomas, and one osteoclastoma in broilers, and similar tu-mors have been reported in other avian species (110, 119). Osteosarcomas may be composed of abundant mineralized tra-becular bone, although in some cases there may be a much more cellular tumor composed of spindle-shaped cells and poorly min-eralized trabeculae. Even in such cases, some foci of ossification usually can be found. Osteosarcomas may metastasize to the lungs. Multipotent mesenchymal tumors usually occur on the ex-tremities of long bones and contain solid masses of dysplastic bone, islands of cartilage, dense drifts of fibrous tissue and foci of myxomatous tissue. These are frequently described as os-
15.101.   Osteoma showing thick irregular trabeculae. H & E, ×90. (Courtesy of *Avian Pathology*)

teosarcomas. Osteomas are well-circumscribed and composed of disorganized bony trabeculae (Fig. 15.101). A tumor with both osteoid and cartilagenous elements involving the tracheal rings of a lovebird has been described (154).
15.102. Multifocal chondroma of the footpad of a goose showing lobules of cartilage separated by fibrovascular trabeculae. H & E, ×75. (Courtesy of *Avian Pathology*)

Chondroma and Chondrosarcoma

Chondromas of poultry are rare. Multifocal chondromas of the plantar aspect of the footpads of nine geese, ducks, and other anseriformes, and other mesenchymal tumors (3 myxomas and an osteoma) in the footpads of other Anseriformes were described by the author (119). The etiology of these was not determined, but approximately 10% of two flocks of wild mallards were affected. The chondromas were characterized by lobules of chondrocytes separated by trabeculae (Fig 15.102).

II Bacterial Diseases

Chapter 16
Salmonella Infections

Introduction
Richard K. Gast

Infections with bacteria of the genus *Salmonella* are responsible for a variety of acute and chronic diseases in poultry. These diseases continue to cause economically significant losses in many nations and absorb a large investment of resources in testing and control efforts in others. Infected poultry flocks are also among the most important reservoirs of salmonellae that can be transmitted through the food chain to humans. Poultry producers are faced with intensifying pressures from public health and regulatory authorities to protect consumers from illness transmitted by contaminated poultry meat and eggs. Poultry and poultry products are consistently among the leading animal sources of salmonellae that enter the human food supply. This circumstance is partly due to the high prevalence of *Salmonella* infections in poultry, but also reflects both the immense numbers of commercially raised chickens and turkeys and the application of extensive and active programs for identifying infected poultry flocks and products. The increasingly international scope of the modern poultry industry has created new and more complex opportunities for the spread of *Salmonella.*

The genus *Salmonella* (of the family Enterobacteriaceae), named for USDA veterinary bacteriologist Daniel E. Salmon (1850–1914), consists of more than 2500 serologically distinguishable variants (or serovars) that are frequently named for the place of initial isolation. Although recent taxonomic refinements have indicated that all salmonellae associated with poultry are members of a single genetically defined species—*Salmonella enterica*—the distinctions between the various serovars of *Salmonella* are often epidemiologically significant. Accordingly, *Salmonella* isolates are still most often described by reference to their traditional serotype nomenclature.

Infections of poultry with salmonellae can be grouped into three categories, each of which is the subject of a separate section of this chapter. The first section discusses infections with the two nonmotile serovars, *S.* Pullorum and *S.* Gallinarum*,* which are generally host-specific for avian species. Pullorum disease, caused by *S.* Pullorum*,* is an acute systemic disease of chicks or poults. Fowl typhoid, caused by *S.* Gallinarum*,* is an acute or chronic septicemic disease that most often affects mature birds. Both of these diseases have been responsible for serious economic losses to poultry producers in the past, and have been addressed by the implementation of extensive testing and eradication programs.

The second section of this chapter discusses infections with the numerous motile and non-host-adapted *Salmonella* serotypes referred to collectively as paratyphoid salmonellae. Found nearly ubiquitously in wild and domestic animals, this diverse group of serotypes is principally of concern as a cause of food-borne disease in humans. Although paratyphoid infections of poultry are very common, they seldom cause acute systemic disease except in highly susceptible young birds subjected to stressful conditions. More often, paratyphoid *Salmonella* infections of chickens and turkeys are characterized by asymptomatic and sometimes persistent colonization of the intestinal tract and internal organs, potentially leading to contamination of the finished carcass. Some serotypes, especially *S.* Enteritidis*,* can be deposited in the contents of clean and intact eggs laid by systemically infected hens. Because there are so many potential sources of introduction of paratyphoid salmonellae into poultry flocks, effective strategies for controlling these organisms require the combined and sustained implementation of a comprehensive set of risk reduction practices throughout the production continuum.

The third section of this chapter discusses infections with *S. enterica* subspecies *arizonae,* a motile serotype which was formerly designated *Arizona hinshawii.* This organism, although biochemically distinct, causes an acute septicemic disease that is not clinically distinguishable from other *Salmonella* infections. Arizonosis has re-emerged as an economically significant disease of young turkeys in recent years.

Pullorum Disease and Fowl Typhoid

H. L. Shivaprasad and P. A. Barrow

Introduction

Pullorum disease and fowl typhoid in terms of history, clinical signs, epizootiology, lesions, and control and eradication procedures have many similarities. However, differences have been reported for these two diseases, and they are caused by different species of bacteria (i.e, *Salmonella* Pullorum and *S.* Gallinarum, respectively). Recently, these two bacteria have been placed in a single species. *S. enterica* subsp. *enterica* serovar Gallinarum-Pullorum, but debate continues as to whether they are single or different taxa within the same serovar.

Pullorum disease (PD) and fowl typhoid (FT) are septicemic diseases affecting primarily chickens and turkeys, but other birds such as quail, pheasants, ducks, peacocks, and guinea fowl are also susceptible. Both diseases can be transmitted through the egg by transovarian infection. *S. enterica* subsp. *enterica* Pullorum-Gallinarum is highly host adapted and seldom causes significant clinical signs, morbidity, or mortality in hosts other than chickens and turkeys.

Definition and Synonyms

Bacillary white diarrhea was a term used to designate PD before 1929, but the term *pullorum disease* has since gained universal acceptance.

Economic Significance

The elimination of PD and FT from commercial flocks in the United States in the mid-1900s was largely a result of the pullorum-typhoid control program, the National Poultry Improvement Plan (NPIP), instituted by a voluntary organization (10). Similar government-backed approaches contributed to reductions in Europe. Even though PD is rare in commercial chickens, the disease still occurs in backyard flocks (9, 56, 142, 167). The major economic cost from PD over the last 20 years has been the cost involved in testing breeding flocks of chickens and turkeys to ensure that they are free of the infection. Both diseases remain of considerable economic significance in those countries which have only recently begun to intensify their industries and where extensive breeding remains important or where the ambient conditions are such that environmental infection is difficult to control through improvements in housing.

Public Health Significance

Rare cases of PD in humans have resulted from massive exposure following the ingestion of contaminated foods or experimental challenge (110, 115). The clinical signs are characterized by a rapid onset of acute enteritis, followed by prompt recovery without treatment. *S.* Gallinarum is rarely isolated from humans and is of little public health significance (9, 124). According to a Centers for Disease Control and Prevention report (8), 18 *S.* Pullorum isolates and 8 *S.* Gallinarum isolates were reported out of a total of 458,081 *Salmonella* isolates from humans between 1982 and 1992. Experimental reproduction of salmonellosis with four strains of *S.* Pullorum in humans with large numbers (billions) of bacteria produced only transient clinical signs followed by prompt recovery (115).

History

Only the salient features of these two diseases are provided here. Further information on the history of these two diseases can be found in previous editions of this book, as well as in a historical review by Bullis (39).

The etiologic agent of PD was described by Rettger in 1899, and the disease was called fatal septicemia of young chicks (128). Later, the disease was designated as bacillary white diarrhea to distinguish it from other diseases of chicks (129). At that time PD was widespread in the United States and in many other countries throughout the world. Mortality associated with this disease in chicks ranged up to 100% (130), seriously threatening the chicken industry. Between 1900 and 1910, PD was shown to be an egg-borne infection. In 1913, the practical application of the macroscopic tube agglutination antibody test for detection of carriers of the organism was described (86). Standard methods of diagnosis of PD in barnyard fowl were formulated by the Conference of Research Workers in Animal Diseases of North America and later adopted by the USA Livestock Association, now the United States Animal Health Association (USAHA), in 1932 (5, 6). A modified whole blood test method in which stained antigen is used was developed in 1931 (137). It has been widely used because of its simplicity.

The NPIP, established in 1935, is administered by state agencies cooperating with the USDA, and was designed in part to control PD in chickens. Pullorum disease was first recognized in turkeys in 1928 (74), and by 1940, the disease was widespread in turkeys and responsible for severe economic losses. A National Turkey Improvement Plan, similar to NPIP, was organized in 1943. A series of modifications of these plans during a number of years has helped in the eradication of PD in commercial poultry.

Fowl typhoid, a disease very similar to PD, was first recognized in 1888, even before PD (91). Initially, the causative agent was named *Bacillus gallinarum,* later changed to *B. sanguinarium* and later to *S. gallinarum* (91). The name fowl typhoid was applied in 1902, and it was soon used in other parts of the world such as Germany and Holland. Control of FT was included in the NPIP in 1954. This resulted in the inclusion of FT in the same category as PD and is one of the main reasons for the eradication of FT in commercial poultry and its low incidence in all poultry.

The control and reduction of FT and PD have been suggested to be one of the reasons for the emergence of *S.* Enteritidis in the 1980s (126). Whether this is true or not remains to be seen.

Etiology

Classification

Pullorum disease and FT are caused by *S.* Pullorum and *S.* Gallinarum, respectively. However, these two bacteria have been placed in a single species, *S. enterica* subsp. *enterica* serovar Pullorum-Gallinarum of the family Enterobacteriaceae, which is highly host adapted. It is one of the few members of the genus that is non-motile and belongs to the serogroup D according to the Kauffman White scheme. Classification of the etiology of PD and FT has been confusing and has changed in the last few years from separate species of *S. pullorum* and *S. gallinarum* to a single species. *Bergey's Manual* once used the designation *Salmonella gallinarum* for the etiology of PD and FT, but more recently the designation of *S. gallinarum-pullorum* has been used. In some classification schemes, the etiology of PD and FT are given different serovar status (*S. enterica* subsp. *enterica* serovar Pullorum and *S. enterica* subsp. *enterica* serovar Gallinarum, respectively, as well as *S. enterica* serovar Gallinarum biovars gallinarum and pullorum) because of biochemical differences and epizootiology. For simplicity in this chapter, the etiology of PD will be termed *S.* Pullorum, and the etiology of FT will be termed *S.* Gallinarum.

Nonmotile salmonellae such as *S.* Pullorum and *S.* Gallinarum are monophyletic, and the most recent common ancestor is non-motile (102). Since diverging from this ancestor, the Pullorum lineage has evolved more rapidly than the Gallinarum lineage as shown by multilocus enzyme electrophoresis and estimation of the chromosomal genotypic diversity (102). Using multilocus enzyme electrophoresis, it was shown that *S.* Enteritidis, a polyphyletic serotype, is closely related to *S.* Pullorum and *S.* Gallinarum (155). Genetic differences were also found between isolates of *S.* Pullorum isolated prior to the 1980s and isolates of *S.* Pullorum isolated during the 1990s based on random amplified polymorphic DNA assay (52). This has been supported more recently by microarray comparisons of whole genomic DNA (43, 125), and full analysis of the recently sequenced genomes (www.sanger.ac.uk/Projects/Salmonella) will enable extensions of these comparisons. Chromosomal rearrangements have also been observed in these serovars which, it has been speculated, are related to host adaptation (103, 184). Some differences also exist between the two taxa including deletions in Pullorum strains in the Tor respiration system and in the std fimbriae and chemotaxis genes in Gallinarum strains (125) and more unusual strains with large deletions were also seen.

Gallinarum strains can also be differentiated from Pullorum strains by PCR based assays reflecting local genomic sequence differences such as those in the rfbS (140) and glgC genes (111).

Morphology and Staining

The organisms are Gram-negative, non-sporogenic, and facultatively anaerobic. They are slender rods measuring 0.3 to 1.5 mm in width and 1.0 to 2.5 mm in length. The bacilli mostly occur singly, but occasionally two or more can be found to be united. Both *S.* Pullorum and *S.* Gallinarum are considered as non-motile. However, motility and flagellation have been shown in *S.* Pullorum grown on special types of solid media (45, 68, 77). However, other workers were unable to induce motility in *S.* Pullorum when grown on Hektoen agar (44).

Growth Requirements

S. Pullorum and *S.* Gallinarum grow readily on beef agar, broth, or other nutrient media. They are aerobic or facultatively anaerobic and grow best at 37°C. The organisms will grow in selective enrichment media such as selenite-F and tetrathionate broths, and differential plating media such as MacConkey, bismuth sulfite, and brilliant green agars. It has been shown that *S.* Pullorum occasionally fails to grow on certain selective media such as brilliant green or salmonella-shigella agar but grows satisfactorily on bismuth sulfite and MacConkey agars (41). *S.* Pullorum appears to grow slower than *S.* Gallinarum, and this has been attributed to its inability to oxidatively assimilate a variety of amino acids (156).

Colony Morphology

Colonies of *S.* Pullorum and *S.* Gallinarum on meat extract or infusion agar (pH 7.0–7.2) appear as small, discrete, smooth, blue-gray or grayish white, glistening, homogenous, and entire. The growth of *S.* Pullorum and *S.* Gallinarum is luxuriant and markedly translucent on liver infusion agar. Covered colonies remain small (1 mm or less), but isolated colonies may have a diameter of 3–4 mm or more. Surface markings may appear as the colonies increase in size and age, but as a rule, young colonies in a heavily seeded plate change little with age. Occasionally, morphologically abnormal strains are encountered. Inoculation of gelatin slants yields grayish-white surface growth with filiform growth in the stab and no liquefaction. Growth in broth is turbid with heavy flocculent sediment.

Biochemical Properties

More similarities than differences are identified between *S.* Pullorum and *S.* Gallinarum in their biochemical properties (33, 50, 163). Both organisms can ferment arabinose, dextrose, galactose, mannitol, mannose, rhamnose, and xylose to produce acid, with or without gas production. Substances not fermented include lactose, sucrose, and salicin. One important biochemical difference between these two organisms is that *S.* Gallinarum ferments dulcitol, whereas *S.* Pullorum does not. Also, *S.* Pullorum only occasionally ferments maltose. The major difference between the two organisms is, however, that *S.* Pullorum cultures produce rapid decarboxylation of ornithine, whereas cultures of *S.* Gallinarum do not. In addition, *S.* Gallinarum uses citrate, D(2) sorbitol, L(2) fucose, D(2) tartrate, and cysteine hydrochloride gelatin (163). Some of these differences are helpful in differentiating the two organisms; however, variation in the characteristics of some strains can be observed occasionally, especially in regard to gas production.

Ribotyping by the use of the enzyme *Eco*RI has been suggested as an important tool to differentiate between *S.* Pullorum and *S.* Gallinarum (49). Also, profiles of whole-cell fatty acid methyl ester have been helpful for separation and identification of *S.* Pullorum and *S.* Gallinarum (133). More recently it has

been demonstrated that *S.* Pullorum can be differentiated from *S.* Gallinarum by the analysis of the phase 1 *flagellin* C gene (*flic*) by single-strand conformational polymorphism (98).

Susceptibility to Chemical and Physical Agents

In general, the susceptibility of *S.* Pullorum and *S.* Gallinarum is about the same as that of members of the paratyphoid groups (123, 153). They may survive for several years in a favorable environment, but they are less resistant than paratyphoid salmonellae to heat, chemicals, and adverse environmental factors. For example, *S.* Gallinarum was killed within 10 minutes at 60°C; within a few minutes by direct exposure to sunlight; in 3 minutes by 1:1000 phenol, 1:20,000 dichloride of mercury, or 1% potassium permanganate; and in 1 minute by 2% formalin (153). *S.* Gallinarum grown on agar cultures may rapidly lose their virulence. Orr and Moore (117) found that *S.* Gallinarum retained viability up to 43 days when subjected to daily freezing and thawing. Organisms in liver survived more than 148 days at –20°C, even though they were accidentally thawed twice. *S. Gallinarum* can survive in feces from infected chickens up to 10.9 days when kept in a range house and 2 days less in the open (148).

Antigenic Structure

Both *S.* Pullorum and *S.* Gallinarum possess the O antigens 1, 9, and 12. Variation involving antigen 12 occurs in *S.* Pullorum strains based on serologic testing, but there is no evidence for such strain variation in *S.* Gallinarum. However, DNA fingerprint analysis has raised doubts regarding such variation in the major somatic antigen 12 of *S.* Pullorum (180).

The first serologic evidence of antigenic variation in *S.* Pullorum strains was discovered when progeny infected with a new strain were negative for antibodies using a standard agglutination test. Sera from infected chicks agglutinated homologous-strain antigen but not standard-strain antigens. This antigenic variation, characteristic of *S.* Pullorum, was studied extensively (54, 55, 178, 185). The antigenic composition of *S.* Pullorum was shown to contain O antigens 9, 12_1, 12_2, and 12_3, but the quantity of antigens 12_2 and 12_3 varies with strains. Standard strains contain a large amount of 12_3 and a very small amount of 12_2, but in variant strains, the content of the two antigens is reversed. Extensive examination of individual colonies, sometimes through successive transfers, has been necessary to determine accurately the antigenic form of a culture. Most isolates tend to stabilize during passage on artificial media. Standard-form cultures usually contain a small percentage of 12_2-predominant colonies even after long artificial cultivation. Variant forms of cultures are often pure or nearly pure for 12_2 and 12_3 factors. Colonies of intermediate strains are usually mixtures of 12_2- and 12_3-predominant colonies or rarely are uniform and contain appreciable amounts of both factors in individual colonies. Strains may also vary in content of the O–1 antigen.

Early reports indicated that as many as one-third of the *S.* Pullorum isolates from some areas of the United States were of the variant type; by 1950, only 13% of total isolates were of that type (177), a reduction believed to be the result of the extensive use of polyvalent testing antigens.

Tests to differentiate standard, intermediate, and variant types of *S.* Pullorum have been described (174, 175). Phage typing of *S.* Pullorum can be used for type identification, epidemiologic investigations, and genetic studies (50, 164, 165).

Virulence Factors

S. Pullorum and *S.* Gallinarum*,* being Gram-negative bacteria, have endotoxin. Unfortunately, this has not been studied extensively. *S.* Pullorum contains a thermostable toxin to which rodents, but not chicks, are susceptible. Similarly, *S.* Gallinarum contains a toxin that was lethal to rabbits (152). Endotoxins from *S.* Gallinarum can cause clinical signs within a few hours after intravenous injection in chicks (151). Most of the clinical signs subsided within 24–48 hours. Storing *S.* Gallinarum at 275 or 220°C did not have any effect on the subsequent pathogenicity test results (151).

Like most pathogenic microorganisms, *S.* Gallinarum*,* and probably *S.* Pullorum*,* may lose virulence rapidly during propagation and passage on artificial media; hence, cultures should be passaged serially in their natural host, the chicken, before testing the pathogenicity of the organisms. Pathogenicity of such cultures is best maintained in the lyophilized or frozen state. Passage on artifical media by different investigators have found wide variation in virulence among cultures of *S.* Gallinarum.

An 85-kb plasmid plays a role in the virulence of *S.* Pullorum and *S.* Gallinarum in chickens (18, 21, 50, 112). Plasmids of sizes other than 85-kb, either alone or in combination, or isolates absent in plasmids have also been reported in *S.* Gallinarum (4, 112).

As might be expected from *Salmonella* species causing systemic typhoid-like diseases, *Salmonella* Pathogenicity Island 2 is essential to virulence and survival and multiplication intracellularly (87, 173, 139) although the contribution of SPI1 encoding genes required for invasion of nonprofessional phagocytes is unclear. Other virulence gene clusters can also be identified although have not yet been fully characterized.

Certain genes are responsible for efficient adherence and entry of various salmonellae into cultured epithelial cells (2). When a mutated version of one of these genes, *invH,* was introduced into different *Salmonella* strains, some of these salmonellae (including *S.* Gallinarum) were rendered deficient for adherence and invasion of cultured cells. In one study, significant variability was observed among *S.* Pullorum isolates in their ability to invade avian epithelial cells despite the presence of *Salmonella* invasion genes *spvB* and *invA* (52). However, the relative role of the various fimbriae expressed by these and other *Salmonella* species has not been fully assessed. Genes homologous to K88 genes *fae*H and *fae*I have been demonstrated on the virulence plasmid of *S.* Gallinarum, which may influence intestinal invasion (132) and which may be equivalent to the Pef fimbriae of *S.* Typhimurium. Sef fimbriae are also produced (127).

Toxins produced by *Salmonella* serovars continue to be reported. Amongst these are a hemolysin (1) considered to be a regulatory gene rather than a structural toxin.

Pathobiology and Epidemiology

Incidence and Distribution

Pullorum disease and FT are worldwide in distribution (15, 32, 36, 47, 78, 79, 84, 98, 104, 106, 109, 112, 116, 136, 145, 146, 185, 186). Pullorum disease is rare in commercial poultry in the United States and perhaps in other parts of the world such as Canada, Australia, Japan, and Western Europe. Pullorum disease is also less commonly reported from backyard chickens in the United States (9). Except for one epizootic of PD in commercial chickens in the United States during 1990–1991, there have been no recent outbreaks (85, 134). This epizootic involved a single integrated broiler operation in five states (Delaware, Maryland, North Carolina, Alabama, and Florida). The outbreak involved 18 breeder flocks and more than 261 broiler rearing facilities.

No outbreaks of FT in commercial poultry in the United States have been reported since 1980 (7, 121). Canada and several European countries have a low incidence or absence of FT. Mexico, Central and South America, Africa, and the Indian subcontinent continue to report PD and FT in poultry flocks (16, 32, 36, 84, 104, 106, 109, 112, 136, 145, 146). Recently, a few outbreaks of FT have been reported in commercial poultry in Denmark and Germany as a result of importation from Eastern Europe (51).

Natural and Experimental Hosts

Chickens are the natural hosts for both *S.* Pullorum and *S.* Gallinarum; however, naturally occurring outbreaks of PD and FT have been described in turkeys, guinea fowl, quail, pheasants, sparrows, and parrots (120, 123, 143, 153). In addition, naturally occurring outbreaks of PD have been described in canaries and bullfinches, and FT has been described in ring doves, ostriches, and peafowl. The susceptibility of ducks, geese, and pigeons to *S.* Gallinarum has been variable, but most breeds used currently appear to be resistant to this pathogen. Ducks were found to be resistant to experimental infection with *S.* Pullorum and *S.* Gallinarum (19, 38).

Significant differences in susceptibility to PD among breeds of chickens have been described (40, 138). The lighter breeds, particularly leghorns, appear to be more resistant than the heavy breeds. PD-resistant and PD-susceptible lines of Rhode Island reds, New Hampshires, and crosses between the two were developed based on the selection for high and low body temperature during the first 6 days of life (81). Enormous differences in resistance to *S.* Pullorum and *S.* Gallinarum have also been shown in inbred lines of white leghorn chickens (35) much of which can be attributed to one locus, designated *SAL1* although TLR4 and *NRAMP1* also contribute (80, 101, 107). It appears that a greater percentage of females than males stay as reactors, probably due to local infection being sequestered in the ovarian follicles.

Pullorum disease has been described as a naturally occurring or experimental infection in mammals including chimpanzees, rabbits, guinea pigs, chinchillas, pigs, kittens, foxes, dogs, swine, mink, cows, and wild rats. *S.* Gallinarum was able to be cultured for up to 121 days from the feces of experimentally infected rats (13). Human salmonellosis caused by *S.* Pullorum occasionally

has been reported (8, 110, 115). The basis of host adaptation is unknown (42) although it is apparent that it is predominantly expressed at the level of the macrophage-monocyte series (17).

Age of Hosts Commonly Infected

Mortality from PD usually is confined to the first 2–3 weeks of age. Acute infections in older chickens, particularly among brown egg-producing strains, have been reported occasionally. Similarly, mortality due to PD in semi-mature and mature turkeys has been observed. A certain percentage of chickens and turkeys that survive the initial infection become carriers with or without the presence of lesions.

Although FT is frequently referred to as a disease of adult birds, there have been reports of high mortality in young chicks (22, 25, 97, 108, 183). Fowl typhoid can cause mortality as high as 26% in chicks during the first month of life. Mortalities of 65% and 100% within 11 days after inoculation of one-day-old broiler chicks with 10^4 CFU and 10^8 CFU per ml of *S.* Gallinarum, respectively, have been reported (183). As in PD, FT losses begin at hatching time; however, in FT they also continue to laying age. Certain strains of *S.* Gallinarum produce lesions in chicks indistinguishable from those associated with PD (154). Therefore, as a result of experimental and field observations we can conclude that chicks and poults are highly susceptible to *S.* Pullorum and *S.* Gallinarum, whereas adults are more susceptible to *S.* Gallinarum.

Transmission

Like many other bacterial diseases, PD and FT can be transmitted in several ways. The infected bird (reactor and carrier) is by far the most important means of perpetuation and spread of the organism. Birds may infect not only their own generation by horizontal transmission, but also succeeding ones through egg transmission. Egg transmission may result from contamination of the ovum following ovulation (22, 25), but localization of *S.* Pullorum or *S.* Gallinarum in the ovules before ovulation is likely and probably constitutes the chief mode of vertical transmission. The relative contribution of vertical transmission in the two organisms is unclear since it is easy to establish persistent infections and egg transmission with *S.* Pullorum (31) but much less easy with *S.* Gallinarum and it may be that horizontal transmission is more important in this highly virulent organism where experimental infection generally either results in clinical disease and mortality or no infection depending on the genetic background of the host. Egg transmission has been influenced by levels of antibodies in the yolk (169). Maternal antibodies against *S.* Pullorum may be critical in the prevention of embryonic mortality in infected eggs, thus allowing successful egg transmission.

The exact mechanism surrounding persistent infection and carriage which results in infection of the reproductive tract is still unclear. However, it is known that *S.* Pullorum persists within macrophages in the spleen during the carrier state (170) and although numbers gradually reduce they are not eliminated (31) and at sexual maturity the numbers increase as a result of reduced capacity of T cells to respond specifically and nonspecifically to

antigens (171), probably following increases in sex hormones. The reduced immune responsiveness enables the bacteria to spread to the reproductive tract.

Transmission through shell penetration and feed contamination by *S. Pullorum* has been reported but appears to be of minor importance (176). The number of eggs infected with *S. Pullorum* or *S. Gallinarum* can be as high as 33% of the total laid by an infected hen. Contact transmission of infected chicks or pullets can be an important route of dissemination of *S. Pullorum* and *S. Gallinarum*. This can happen in the hatcher and can be partially prevented only by formaldehyde fumigation (75). Mortality as high as 60.9% of the exposed flock due to *S. Gallinarum* has been reported (66). Transmission may also occur within a flock as a result of cannibalism of infected birds, eating of infected eggs, and through wounds on the skin. Feces from infected birds are also a source of bacteria. Contaminated feed, water, and litter can also be sources of both *S. Pullorum* and *S. Gallinarum*. Attendants, feed dealers, chicken buyers, and visitors who move from house to house and from farm to farm may also spread these diseases unless precautions are taken to disinfect footwear, hands, and clothing. Similarly, trucks, crates, and feed sacks may also be contaminated. Wild birds, mammals, and flies may be important mechanical spreaders of the organisms.

Clinical Signs

PD and FT are primarily diseases of chicks and poults. However, FT is a more significant disease in growing and adult chickens and turkeys than PD. The signs noted in young chicks and poults associated with both diseases are very similar as a result of the transovarian transmission of these diseases. Occasional cases of PD can be subclinical, even though the disease may originate by egg transmission.

Chicks and Poults

If birds are hatched from *S. Pullorum* or *S. Gallinarum* infected eggs, moribund and dead birds may be observed in the incubator or within a short time after hatching. The birds can manifest somnolescence, weakness, depressed appetite, poor growth, and adherence of chalky white material to the vent. Death may soon follow. In some cases, evidence of PD is not observed until 5–10 days after hatching, but the disease gains momentum during the following 7–10 days. Mortality usually peaks during the second or third week of life. In these situations, the birds exhibit lassitude and an inclination to huddle together under heaters, having droopy wings, and distorted body appearance.

Labored breathing or gasping may be observed as a result of extensive involvement of the lungs due to PD. Survivors may be greatly retarded in their growth and appear underdeveloped and poorly feathered. These birds may not mature into vigorous or well-developed laying or breeding birds. Flocks that have passed through a serious outbreak usually have a high percentage of carriers at maturity.

Blindness, as well as swelling of the tibiotarsal and the humeroradial and ulnar articulations, due to *S. Pullorum* infection in chicks has been described (26, 57, 59, 85, 109, 134). In certain instances, a relatively high incidence of infection in the joints, which can produce lameness and obvious joint enlargement, can occur in chicks. In the 1990–1991 outbreaks of PD in the eastern part of the United States, swelling of the hock joint, due to synovitis, was commonly seen (134). Similar lesions in turkey poults have also been reported. This may suggest that some strains of *S. Pullorum* may have a tropism for these sites.

Growing and Mature Fowl

Infected birds may not exhibit any signs and cannot be detected by their physical appearance, especially in the case of PD. Acute outbreaks of FT in chickens may begin by a sudden drop in feed consumption, with birds being droopy, showing ruffled feathers and pale and shrunken combs. Other signs, such as a drop in egg production, decreased fertility, and diminished hatchability, can sometimes be observed in both PD and FT, depending upon the severity of infection. Death may occur within 4 days of exposure, but usually occurs after 5–10 days. There may be an increase in body temperature of 1–3 degrees within 2–3 days after exposure. In some cases of PD in semi-mature and mature flocks, the predominant clinical signs include anorexia, diarrhea, depression, and dehydration (56).

Clinical signs due to PD and FT in turkeys may consist of thirst, inappetence, listlessness, a tendency to separate from healthy birds, and green to greenish-yellow diarrhea. However, deaths may occur with no prior clinical signs, but body temperature may increase several degrees initially. The first outbreak on a farm usually causes the highest mortality followed by intermittent recurrence and less severe losses (76).

Morbidity and Mortality

Both morbidity and mortality are highly variable in chickens and are influenced by age, strain of bird, nutrition, flock management, concurrent diseases and route and dose of exposure. Mortality from PD may vary from 0 to 100%. The greatest losses usually occur during the second week after hatching, with a rapid decline between the third and fourth week of age in PD. Mortality ranging from 10 to 93% due to FT have been reported in chicks (72). One hundred percent mortality in 11 days was reported in broiler chicks after they were inoculated at one day of age with 10^8 CFU per ml of *S. Gallinarum* (183).

Morbidity is often much higher than mortality with some of the affected birds recovering spontaneously. Birds hatched from an infected flock and raised on the same premises exhibit less mortality than those subjected to the stress of shipping. Losses may be as severe in turkeys as in chickens.

Pathology

Gross Lesions

Descriptions of gross and microscopic lesions associated with PD and FT are sporadic. Some of the earliest descriptions were those by Rettger (129, 130). Since then, there have been many reports in various species of birds, primarily involving chickens and turkeys, but also in pheasants, quail, and guinea fowl (22, 27, 46, 53, 56, 57, 65, 72, 73, 74, 75, 95, 96, 108, 109, 120, 141, 142, 143, 160, 183, 185).

Chicks

In peracute cases of PD and FT, birds that die suddenly in the early stages of brooding may show no gross lesions. In acute cases, enlarged and congested liver, spleen, and kidneys may be seen (Fig. 16.1A). Livers may have white foci of 2–4 mm in diameter (Fig. 16.1B). The yolk sac and its contents may or may not reveal any abnormalities, but in protracted cases, interference with yolk absorption may occur. In such cases, the yolk sac contents may be of creamy or caseous consistency. Occasionally, those birds with respiratory signs may have white nodules in the lung (Fig. 16.1H), and white nodules, resembling Marek's disease tumors, may be present in the cardiac muscle (Fig. 16.1C) or pancreas. Occasionally, nodules in the heart may become so large they distort the shape of the heart (Fig.16.1D). This, in turn, may lead to chronic passive congestion of the liver and ascites. The pericardium may be thickened, and the pericardial sac may contain yellow serous or fibrinous exudate. Similar nodules may be present in the muscle of the ventriculus (gizzard) (Fig. 16.1E) and occasionally in the wall of the ceca and rectum. The ceca may contain caseous cores. Some birds may exhibit swollen joints containing yellow viscous fluid (27) (Fig. 16.1G); this was one of the most commonly reported gross lesions in the 1990–1991 outbreak of PD in commercial broilers in the United States (134). Among the joints, the hock joint is most commonly involved, but other joints such as the wing joint and the footpad may be affected. Other changes that can be seen include exudate in the peritoneal cavity, thickening of the wall of the intestine, and exudate in the anterior chamber of the eye.

Splenomegaly, gray necrotic foci with petechial hemorrhages in lungs, and pale or discolored livers were observed in bobwhite quail inoculated with *S.* Pullorum (38). In young pheasants, yolk sac infection, pneumonia, hepatitis, and typhlocolitis were the most common lesions associated with PD (120).

Adult Chickens

Lesions due to PD may be minimal in some birds, even though they may be active serologic reactors. Sometimes, only a minimal lesion, such as a small nodular or regressing ovarian follicle, can be found. However, the lesions found most frequently in chronic carrier hens with PD and FT are a few misshapen, discolored cystic or nodular ova among a few normal-appearing ovules (Fig. 16.1H and I). The involved ova may contain oily and caseous material enclosed in a thickened capsule. These degenerative ovarian follicles may be closely attached to the ovary, but frequently they are pedunculated and may become detached from the ovarian mass. In such cases, they may become embedded in the inner lining of the peritoneal cavity. Often, the oviduct contains caseous exudate in the lumen. Ovary and oviduct dysfunction may lead to peritoneal ovulation or oviduct impaction, which in turn may bring about extensive peritonitis and adhesions of the abdominal viscera. Fibrinous peritonitis and perihepatitis, with or without involvement of the reproductive tract, may sometimes be seen. Ascites also may develop, especially in turkeys. However, it may be difficult to culture *Salmonella* from advanced chronic lesions.

Frequently, pericarditis is observed. Changes in the peri-

cardium, epicardium, and pericardial fluid depend on the duration of the disease. In some cases, the pericardium exhibits only a slight translucency, and the pericardial fluid may be increased in volume and turbid. In the more advanced stages, the pericardial sac is thickened and opaque, and the pericardial fluid is greatly increased in amount, containing considerable exudate. More advanced cases have chronic thickening of the pericardium and epicardium and partial obliteration of the pericardial cavity by adhesions. Occasionally, small cysts containing amber, caseous material may be found embedded in the abdominal fat or attached to the ventriculus and intestine. Frequently, the pancreas may have white foci or nodules.

In the male, testes may have white foci or nodules (65). Occasionally, caseous granulomas can be found in the lungs and air sacs (56).

Turkeys

Lesions due to PD and FT in turkeys are similar to those observed in chickens (74). Enlarged mahogany or brown-streaked livers, splenomegaly, areas of necrosis in the heart, and grayish lungs are characteristic lesions of FT in turkey poults. Ulceration throughout the small intestine and ceca is a common type of lesion in turkeys but uncommon in chickens. In adult carriers, there is a predilection of infection for the reproductive organs similar to that seen in chickens.

Ducks and Guinea Fowl

Lesions due to FT in ducklings and adult ducks are similar to those in chickens. In guinea fowl, FT lesions involve the respiratory tract and are characterized by congested lungs and increased mucus in the nasal cleft and trachea.

Histopathology

A very limited amount of information on microscopic lesions is available for PD or FT. Most of the PD lesions described are from field cases, which might have been complicated by other bacterial and/or viral agents (53, 160). There is one report on experimental pathology of FT in chicks (183).

In peracute cases of PD and FT, only severe vascular congestion in various organs, especially liver, spleen, and kidney, can be identified. In acute to subacute cases, there is multifocal necrosis of hepatocytes (Fig. 16.2) with accumulation of fibrin and infiltration of heterophils in the hepatic parenchyma. Periportal infiltration of heterophils mixed with a few lymphocytes and plasma cells can also be seen in the liver. In chronic cases, especially in cases in which there are large nodules in the heart, the liver will have chronic passive congestion with interstitial fibrosis. The spleen may have severe congestion or fibrin exudation of vascular sinuses in acute stages, and severe hyperplasia of the mononuclear phagocytic system cells in later stages. The ceca in young chicks may have extensive necrosis of the mucosa and submucosa, with an accumulation of necrotic debris mixed with fibrin and heterophils in the lumen.

However, the most characteristic microscopic lesions are in the heart and ventriculus. In the heart, they begin as necrosis of myofibers with infiltration of heterophils mixed with lymphocytes
16.2.   Liver revealing focal degeneration and necrosis, ×51.
16.3.   Myocardium from a *S.* Pullorum-infected chick showing infiltration with histiocytic-type cells, ×62.

and plasma cells. In later stages, these cells are replaced by massive numbers of uniform histiocytes (Fig. 16.3). These cells are fairly large, with irregular vesicular nuclei and faintly staining, foamy eosinophilic cytoplasm. They may be arranged in solid sheets, forming nodules that often protrude from the epicardial surface. These nodules, both grossly and histologically, can be confused with lymphoid tumors caused by Marek's disease virus and possibly retroviruses. A similar process can be seen in the ventriculus and pancreas. The lesions in the pancreas can be so severe that the normal architecture is obliterated.

Other changes such as serositis of various organs including the pericardium, pleuroperitoneum, synovium, and serosa of the intestinal tract and mesentery can be seen in a high percentage of cases (160). In acute stages, these lesions can be associated with heterophils and fibrin, but in later stages, only lymphocytes, plasma cells, and histiocytes will be found.

Microscopic lesions in the ovary range from acute fibrinosuppurative inflammation to severe pyogranulomatous inflammation of the ovules (Fig. 16.4). The pyogranulomatous inflammation is characterized by infiltration of heterophils mixed with fibrin and bacterial colonies in the coagulated yolk material. In turn, the core is surrounded by successive layers of multinucleated giant cells and a mixed population of inflammatory cells that can include macrophages, plasma cells, heterophils, and lymphocytes. In males, degeneration, necrosis, and inflammation of the epithelial cells lining the seminiferous tubules can be seen (96). Other, but less common, changes are catarrhal bronchitis, catarrhal en-

teritis, and interstitial inflammation of the lungs and kidneys. Minimal and nonspecific changes in endocrine glands, such as the hypoplasia of thyroid and hypertrophy of adrenal and pituitary glands due to FT, have been described (61).

Pathogenesis of Infectious Process

Differences in the ability of various salmonellae, including *S.* Pullorum and *S.* Gallinarum, to survive and multiply in visceral organs (especially in spleen and liver) have been attributed to an unknown mechanism involving the mononuclear phagocyte system (MPS) of the host (17). Ducks may be resistant to *S.* Gallinarum due to the inherent inability of the bacteria to multiply in the MPS of ducks (19). Because of the ability of these bacteria to infect and multiply within the cells of the MPS of chickens and turkeys, it is probable that cell-mediated immunity to *S.* Pullorum and *S.* Gallinarum may play a role in recovery and resistance to infection in chickens and turkeys (171).

In one study, it was found that an *S.* Gallinarum infection of primary chicken cells caused a reduction in IL-1beta and no change in IL-6 (89). Modest increases in IL-ß were also found *in vivo* following vaccination with the 9R vaccine (172). The reduction in IL-1beta was interpreted as a lack of an inflammatory response resulting in systemic infection of *S.* Gallinarum (89). This, it was argued, was a strategic approach to facilitate invasion without stimulating the strong inflammatory responses associated with infection with most *Salmonella* strains (181, 182). Since signaling via TLR5 with flagella may be important, the absence of flagella
16.4. Ovule from an adult hen with pullorum disease showing fibrinosuppurative inflammation and bacterial colonies, ×20.

in these species may be highly significant (82). It is likely that these early responses are largely mediated through heterophilic granulocytes (92) which are not induced by these serovars unlike *S.* Enteritidis. In another study it was demonstrated that *S.* Pullorum preferentially targeted the bursa of Fabricius prior to eliciting inflammation in the intestine (73). In a study with *S.* Gallinarum in chickens, leucocytosis was observed on the third day PI but was followed by leukopenia that lasted for 10 days (93). This was followed by a leucocytosis as late as 21 days PI, and it was associated with heterophilia but a relative lymphopenia (93). Infection with *S.* Gallinarum may cause anemia (48) and an increase in sialic acid content in serum (94).

In most cases of FT, the organism is disseminated via intestinal lesions although the nature of this process and the cells involved are not understood.

Immunity

Very little information regarding immunity to PD and FT is available, due in part to the great success in the eradication of these diseases in commercial poultry. Chicks orally infected at 4 days of age did not produce detectable agglutinating antibodies until 20–40 days of age, but mature birds produced agglutinating antibodies within 3–10 days following infection. In chicks, maximum antibody production was not reached until 100 days after infection. The possible role of agglutinating antibodies in affecting the course of infection in the host is poorly understood.

It seems likely that with systemic diseases cell-mediated immunity is likely to be of major important in clearance (58). Little information is available specifically on *S.* Pullorum and *S.* Gallinarum. With S. Typhimurium, clearance is correlated with IFN-γ levels (24) and a strong T cell response (23). A recent study has also shown high IFN-γ levels following vaccination with the live 9R vaccine and strong lymphoproliferative responses (172). Although it is assumed that a strong Th1-type response is responsible for immunity the absence of studies involving Th2-type responses restricts analysis. It is thought that *S.* Pullorum induces a stronger Th2-type response which is responsible for the persistent infection and it is known that SPI2 secreted proteins are involved (173).

Diagnosis

A definitive diagnosis of PD or FT requires the isolation and identification of *S.* Pullorum or *S.* Gallinarum, respectively. A tentative diagnosis, however, can be made based on flock history, clinical signs, mortality, and lesions. Positive serologic findings can also be of major value in detecting infection; however, negative results should not be considered adequate for a definite diagnosis because of the delay of 3–10 days in the appearance of agglutinating antibodies following infection. Similarly positive results should be interpreted with caution because of cross-reactions with other serogroup D salmonellae such as *S.* Enteritidis (63, 64, 144, 168).

Isolation and Identification of Causative Agent

Acute PD and FT are characteristically systemic infections; causative organisms can be isolated from most internal organs. The liver, spleen, and ceca usually are involved and are the preferred organs to culture. Lesions may occur in lungs, heart, ventriculus, pancreas, or yolk sac, and these are also dependable samples for culturing. In mature birds, if lesions are present in the reproductive organs, ovarian follicles and testes can be cultured. Other sites for culturing are the peritoneum, synovial fluid, and the interior of the eye. Beef extract or infusion, or tryptose agar, in tubes or petri dishes, are all satisfactory for primary isolation. Enrichment broths or selective media may also be used if tissues are decomposed.

Birds with chronic PD or FT that are detected by serologic tests may or may not have gross lesions. If such birds are submitted to the laboratory as carriers, thorough culturing of internal organs is necessary. A detailed outline for testing such specimens is provided in the procedures manual of the NPIP (10). This procedure may be summarized as follows.

Grossly normal or diseased internal organs should be cultured directly on veal infusion (VI) and brilliant green (BG) agar plates and incubated for 48 hours at 37°C. In addition, portions of the internal organs should be pooled, ground, or blended in 10 times their volume of VI broth; 10 ml aliquots of the suspension are transferable to 100 mL of both VI and tetrathionate BG (TBG) broth and incubated for 24 hours at 37°C. The broths then are plated on VI and BG agar and incubated and examined after 24 and 48 hours. If contamination with proteus or pseudomonas is a problem, platings can be done on BG sulfapyridine (BGS) agar.

The digestive tract should be cultured using individual cotton swabs for the upper, middle, and lower intestinal tract, including both the ceca and the rectum-cloaca area. The swabs should be deposited in 10 mL TBG broth, incubated, and plated as previously described for the internal organs. In addition, portions of the gut should be pooled, ground, or blended in 10 times their volume of TBG broth. Ten mL of the suspension from the digestive tract are transferred to 100 mL TBG broth and incubated at 42 or 37°C for 24 hours. The higher incubation temperatures for TBG broth reduce populations of competitive flora common in gut tissue.

Suspect colonies are transferred to triple sugar-iron (TSI) agar and lysine-iron (LI) agar and incubated at 37°C for 24 hours. Cultures revealing typical reactions of salmonellae or arizonae on TSI or LI agar slants should be identified by appropriate biochemical and other tests. All *Salmonella* cultures should be serologically typed.

Use of nonselective media demands careful aseptic techniques but has the advantage of more dependably ensuring the isolation of *S.* Pullorum and *S.* Gallinarum. Also, other bacteria capable of producing cross-reactions with pullorum-typhoid antigen may be more dependably isolated.

Identification of Cultures

The colonies of *S.* Pullorum may appear small, smooth, and translucent on nutrient media after 24 hours of incubation. With *S.* Gallinarum*,* colonies are smooth, blue-gray, moist, circular, and entire. Careful initial culture of tissues on nonselective media should usually result in pure cultures. If pure cultures are not secured, or if an enriched medium has been used, it is often advantageous to transfer individual colonies to TSI agar slants for preliminary differentiation. *S.* Pullorum and *S.* Gallinarum produce a red slant with a yellow butt that shows delayed blackening from H_2S production. Reactions listed in Table 16.1, which can be determined within 24 hours, provide identification of a number of other common pathogens and allow differentiation between the two organisms.

Additional differentiation tests described under Etiology may be necessary to identify isolates that produce nontypical reactions (chiefly fermentation of maltose or no gas production). Decarboxylation of ornithine by *S. pullorum* is the single most dependable test for differentiating maltose-fermenting *S.* Pullorum strains from *S.* Gallinarum. Polymerase chain reaction has also been used to identify isolates of *S.* Pullorum and *S.* Gallinarum (88, 89, 166).

Serology

Serologic tests to detect PD and FT include the macroscopic tube agglutination (TA) test, rapid serum (RS) test, stained antigen whole blood (WB) test, and the microagglutination (MA) test using tetrazolium-stained antigens (62, 86, 123, 131, 137, 153, 162, 179). The standard procedure in the United States for detecting breeding flocks chronically infected with *S.* Pullorum and *S.* Gallinarum is to use the standard strains of *S.* Pullorum (O–1, 9, 12_3) for tube and serum plate antigens and both standard (O–1, 9, 12_3) and variant (O–1, 9, 12_2) strains of *S.* Pullorum for the

polyvalent rapid whole blood plate antigens. These antigens will detect flocks infected with either *S.* Pullorum or *S.* Gallinarum. Hens infected with antigenically intermediate or variant strains of *S.* Pullorum were detected as seropositive less often than were hens infected with antigenically standard strains with two commercially available plate test antigens (62).

The techniques and procedures for official testing of chicken and turkey breeding flocks and the interpretation of tests are described in detail in the latest version of the NPIP (10).

Enzyme-linked immunosorbent assays (ELISA) for detecting *S.* Pullorum and *S.* Gallinarum antibodies have been developed by using lipopolysaccharides or whole cell antigen from these salmonellae (16, 30, 113, 114). This technique can be used for screening large numbers of blood or egg yolk samples and can be adapted to differentiate vaccinated birds from those infected with wild-type strains (16, 113, 114). Infection with both serovars can also be differentiated serologically from *S.* Enteritidis infection using flagella as an antigen (16, 30, 64). Another test, a dot immunobinding assay (DIA), was found to be more sensitive compared to the tube agglutination test for detecting high titers of antibodies in birds challenged with *S.* Gallinarum (105). This test also detected antibodies to *S.* Gallinarum in vaccinated birds that failed to react by TA.

Differential Diagnosis

The clinical signs and lesions produced by PD or FT are not pathognomonic. Other *Salmonella* infections may produce similar lesions in the liver, spleen, and intestine, which cannot be distinguished grossly or microscopically from those produced by PD or FT. *Aspergillus* or other fungi may produce similar lesions in the lungs.

S. Pullorum and *S.* Gallinarum can localize in major joints and tendon sheaths of chicks. Such signs and lesions resemble those produced by organisms such as *Mycoplasma synoviae*, *Staphylococcus aureus*, *Pasteurella multocida*, or *Erysipelothrix rhusiopathiae.* Sometimes the white nodules in the heart of young chicks may resemble Marek's disease tumors and those in the

liver resemble those produced by *Yersinia pseudotuberculosis* with which it shares some antigenic relationships. Local infections with *S.* Pullorum and *S.* Gallinarum in adult carriers, particularly of the ovary, may appear identical to those produced by other bacterial infections such as coliforms, staphylococci, *P. multocida,* streptococci, and other salmonellae. Birds of any age may be infected with *S.* Pullorum or *S.* Gallinarum but fail to show grossly discernable lesions. A definitive diagnosis of PD and FT can be made only following the isolation and identification of *S.* Pullorum and *S.* Gallinarum, respectively.

Intervention Strategies

It has long been established that chicken and turkey flocks can be developed and maintained free of PD and FT by adhering to well-defined procedures. Both PD and FT are good examples of diseases that have decreased in incidence over the years by the application of basic management procedures. In the simplest sense, the only requirement is to establish breeding flocks free of *S.* Pullorum and *S.* Gallinarum and to hatch and rear their progeny under conditions that preclude direct or indirect contact with infected chickens or turkeys.

Management Procedures

Methods of management broadly designed to prevent the introduction of infectious agents are applicable to preventing the introduction of *S.* Pullorum and *S.* Gallinarum. Because of egg transmission, only eggs from flocks known to be free of PD and FT should be used in hatcheries. Under the NPIP, chicken and turkey breeding flocks and their progeny may be recognized as free of PD and FT.

Management practices should be broadly applied to prevent the introduction of PD or FT. If PD or FT is encountered, elimination of carriers must be carried out regularly until the breeder flocks are free of PD and FT.

1. Chicks and poults should be obtained from sources free of PD and FT.
2. Pullorum-free and typhoid-free stock should not be mixed with other poultry or confined birds.
3. Chicks and poults should be placed in an environment that can be cleaned and sanitized to eliminate any residential salmonellae from previous flocks (see "Susceptibility to Chemical and Physical Agents").
4. Chicks and poults should receive pelletized, crumbled feed to minimize the introduction of *S.* Pullorum and *S.* Gallinarum and other salmonellae through contaminated feed ingredients. Use of feed ingredients free of salmonellae is essential.
5. Introduction of salmonellae from outside sources must be minimized by the use of a sound biosecurity program.
   a. Free-flying birds are commonly found to be carriers of other salmonellae, although rarely with *S.* Pullorum or *S.* Gallinarum. Poultry houses should be bird proof.
   b. Rats, mice, rabbits, cats, dogs, and pests may be carriers of other salmonellae, but they are infected rarely with *S.* Pullorum or *S.* Gallinarum. Nevertheless, poultry houses should be vermin proof.
   c. Insect control is important, particularly against flies, poultry mites, and the lesser mealworm. These pests may provide a means of survival for salmonellae and other avian pathogens in the environment.
   d. Potable drinking water must be used, or chlorinated water should be provided. In some areas, a danger is posed by surface water collected in open ponds for use as drinking water for livestock and poultry.
   e. Mechanical carriers of the organism include footwear and clothing of humans, as well as poultry equipment, processing trucks, and poultry crates. Every precaution should be made to prevent the introduction of *S.* Pullorum or *S.* Gallinarum by fomites.
   f. Proper disposal of dead birds is essential.

Elimination of Carriers

The foundation of the PD control program was established in 1913 by use of TA for detecting infected chickens (86). The test was promptly applied in state programs to eliminate the disease from flocks by the detection and removal of reactors.

Early field testing results indicated that removal of reactors following a single test usually was not sufficient for the complete elimination of infected birds from a flock. Such results may be expected because of three possible intercurrent characteristics: 1) serum agglutinin titers of infected birds tend to fluctuate and may for brief periods fail to produce significant agglutination at the usual dilution of 1:25 or 1:50; 2) a delay of at least several days exists between infection and the development of agglutinins; and 3) following the removal of reactors, environmental contamination may serve as a source of infection for other birds at a later date.

Serologic Tests

As noted previously, in addition to the TA test, other serologic tests such as the RS, WB, and MA tests have been developed (131, 137, 179). All of these are effective in detecting carriers. The MA test is as dependable as the TA test and offers an important advantage in lower cost. The NPIP (10), which details testing methods, accepts four tests for testing chickens: standard TA test, WB test, RS test, and MA test. Of the four, only the WB test is not satisfactory for turkeys. Testing for accreditation is allowed after chickens and turkeys reach approximate immunologic maturity at 16 weeks of age.

In contrast to requirements in the United States for producing antigen from cells grown on the surface of appropriate agar, a different WB test antigen was developed in Japan, where it is officially used (161). This antigen is prepared from cultures grown in a continuous-flow, broth-culture system, in which it is necessary to blend sublots to secure desired agglutinability. An ELISA test is also available for screening of flocks for PD and FT (16, 113, 114).

Serologic evidence of infection should be confirmed by bacteriologic examination of one or more reactors. If only suspicious reactions are observed in a flock, the birds reacting most strongly should be submitted to a laboratory for retesting and a thorough bacteriologic examination. In routine testing, flocks should not

be interpreted as infected solely on the basis of doubtful or atypical reactions, because such reactions may result from infections other than *S.* Pullorum or *S.* Gallinarum (63, 64, 144, 168).

Non-pullorum/Non-gallinarum Reactors

Non-pullorum, and possibly non-gallinarum, reactions occasionally cause problems in interpretation (60, 168). A variety of bacteria possessing antigens in common with, or closely related to, those of *S.* Pullorum may infect birds and produce an agglutinin response. It was reported that non-pullorum reactions occur more frequently with variant than with standard-form antigen. Infections with coliforms, micrococci, and streptococci, particularly those belonging to the Lancefield group D, were found to be responsible for a large percentage of non-pullorum reactions in chickens. Infections with other bacteria, such as *Staphylococcus epidermidis*, *Micrococcus* spp., *Aerobacter aerogenus*, *Y. pseudotuberculosis*, *Proteus* spp., *Escherichia coli,* and species of *arizonae, Providentia,* and *Citrobacter,* were responsible for many non-pullorum reactions. Other salmonellae, particularly those in group D, such as *S.* Enteritidis*,* may also produce cross-reactions. Non-pullorum reactors range from a few birds in a flock to as high as 30–40%. The character of the agglutination may be variable. Thorough bacteriologic examination of representative reactors is often the only dependable method of determining the infection status of a flock, and it is usually the only method of distinguishing between infections by *S.* Pullorum and *S.* Gallinarum.

National Control Program

The NPIP (10) details specific criteria for establishing and maintaining official U.S. pullorum-typhoid-clean flocks and hatcheries. These criteria are based on farm and hatchery management practices that prevent direct or indirect contact with infected stock and annual testing of all, or a representative portion, of the birds in the flocks.

If an attempt is made to free a flock of infection, retesting of the infected flock should be done at 2–4-week intervals until two consecutive negative tests of the entire flock are secured at not less than a 21-day interval. In the majority of cases, infection can be eliminated from the flock through short-interval testing. Two or three retests are often sufficient to detect all infected birds; occasionally, however, infection continues to spread within a flock. In some situations, the disease may not be eliminated through repeated testing.

Area Eradication

Here are the essentials of an eradication program for an area:

1. PD and FT must be mandatory reportable diseases.
2. Outbreaks must be placed under quarantine, and infected flocks marketed under supervision.
3. All reports of PD and FT must be investigated by an authorized state or federal official.
4. Importation regulations must require shipments of poultry and hatching eggs to be from sources considered free of PD and FT.

5. Regulations must require poultry going to public exhibition to be from flocks free from PD and FT.
6. Total participation of poultry breeding flocks and hatcheries must be required in a pullorum-typhoid control program, such as NPIP programs or the equivalent.

Forty-three states in the United States had qualified under the preceding program as pullorum-typhoid-clean states by 2000; however, a reservoir of PD still exists in small backyard and hobby flocks. This reservoir of infection may be larger than indicated, because not all states have a program to test noncommercial and exhibition poultry. Experience indicates that the usual separation of commercial and noncommercial poultry is quite effective in preventing the transmission of *S.* Pullorum and *S.* Gallinarum between these populations. Nevertheless, infected backyard flocks pose some danger to commercial flocks. It is necessary to continue to test commercial breeding flocks to enable earlier identification of accidental infections from noncommercial poultry.

Vaccination

Because PD has been mostly eradicated from commercial flocks over the years and the eradication program is in place, very little incentive exists for the production of vaccines to control PD. Fowl typhoid, however, continues to be a problem in some parts of the world. No federally licensed *S.* Gallinarum killed bacterin is produced in the United States, and live modified vaccines used in other countries are not permitted in the United States. Various investigators have evaluated killed and modified live vaccines as well as virulence plasmid-cured derivatives (11, 20, 28, 37, 69, 70, 71, 119, 147, 149, 187, 188). With the upsurge of FT in many countries, studies on the use of the 9R strain (149) as live oral or injectable vaccine, with or without oil adjuvants, have been reported with variable results (11, 69, 70, 71, 119, 147). Similarly, outer membrane proteins from *S.* Gallinarum have been reported to offer better protection than the 9R live vaccine in terms of clearance of the pathogenic strain from internal organs (30, 32). More recently, immunization against FT by the use of mutant strains of *S.* Gallinarum and a virulence plasmid-cured derivative of *S.* Gallinarum and other types appear to be promising in protecting birds challenged with *S.* Gallinarum (14, 15, 20, 67, 188).

Other Approaches

Incorporation of commercial formic acid preparations in the feed has been found to significantly reduce the experimental incidence and severity of FT (B29).

Competitive exclusion using gut flora preparations has also been reported to be effective against FT (118).

Treatment

Reasonably effective prophylactic and therapeutic drugs have been developed against PD and FT. In Canada and the United States, every effort has been made to eradicate these diseases so treatment is neither feasible nor desired.

Various sulfonamides, nitrofurans, chloramphenicol, tetracy-

clines, and aminoglycosides have been found to be effective in reducing mortality from PD and FT; however, no drug or combination of drugs has been found capable of eliminating infection from a treated flock. Sulfonamides, in particular, frequently suppress growth and may interfere with feed and water intake and egg production. Sulfonamides that have been used in the treatment of PD and FT include sulfadiazine, sulfamerazine, sulfathiazole, sulfamethazine, and sulfaquinoxaline (3, 34, 122).

Most of the studies have indicated, however, that appreciable numbers of infected birds remain among medicated survivors (29, 103). Spraying eggs with neomycin sulfate prior to incubation has also been helpful in controlling PD in chicks (157). Dipping contaminated eggs in antibiotic solution containing 400 ppm and 800 ppm of gentamicin was helpful in controlling *S.* Gallinarum in eggs (12). In addition, variable resistance to chlortetracycline and nitrofurazone has been reported among isolates of *S.* Pullorum (90, 135). Similar drug resistance to furazolidone (72, 150, 158, 159), to quinolones (99) and other antibiotics (100) by certain strains of *S.* Gallinarum has been reported.

Paratyphoid Infections

Richard K. Gast

Introduction

The numerous motile members of the bacterial genus *Salmonella* are often referred to collectively as paratyphoid (PT) salmonellae. Found throughout the world, these organisms can infect a very wide variety of hosts (including invertebrate and vertebrate wildlife, domestic animals, and humans) to yield either asymptomatic intestinal carriage or clinical disease. First reported in avian species in 1895 in an outbreak of infectious enteritis in pigeons, PT infections have long been known to cause significant disease losses in young poultry. More recently, PT salmonellae have additionally been identified as important agents of food-borne human disease. Advances in poultry production practices, changes in consumer lifestyles and preferences, and heightened nutritional awareness have all combined to place poultry products among the leading sources of animal protein for much of the world. However, contaminated poultry meat and eggs have also consistently been among the most frequently implicated sources of human *Salmonella* outbreaks. Controlling PT infections in poultry flocks has thus become an important objective from both the economic and public health perspectives.

Economic Significance

Human illnesses resulting from the consumption of poultry products contaminated by *Salmonella* can be expensive for the poultry industry, governments, and affected individuals. The total combined costs of medical care, lost productivity, and premature deaths resulting from food-borne *Salmonella* infections of humans in the United States have been estimated to exceed $2 billion per year (142). Widely circulated media reports regarding *Salmonella* contamination of particular foods can significantly affect consumer demand for those items. International markets for poultry products are increasingly subject to restrictions based on food safety considerations.

Poultry producers also face many direct expenses from *Salmonella* infections in their flocks. Infections acquired vertically from parents or horizontally in the hatchery can cause significant growth depression or even mortality in young chicks or poults. Other diseases or stressful conditions can predispose mature poultry to severe *Salmonella* infections. Conversely, infection with *Salmonella* can increase the susceptibility of birds to other pathogens. Preventing the transmission of salmonellae to progeny or to humans can also be expensive for producers. The cost of risk reduction practices (including biosecurity, cleaning and disinfecting of facilities, rodent control, vaccination, and testing) for controlling *S*. Enteritidis infections in laying flocks in the United States has been estimated to be nearly 1 cent per dozen eggs produced (308).

Public Health Significance

Despite mounting concerns about other pathogens in recent years, *Salmonella* remains among the leading causes of food-borne disease throughout the world. According to the Centers for Disease Control and Prevention (CDC), salmonellae are responsible for at least 1.4 million illnesses, 15,000 hospitalizations, and 400 deaths each year in the United States (430). Widespread commercial distribution of contaminated foods can sometimes involve huge numbers of consumers in *Salmonella* outbreaks. For example, a 1994 *S*. Enteritidis outbreak associated with ice cream in the United States affected 224,000 people (200). *Salmonella* outbreaks can have particularly severe consequences for highly vulnerable populations in facilities such as day care centers and nursing homes.

Poultry products are frequently identified as important sources of salmonellae that cause human illness. An estimated 182,060 Americans became infected with *S. Enteritidis* during 2000 after consuming contaminated eggs (381). Approximately 80% of *S*. Enteritidis outbreaks occurring in the United States between 1985 and 1999 with an identified food source were attributed to eggs (340). Eating contaminated chicken has also been identified as a significant risk factor for *S*. Enteritidis infection (246). Illustrating the importance of poultry as a reservoir for the transmission of salmonellae to humans, many of the serotypes that are most prevalent in humans (such as *S*. Typhimurium and *S*. Enteritidis) are also found commonly in poultry (423).

Etiology

Classification and Nomenclature

The genus *Salmonella* is a member of the bacterial family Enterobacteriaceae and consists of five biochemically distinct subgenera (262). However, subdivision of this genus according to genetic relatedness yields only two species (178). One of these, *S. enterica*, includes more than 2500 motile and non-host-adapted PT serotypes such as *S. enterica* subspecies *enterica* serovar Enteritidis and *S. enterica* subspecies *enterica* serovar Typhimurium. The more traditional and succinct serotype desig-

nations (such as *S.* Enteritidis and *S.* Typhimurium) are still used to provide concise and convenient nomenclature for diagnostic classification and epidemiologic analysis.

Morphology and Staining

Salmonellae are straight, non-spore-forming rods, measuring about 0.7–1.5 × 2.0–5.0 μm. Salmonellae are Gram-negative, but cells can readily be stained with common dyes such as methylene blue or carbolfuchsin. PT salmonellae are usually peritrichously flagellated and motile, although naturally occurring nonmotile mutants are occasionally encountered.

Growth Requirements

Salmonellae are facultatively anaerobic and can grow well under both aerobic and anaerobic conditions. The optimum temperature to support *Salmonella* multiplication is 37°C, but some growth is observed over a range from about 5 to 45°C. Salmonellae can grow within a pH range of approximately 4.0 to 9.0, with an optimum pH around 7.0, although cellular components such as flagella and fimbriae may not be expressed under extreme pH conditions. The nutritional requirements of salmonellae are relatively simple, and most culture media that supply sources of carbon and nitrogen can support their growth. The viability of *Salmonella* cultures can be maintained for many years in simple media, such as peptone agar or nutrient agar, which have been stab-inoculated, sealed, and held at room temperature.

Colony Morphology

Typical *Salmonella* colonies on agar media are about 2 to 4 mm in diameter, round with smooth edges, slightly raised, and glistening.

Biochemical Properties

Typical PT salmonellae (211) ferment glucose (to produce both acid and gas), dulcitol, mannitol, maltose, and mucate, but do not ferment lactose, sucrose, malonate, or salicin. They can produce hydrogen sulfide on many types of media, decarboxylate ornithine and lysine, utilize citrate as a sole source of carbon, and reduce nitrates to nitrites. PT salmonellae do not hydrolyze urea or gelatin and do not produce indole.

Most PT salmonellae can be readily distinguished from the avian host-adapted serotypes, *S.* Pullorum and *S.* Gallinarum, on the basis of the inability of *S.* Pullorum strains to ferment mucate or dulcitol and the inability of *S.* Gallinarum strains to decarboxylate ornithine or produce gas from glucose fermentation. In addition, PT salmonellae are usually motile but *S.* Pullorum and *S.* Gallinarum are typically nonmotile. Strains of *S. enterica* subspecies *arizonae,* a clinically important pathogen of young turkeys, are differentiated from PT salmonellae by their ability to ferment malonate and their inability to ferment dulcitol.

Susceptibility to Chemical and Physical Agents

Physical Agents: Heat and Irradiation

Except for a few distinctively thermoresistant strains (such as *S.* Senftenberg 775W), salmonellae are generally susceptible to destruction by heat. Cooking poultry meat to an internal tempera-

ture of 74°C or higher will dependably destroy salmonellae (380). Heating at 57°C for at least 70 minutes can eliminate salmonellae inside intact eggs (42). Liquid whole egg is pasteurized in the United States according to USDA specifications that require a minimum treatment time of 3.5 min at 60°C (18). However, *Salmonella* can survive cooking methods for eggs that allow some of the yolk to remain liquid (115). Steam pelleting treatment of poultry feed under precisely defined conditions has been reported to kill salmonellae in a manner dependent on temperature, time, and moisture (204). Heating to at least 60°C (at 100% relative humidity) has been reported to provide an effective method for the decontamination of laying houses (177). The heat resistance of *Salmonella* can be increased by heat shock (440) or exposure to alkaline conditions (233), and decreased by refrigeration (373).

Irradiation has also been considered as an option for eliminating salmonellae from foods and feedstuffs. Most *Salmonella* strains appear to be highly susceptible to the lethal effects of irradiation (408). Gamma radiation has been successfully applied to reducing the levels of *Salmonella* contamination in poultry meat (325), egg products (291), shell eggs (401), and poultry feeds (274). Combined heat and radiation treatments have been shown to be more effective in destroying salmonellae than either treatment alone (409). Ultraviolet radiation has been found effective for reducing *Salmonella* contamination of poultry carcasses (432), hatching eggs (11), shell eggs (143), and egg belts (143).

Chemical Disinfectants

Diverse chemical treatments have shown efficacy for reducing the levels of contaminating salmonellae on poultry carcasses and eggs and in poultry facilities. However, recontamination of surfaces after disinfection can sometimes diminish the potential benefits of chemical treatments (37). Moreover, sublethal chemical treatment has been reported to induce bacterial thermotolerance (374). Hydrogen peroxide (313), acetic acid (122), lactic acid (237), potassium sorbate (310), chlorine (310), and trisodium phosphate (41) have all been reported to lower the incidence or level of *Salmonella* contamination on broiler carcasses. Fumigating with formaldehyde (445), hydrogen peroxide (11), or ozone (11), spraying with polyhexamethylene biguanide hydrochloride (87), or dipping in hydrogen peroxide (92), lactic acid (92), or a peroxidase catalyzed compound (264) have all been found to be useful for controlling salmonellae on hatching eggs. Standard commercial application of chlorine-based detergent-sanitizer compounds has demonstrated efficacy against salmonellae on shell eggs (318), as have iodine-based disinfectants (253), electrolyzed oxidizing water (38), and ozone (366).

Chemical disinfectants (especially phenolic and quaternary ammonium compounds) are also widely used in poultry housing facilities. However, cleaning and disinfection were only able to eliminate *S.* Enteritidis from 50% of contaminated laying houses during a large field trial in Pennsylvania (378). Disinfectants may not be effective against all strains of the same bacterial species (375) or against organisms in biofilms (356). The presence of chick fluff, feces, feed, or wood shavings can interfere with the

activity of many disinfectants (34). Some disinfectants also appear to have reduced potency when used with field (well, stream, or pond) sources of water (111). Chemical disinfection of poultry facilities can be compromised by the improper performance of cleaning and disinfection protocols or by recontamination of the environment by infected mice (107, 109). Formaldehyde fumigation can be highly effective for decontaminating poultry facilities (441), but safety considerations have limited its availability and use. Ozone fumigation has also been considered as a safer (although less effective) alternative (441).

Chemical treatment of poultry feedstuffs to inhibit salmonellae has also been evaluated. The inclusion of ethyl alcohol (189) or organic acids such as zinc acetate and zinc propionate (339) has been reported to significantly reduce *Salmonella* levels in experimentally inoculated feed. However, a study of 12 potential antagonists of salmonellae in poultry feed (including organic acids) found that only formalin was consistently effective (391).

Environmental Factors
The environmental persistence of PT salmonellae creates continuous opportunities for horizontal transmission of infection within and between flocks. *S.* Enteritidis has been observed to survive in litter and feed for 26 months after removal of an infected flock (103). However, used litter has sometimes been reported to exert an inhibitory effect on *Salmonella* growth or survival, perhaps because dissolved ammonia leads to a gradual increase in pH over time (415). The addition of lime was shown to increase the pH of poultry litter and reduce *Salmonella* survival (33). Moisture levels are an important supporting factor in allowing the persistence of salmonellae in poultry houses. The numbers of viable *Salmonella* detected in poultry litter have been found to be directly related to water activity levels (130) and accordingly tend to increase in regions of houses with reduced airflow (320).

Antigenic Structure
The traditional Kauffmann-White schema for antigenic classification of salmonellae is based on both somatic and flagellar antigens (133). The somatic "O" antigens are determined by polysaccharides associated with the body of the cell and are identified by arabic numerals. Serogroups (designated with uppercase letters) of salmonellae are defined by particular somatic antigens that are unique to members of the group. Most *Salmonella* isolates found in poultry belong to serogroups B, C, or D. The "H" antigens are determined by flagellar proteins and are usually identified by lower-case letters. Flagellar antigens sometimes occur in two different phases. The serotype of a particular *Salmonella* isolate is determined by the combination of O and H antigens that it expresses. Serotyping of isolates is generally accomplished using agglutination tests with batteries of specific antisera.

Strain Classification
Phage Typing
The differentiation of epidemiologically relevant strains within serotypes is often accomplished by determining their patterns of lysis with a defined set of bacteriophages. Phage typing has sometimes provided better discrimination between strains than antimicrobial susceptibility testing, plasmid analysis, ribotyping, or pulsed field gel electrophoresis (420). The various phage types of *S.* Enteritidis have provided the most widely used point of reference for establishing relationships between isolates from different sources (209). However, the dependability of phage typing is limited by the potential for the conversion of isolates to different phage types by mutation (349) or by the introduction of plasmids (44) or temperate phages (358).

Molecular and Antibiotic Susceptibility Typing
Numerous and diverse genetic analyses have been evaluated for their usefulness in improving the discrimination of epidemiologically relevant *Salmonella* isolates between and within serotypes and phage types. However, no single approach is demonstrably superior for all applications. The various available methods often differ in their relative utility for discrimination within particular serotypes (277). The most successful molecular typing methods for *Salmonella* isolates include pulsed field gel electrophoresis of chromosomal DNA (327), ribotyping (68), random amplification of polymorphic DNA (284), and plasmid profiling (276). The combined use of two or more typing methods frequently provides the most detailed differentiation of *Salmonella* strains (274). The pattern of resistance to antimicrobial agents (the antibiogram) has also been valuable as a *Salmonella* typing tool and is often used in conjunction with molecular analyses (327). These techniques have been reported to be capable of distinguishing between epidemiologically important outbreak strains of salmonellae and unrelated strains (65) and between strains from different geographic locations (226). They have also been used to link isolates obtained from diverse sources within an integrated commercial poultry enterprise (278) and to establish relationships between *Salmonella* isolates from poultry flocks and human disease outbreaks (316).

Virulence Factors
Toxins
Two general categories of toxins have been reported to play roles in the pathogenicity of PT salmonellae. Endotoxin is associated with the lipid A portion of *Salmonella* cell wall lipopolysaccharide (LPS). If released into the bloodstream of an infected animal when bacterial cells are lysed, endotoxin can produce fever. Intravenously administered *S.* Enteritidis endotoxin caused liver and spleen lesions in 2-week-old chickens (416). Lipopolysaccharide also contributes to the resistance of the bacterial cell wall to attack and digestion by host phagocytes. Loss of the ability to synthesize complete LPS has been associated with an impaired ability of *S.* Typhimurium to colonize the ceca and invade to the spleen in broiler chicks (96).

Several proteinaceous toxins have also been identified in *Salmonella*. Enterotoxin activity by salmonellae induces a secretory response by epithelial cells that results in fluid accumulation in the intestinal lumen (259). The heat-stable cytotoxin of salmonellae causes structural damage to intestinal epithelial cells, perhaps by inhibiting protein synthesis (257).

Adherence, Invasiveness, and Intracellular Survival

The adherence of PT salmonellae to intestinal epithelial cells is the pivotal first step in the sequence of events that produces disease. Strains of *Salmonella* with reduced ability to colonize the intestinal tract of chicks also have severely attenuated virulence (417). Both flagella and fimbriae of salmonellae have been extensively investigated as potential mediators of attachment. Mutants of *S.* Enteritidis lacking flagella were reported to exhibit reduced adherence to cultured avian intestinal cells (4) and did not compete effectively with wild-type strains to colonize the ceca of chicks (3). Similarly, *S.* Enteritidis strains lacking fimbriae were less often isolated from the ceca of inoculated chicks than were fimbriated strains (410). Glycosphingolipid and ganglioside receptors in the intestinal mucosa have been identified as relevant to fimbria-mediated attachment of *Salmonella* (273). However, some investigators have concluded that neither flagella nor fimbriae are entirely essential for *S.* Enteritidis colonization of the avian intestinal tract (121, 354). Lipoplysaccharide (O-antigen) has also been proposed to play a role in gastrointestinal attachment by salmonellae (54).

The overall virulence of salmonellae also depends heavily on the degree of mucosal invasiveness following adherence (5). Adherence and invasion appear to be separately regulated activities. Mutations that affected the intestinal colonization of chicks after oral infection with *S.* Enteritidis and *S.* Typhimurium did not affect virulence after intraperitoneal administration (348). Although adherence may not involve ongoing bacterial metabolic activity, the subsequent invasion of host cells requires protein synthesis by live salmonellae (286). The expression of some invasion-related bacterial proteins is evidently induced by contact with epithelial cell surfaces (463). Flagella and some types of fimbriae were found to play a role in *S.* Enteritidis invasion and dissemination to internal organs of chicks (121). Flagella-deficient (but not fimbria-deficient) mutants of *S.* Enteritidis were less able to invade to the livers and spleens of chicks (2). Type 1 fimbriae appear to mediate the colonization of tubular gland cells in the upper oviduct (112). However, other researchers were unable to identify any significant effect on the invasion of enterocytes, ingestion by macrophages, or virulence for chickens when fimbrial genes were inactive (354, 412).

Adherence and invasiveness of salmonellae can be influenced by culture growth conditions. Logarithmically growing *Salmonella* cells are more invasive in tissue culture than are cells in the stationary phase of growth, and salmonellae grown anaerobically have been shown to be both more adherent and more invasive than salmonellae grown aerobically (131, 269). Incubation with acetic acid increased (but incubation with propionic acid decreased) the subsequent invasiveness of salmonellae for chicken cecal epithelial cells (425). The infectivity of *Salmonella* cultures for chicks was lost fairly quickly during combined starvation and desiccation (271). The changing environmental conditions to which an enteric pathogen is exposed during the course of infection in an avian host may induce corresponding changes in the expression of virulence-related genes (127). For example, the high oxygen level and nutrient availability experienced in the gut might promote an invasive bacterial phenotype, but lower oxygen levels and nutrient availability after invasion might induce a different set of virulence proteins (185). Several characterized virulence genes are indeed apparently induced following invasion into cells (343). Different patterns of protein synthesis by *S.* Typhimurium have been observed within intestinal epithelial cells, macrophages, and liver cells (47).

The replication of salmonellae within host cells is also apparently necessary for the full expression of pathogenicity (272). Mutants of *S.* Typhimurium that were unable to survive within host macrophages (141) or to resist the antimicrobial effects of host peptides (179) were reported to exhibit reduced virulence. Both growth and killing of *Salmonella* seemingly occur simultaneously within macrophages (46). Salmonellae that survive after phagosome/lysosome fusion in the macrophage (330) may eventually destroy the macrophage itself (280). The production of iron-chelating siderophores may also contribute to the *in vivo* survival of salmonellae (459).

Plasmids

Plasmids are transmissible extrachromosomal DNA elements that have often been associated with bacterial pathogenicity. Serotype-specific plasmids of characteristic molecular weights have been directly linked with virulence for several salmonellae. Considerable homology has been demonstrated between virulence-associated plasmids of different serotypes (66). *Salmonella* strains cured of their virulence-associated plasmids have been found to be significantly less lethal for mice (198) and less persistent in the ceca of chicks (429). Plasmid-mediated virulence among *S.* Typhimurium and *S.* Enteritidis isolates has been variously associated with invasion of mesenteric lymph nodes, livers, and spleens (186), survival and multiplication in serum (62), intracellular growth (187), lysis of macrophages (184), and immunosuppression (207).

The pathogenicity of salmonellae, however, does not always require the presence of the serotype-specific plasmids. Some strains of *S.* Typhimurium, for example, have been shown to retain their invasiveness in cell culture assays (225) and their lethality for infected mice (337) in the absence of virulence-associated plasmids. Moreover, although a serotype-specific plasmid was found to be essential for the full expression of virulence by *S.* Enteritidis in mice, curing this plasmid did not affect *S.* Enteritidis colonization and invasion of the tissues of orally inoculated chickens (190).

Pathogenicity Differences of Strains, Serotypes, and Phage Types

Strains of PT salmonellae can differ greatly in their abilities to induce pathological effects in poultry. Significant disparities have been reported between *Salmonella* serotypes in the frequencies at which they cause mortality in chicks (370) or invade reproductive organs and contaminate eggs in mature hens (331). These virulence differences appear to be independent of the route of infection (301). However, lethality for chicks can also vary tremendously within single *Salmonella* serotypes, sometimes even among strains of the same phage type (25). Pathogenicity

differences between the various phage types of *S.* Enteritidis have been extensively investigated, with phage type 4 sometimes associated with a particularly high level of invasiveness (20) and lethality (152) for newly hatched chicks. However, in experimental infection studies with chickens, phage type 4 strains yielded similar frequencies of intestinal colonization, invasion to spleens, horizontal transmission, and egg contamination as isolates of other phage types (153, 160). Considerable dissimilarity in metabolic properties has been found to exist within as well as between *S.* Enteritidis phage types (307). Differences between strains of *S.* Enteritidis, crossing phage-type boundaries, have been noted in both virulence for chicks (152) and egg contamination by hens (387). Even within the same clonal genomic lineage, *S.* Enteritidis strains may not have the same virulence properties (335).

Several bacterial characteristics have been identified as contributing to the observed pathogenicity differences between *Salmonella* strains. Although some virulence genes are distributed rather widely in *Salmonella* isolates from diverse sources (401), an analysis of genes induced *in vivo* indicated that regions associated with some virulence attributes have accumulated differentially in individual strains (71). Properties including heat and acid tolerance (236), motility (270), mannose-sensitive hemagglutination (270), and the ability to invade and survive inside cultured cells (328) have been linked to the virulence of *Salmonella* isolates. Invasive properties of *S.* Enteritidis variants have been found to depend on quantitative and qualitative differences in LPS expression (342). The virulence of *S.* Enteritidis isolates for chicks and the frequency of deposition of these strains in eggs laid by infected hens have been associated with both the production of large amounts of high-molecular-weight LPS and with the ability to grow to unusually high cell densities in broth cultures (180, 181). The expression of some *Salmonella* virulence properties appears to be inducible *in vivo*, as strains reisolated from infected laying hens have displayed an increased ability to cause egg contamination (155).

Pathobiology and Epidemiology

Incidence of Salmonellae in Poultry and Poultry Products

Estimates of the incidence of *Salmonella* in meat-type poultry and poultry house environments have varied considerably. For example, surveys of turkey flocks have reported the isolation of salmonellae from 79% of litter samples and 70% of fecal samples in one study (376) and from 13% of litter samples and 11% of cecal samples in another (326). Likewise, surveys of the incidence of *Salmonella* infection in broiler flocks have yielded 39% positive results in one study (52) and 5.5% in another (435). *Salmonella* isolation rates can change considerably from year to year for flocks in a single country (134). The actual prevalence of infection or contamination within *Salmonella*-positive flocks can also vary widely, but appears to usually be relatively low (341). Investigators in the USA reported that the frequency of *Salmonella* isolation from broiler breeder hatcheries increased from 11% to 16% between 1991 and 1998, but the proportion of

samples that were heavily contaminated declined from 36% to 4% over the same time period (93).

Surveys of egg-type poultry have similarly generated diverse results, reporting the recovery of salmonellae from 72% of laying house environmental samples in one study (239) and from 53% of environment and fecal samples in another (345). In a national survey in the USA, 7.1% of commercial laying houses were positive for *S.* Enteritidis (144). The number of *Salmonella* found in individual environmental samples is typically relatively low, although somewhat higher levels can be evident at the beginning of egg-laying and molting (364). The distribution of salmonellae within contaminated laying houses is not necessarily uniform, as illustrated by work in the USA which reported that 10.5% of laying houses, but only 1.1% of individual cage rows within these houses, were positive for *S.* Enteritidis (56).

Surveys of poultry carcasses and meat products have provided dramatically divergent results for different countries in recent years. Intense pathogen reduction programs have led to significant reductions over time in the incidence of *Salmonella* contamination on broiler carcasses in some nations (418, 448). For example, only 5.7% of carcasses in Wales (299) and 10% of carcasses in Belgium (173) were found to be contaminated with salmonellae. On the other hand, *Salmonella* contamination continues to occur at very high frequencies in other countries, as demonstrated by reports that 40% of poultry meat samples from Mexico (460) and 57% of such samples from Thailand (338) were positive. The number of *Salmonella* cells found on contaminated poultry meat products has generally been relatively low. *Salmonella* counts of only about 32 cells (even after storage for 7 days) were observed in carcass rinses in one investigation (16). Another study (431) found only 1–30 *Salmonella* organisms per broiler carcass. Increasing incidences of *Salmonella* contamination at progressively later processing stages suggest cross-contamination of carcasses (53).

Contamination of eggs with salmonellae has also become an important issue since the mid 1980s. *Salmonella* contamination has been reported in 3% to 4% of table eggs in Italy and Brazil (48, 405) and in 19% of liquid egg samples in Japan (316). Field studies of commercial poultry in the USA observed *S.* Enteritidis egg contamination frequencies of less than 0.03% from environmentally positive flocks (250, 378). The U.S. Department of Agriculture estimated the overall national incidence of egg contamination with *S.* Enteritidis at approximately 0.005% (128).

Distribution of Salmonella *Serotypes*

Although more than 2500 serotypes of *Salmonella* have been identified, only about 10% of these have been isolated from poultry. Moreover, an even smaller subset of serotypes accounts for the vast majority of poultry *Salmonella* isolates. The distribution of *Salmonella* serotypes from poultry sources varies geographically and changes over time, although several serotypes are consistently found at a high incidence. Based on data from clinical and environmental isolates submitted to the U.S. Department of Agriculture National Veterinary Service Laboratory between July 2002 and June 2003, the most commonly identified PT serotypes were *S.* Heidelberg, *S.* Kentucky, *S.* Typhimurium, *S.*

Braenderup, and *S.* Enteritidis in chickens and *S.* Senftenberg, *S.* Heidelberg, *S.* Hadar, *S.* Muenster, and *S.* Kentucky in turkeys (140). The important epidemiological connection between the poultry and human reservoirs of salmonellae is sometimes evident in similarities in the distribution of serotypes reported from these sources. Of the 10 serotypes most often reported to the Centers for Disease Control and Prevention from human sources in the United States in 2003 (*S.* Typhimurium and *S.* Enteritidis were most common), 5 appeared on similar lists for either chickens or turkeys during approximately the same period (140). The implementation of intensified food safety regulations in Australia led to changes in the relative incidences of *Salmonella* serotypes, but a significant linkage still remained between the serotypes found in poultry and those associated with human illness (400).

Reports of the frequency of isolation of *Salmonella* serotypes from poultry sources around the world have yielded a wide range of results, although several serotypes appear to be of continuing international significance. The unique epidemiologic association of *S.* Enteritidis with disease transmission via contaminated eggs has made the prevalence of this serotype a topic of particular interest. *S.* Enteritidis has been the most common serotype found in surveys of eggs from Italy (48), chicken carcasses from Poland, Spain, and Korea (51, 67, 300), and chicken flocks in Turkey and the Netherlands (52, 423). Other serotypes that have been found to be most prevalent in individual situations include *S.* Heidelberg in broilers, broiler breeders, and turkeys in Canada (182), layers in the USA (247), and turkeys in Denmark (341); *S.* Typhimurium in broiler chickens in the USA (278); *S.* Infantis and *S.* Livingstone in Japanese poultry environments (316, 317); and *S.* Kentucky and *S.* Agona in poultry meat in the USA (283, 462).

Natural and Experimental Hosts

Paratyphoid Infections in Young Poultry

PT infections often have far different consequences for newly hatched poultry than for more mature birds. In very susceptible young chicks and poults, PT infection can sometimes lead to illness and death at high frequencies. Older birds are considerably less susceptible to the lethal effects of PT salmonellae and may experience intestinal colonization and even systemic dissemination without significant morbidity or mortality. The development of resistance to salmonellae in young birds has often been attributed to the acquisition of protective microflora that either compete with salmonellae for intestinal receptor sites or produce antagonistic factors that inhibit *Salmonella* growth (398). Accordingly, significantly more orally administered *S.* Typhimurium cells adhered in the ceca of 2-day-old chicks than in those of 3- to 7-day-old chicks (146). Such resistance may begin to develop as early as 36 hours after hatching (27).

PT infection has been established by oral, intracloacal, intratracheal, intraocular, navel, and aerosol administration to chicks (86). The usual outcomes of PT infections in chicks and poults involve three stages. Orally introduced PT salmonellae first establish intestinal colonization, often resulting in persistent shedding in the feces. Naturally occurring, horizontal transmission of salmonellae may involve a slower course of infection than is typ-

ically seen in oral inoculation experiments (312). Second, invasion beyond the gastrointestinal tract can lead to *Salmonella* multiplication in the macrophage-phagocyte system of the liver and spleen (25) and eventual dissemination to colonize a variety of internal tissue sites. Third, extensive bacteremia sometimes occurs, occasionally causing high mortality. The incidence of both mortality (136) and intestinal colonization (372) in chicks correlates strongly with the dose of orally administered salmonellae.

Mortality associated with naturally occurring PT infections in poultry is often observed to reach peak levels at about 3 to 7 days of age (309). Studies of experimental PT infections in young poultry have consistently shown that newly hatched birds are highly susceptible to salmonellae, but this susceptibility decreases over time. For example, oral doses of 10^9 *S.* Typhimurium cells were lethal for 50% of 1-day-old broiler chicks, 20% of 3-day-old chicks, and no 7-day-old chicks (136). Age-associated declines in mortality have also been noted for infections with *S.* Enteritidis and *S.* Hadar in chicks (118, 123) and *S.* Typhimurium in turkey poults (39).

The frequency of both intestinal colonization (372) and invasion to internal organs (118) is higher in newly hatched chicks than in older birds. The persistence of salmonellae in various colonization sites is also influenced by the age of the birds when infected (123). Persistent gut colonization was observed after infection of chicks with various *Salmonella* serotypes within 2 days of hatching, but not when infected at 3 weeks (27). Horizontal contact exposure of chicks within 24 hours of hatching has been reported to result in fecal shedding of *S.* Enteritidis for at least 28 weeks (321). Intestinal persistence of *S.* Typhimurium and *S.* Enteritidis was far greater following oral inoculation of chicks at 1 day of age than at 7 days (35, 146). Administration of 10^2 *S.* Enteritidis cells to one-day-old chicks led to a more persistent intestinal infection than administration of 10^9 cell to one-week-old birds (426). After oral inoculation of chicks at 1 day of age, *S.* Enteritidis persisted in the intestinal tract and was shed in the feces of almost half of these birds at 24 weeks of age (158). Other investigators determined that a few chicks infected with *S.* Enteritidis at 2 days of age remained infected for up to 64 weeks (344). Age-related decreases in susceptibility to persistent *S.* Enteritidis infection have likewise been observed in the internal organs of orally inoculated chicks (116). Some internal organs have been reportedly positive for *Salmonella* as long as one year after inoculation of chicks at one day of age (389).

Paratyphoid Infections in Mature Poultry

Morbidity and mortality are not consistently associated with PT infections in mature poultry. Experimental infections of adult chickens with large oral doses of PT salmonellae have often been reported to cause no evident signs of clinical illness (228). Although oral inoculation of laying hens with *S.* Enteritidis resulted in frequent bacteremia and extensive systemic dissemination to internal organ sites, the inoculated birds remained clinically normal except for some brief mild diarrhea (414). However, other investigators observed that six of ten 1-year-old hens died after oral inoculation with a phage type 4 *S.* Enteritidis isolate (232).

The two most consistently observed features of PT infections in mature poultry are intestinal colonization and systemic dissemination to internal organs. During approximately the first 2–4 weeks following experimental oral infection of chickens or turkeys, PT salmonellae can generally be isolated from the intestinal tracts and voided feces of a high percentage of inoculated birds (147). Although the incidence of intestinal colonization and fecal shedding steadily declines thereafter, some *S.* Enteritidis strains have been shown to persist in the intestinal tract of laying chickens for several months after oral inoculation (148, 387).

Gut colonization by PT salmonellae is usually followed by invasion through the intestinal epithelium and dissemination to diverse internal organ sites. Although various other serotypes (including *S.* Typhimurium, *S.* Heidelberg and *S.* Infantis) are also known to be invasive for poultry, the patterns and consequences of systemic dissemination have been documented most extensively for *S.* Enteritidis. After experimental oral inoculation of laying hens, *S.* Enteritidis has been isolated from numerous internal tissues, including the liver, spleen, ovary, oviduct, heart blood, and peritoneum (148, 414). Dissemination of *S.* Enteritidis to diverse internal organs, including the ovary and oviduct, has also been recorded following intravenous (156), intratracheal (322), conjunctival (229), intravaginal (305), or intracloacal (305) inoculation, exposure to contaminated aerosols (156), or insemination with contaminated semen (360). The isolation of *S.* Enteritidis from a wide range of internal organs has similarly been reported in naturally infected poultry (222).

Another aspect of infections of mature chickens with some PT salmonellae that is of particular concern from a public health perspective is the production of *Salmonella*-contaminated eggs. Investigations of laying flocks implicated as the sources of eggs that caused human disease outbreaks have sometimes detected *S.* Enteritidis isolates of the same phage types found in affected humans, often with identical plasmid or chromosomal DNA profiles, in environmental samples, tissue samples, and eggs (201). Internal contamination of eggs with *S.* Enteritidis is usually postulated to be a consequence of highly invasive behavior that leads to colonization of the ovary and oviduct (242). A few other PT serotypes including *S.* Heidelberg (154) and multiple antibiotic-resistant *S.* Typhimurium DT104 (444) have been deposited inside eggs laid by experimentally infected hens.

The reported incidence of *S.* Enteritidis contamination of eggs laid by commercial flocks has usually been extremely low. In studies of 17 naturally infected laying flocks in the United Kingdom, *S.* Enteritidis was found in the contents of less than 1% of the eggs sampled (230). In two Canadian layer flocks that yielded *S.* Enteritidis isolates from both environmental and tissue samples, less than 0.06% of the eggs sampled were contaminated (346). In the USA, 18 of 60 commercial flocks with *S.* Enteritidis in their environments produced contaminated eggs, at a prevalence of 0.0264% (201). Naturally contaminated eggs have generally been found to contain very small numbers of *S.* Enteritidis (235), but the *S.* Enteritidis population in eggs can expand to more dangerous levels if eggs are held at growth-promoting temperatures (151). Contamination of egg contents by *Salmonella* has also been demonstrated in experimentally infected laying hens (156, 388). After oral inoculation of hens, *S.* Enteritidis has been detected in both yolk and albumen, although typically at levels of only a few cells of the pathogen per ml of liquid egg contents (147, 160). Initial *Salmonella* deposition is more likely to occur in association with the albumen or vitelline membrane than with the interior contents of the yolk (161).

Predisposing Factors

A number of factors have been demonstrated to increase the likelihood or severity of PT infection in poultry. Several other infectious agents have been reported to influence the course of infection with salmonellae. Prior infection with coccidia such as *Eimeria tenella* can increase the ability of diverse *Salmonella* serotypes to colonize the intestinal tracts of chickens (351). Exposure to *E. tenella* caused recrudescence of a previous *S.* Enteritidis infection in chickens (352). Decreased levels of *Salmonella*-inhibiting volatile fatty acids and an increased oxidation-reduction potential in the intestine may follow coccidial infection (8). Infection with *E. tenella*, however, was observed to decrease the frequency at which subsequently administered *S.* Enteritidis invaded to the internal organs of chicks, possibly by increasing the thickness of the intestinal lamina propria (406). Prior coccidial infection did not affect organ invasion or the production of internally contaminated eggs by hens inoculated with *S.* Enteritidis (353). Infections of poultry with immunosuppressive viruses or bacteria can also affect the outcome of *Salmonella* infections. Exposure to reticuloendotheliosis virus at 1 day of age increased mortality among chicks inoculated intraperitoneally with *S.* Typhimurium at 1, 7, or 14 days of age (311). Exposure of 1-day-old chicks to infectious bursal disease virus was associated with increased mortality following subsequent *S.* Typhimurium infection (457) and increased gross lesions following inoculation with *S.* Enteritidis (344). Suppression of cell-mediated immunity by *Corynebacterium parvum* led to increased morbidity in chicks subsequently infected with *S.* Typhimurium (85).

Environmental and management factors can also influence the susceptibility of poultry to PT salmonellae. Stressful conditions have often been shown to facilitate or exacerbate *Salmonella* infections. Overall flock health, manure management, ventilation, and watering systems have all been identified as relevant risk factors for *S.* Enteritidis infection in commercial laying flocks in the USA (56). Housing inoculated chicks at a high density in unsanitary conditions was reported to increase cecal carriage of *S.* Enteritidis (7). Lowering the brooding temperature of chicks by 5 to 8° C significantly increased mortality among newly hatched chicks inoculated with *S.* Worthington (407). Water deprivation before inoculation of 7-week-old chickens increased the duration of fecal shedding of orally administered *S.* Typhimurium (45). Feed withdrawal from broiler chickens before slaughter has been linked to increased *Salmonella* contamination of crops (77). In experimental infection studies with *S.* Enteritidis, the induction of molting in laying hens by feed deprivation was reported to increase the incidence and level of fecal shedding (214), the incidence and severity of intestinal lesions (347), the numbers and extent of distribution of *S.* Enteritidis within the intestinal tract

(219), invasion to livers and spleens (219), and horizontal (213) or airborne (220) transmission of infection. Molting also reduced the infectious dose of *S.* Enteritidis necessary to establish intestinal colonization in hens (212) and increased the likelihood of recurrence of previous *S.* Enteritidis infections (221). Feed deprivation appears to lower crop levels of protective lactobacilli and volatile fatty acids while increasing pH (126). A national study in the USA identified induced molting as a significant risk factor for the likelihood of laying flocks being infected with *S.* Enteritidis (144). Recent studies have shown that molting can be induced via alternative diets, including wheat middlings and alfalfa, without causing increased susceptibility to *Salmonella* (382, 452).

Sources, Vectors, and Transmission

PT salmonellae can be introduced into poultry flocks from many different sources. Feeds have often been identified as likely sources of *Salmonella* because of contaminated animal proteins and other ingredients (369). Dust in feed mills is another potential source of introduction of salmonellae into finished feeds (238). Contamination by salmonellae has been reported in 58% of finished feed (mash) samples and 92% of meat and bone meal samples (91). Meal and mash feeds are more often implicated as sources of *Salmonella* than are pelleted feeds (91, 369). The serotypes of salmonellae isolated from live poultry and carcasses have sometimes (but not always) been correlated with the serotypes found in feedstuffs (428, 461). A Japanese study reported similar chromosomal DNA patterns for *S.* Enteritidis isolates obtained from feed given to a commercial laying flock and the contents of eggs laid by these birds (386). Experimental inoculation studies have demonstrated that chicks can be readily infected by very low levels of PT salmonellae in their feed (206). Salmonellae have survived for two years in artificially inoculated feeds (108).

The extremely wide host range of PT salmonellae creates an equally large number of reservoirs of infectious organisms. Biologic vectors can both disseminate and amplify salmonellae in poultry flocks. In a study of 10 egg-laying farms in the United Kingdom, molecular fingerprinting linked *S.* Enteritidis isolates from wildlife vectors, the farm environment, mice, eggs, and hens (275). Insects and other invertebrates, including flies (334), litter or darkling beetles (390), ground beetles (103), cockroaches (258), and centipedes (103) can carry *Salmonella* organisms externally (and sometimes internally). Mice have been identified as particularly important vectors for *S.* Enteritidis in laying flocks (378). A large study of commercial laying flocks in the USA indicated that the prevalence of *S.* Enteritidis in mice from environmentally positive poultry houses was nearly four times greater than from negative houses (144). A single mouse fecal pellet can contain 10^5 *S.* Enteritidis cells (202). Diverse wild birds can carry *Salmonella* infections (359) and contact with wild birds or their droppings has sometimes been identified as a risk factor for commercial poultry (97, 108). Humans can also be a source of salmonellae transmissible to poultry, as shown by a California sewage treatment plant that apparently spread infection to both wild animals and a commercial laying flock (249).

Vertical transmission of PT salmonellae to the progeny of infected breeder flocks can result in internal or external contamination of eggs. Egg shells are often contaminated with PT salmonellae by fecal contamination during oviposition. The penetration of salmonellae into or through the shell and shell membranes can result in direct transmission of infection to the developing embryo or can lead to exposure of the chick to infectious *Salmonella* organisms when the shell structure is disrupted during hatching. Some PT serotypes, particularly *S.* Enteritidis*,* can be deposited in the contents of eggs before oviposition (147, 242). The resulting transovarian transmission of infection to progeny is an important aspect of the epidemiology of *S.* Enteritidis in chickens. The same *Salmonella* serotypes responsible for mortality in naturally infected chicks and poults have often also been isolated from their parent flocks (263, 309). A survey of 10 farms in France led to the conclusion that the greatest contribution to the eventual distribution of *Salmonella* serotypes in broiler houses came from the chicks themselves and not from their environment (266).

Any PT salmonellae carried in or on eggs can be spread extensively in the hatcheries. As chicks or poults pip through egg shells, salmonellae are released into the air and circulated around hatching cabinets on contaminated fluff and other hatching debris. One study found *Salmonella* on 17% of egg shell samples and 21% of chick rinse samples obtained from commercial broiler hatcheries in the USA (13). Another study similarly isolated salmonellae (of 12 different serotypes) from more than 75% of samples of egg fragments, belting material, and paper pads from broiler hatcheries (89). Newly hatched birds, lacking protective intestinal microflora, are highly susceptible to intestinal colonization by salmonellae. Nearly 44% of chicks from uncontaminated eggs became infected with *S.* Typhimurium when hatched along with surface-contaminated eggs (55). The prevalence of *Salmonella* in broiler hatcheries has been found to be greater than at other production stages and the serotypes found in hatcheries have correlated with those isolated from finished carcasses (14).

PT salmonellae can also spread horizontally within and between flocks. Strains of 10 *Salmonella* serotypes spread rapidly from infected day-old chicks to penmates reared on litter (393). *S.* Enteritidis has been found in the feces and internal organs of uninoculated laying hens housed in cages adjacent to those of orally inoculated birds (147, 148). Contaminated poultry house environments are often implicated as leading sources of PT salmonellae (263). One investigation concluded that *Salmonella* serotypes present in broiler houses or introduced into houses by vectors during the rearing period were more likely to appear on processed carcasses than were serotypes originating in the hatchery (265). Studies in Dutch and Japanese laying flocks have likewise suggested that infection was more likely acquired from farm environments than from breeding stocks (421, 458).

Horizontal transmission can be mediated by mechanisms including direct bird-to-bird contact, ingestion of contaminated feces or litter, contaminated water, or personnel and equipment. *Salmonella* isolation from the environment of turkey poults was reported to reached peak levels by two weeks after the placement of infected birds in the house (223). Another study (108) reported that *S.* Enteritidis persisted for at least 1 year in dust in an empty

poultry house (even after cleaning and disinfection). In France, 70% of examined flocks had *Salmonella*-positive dust or litter samples (369). Air samples collected both inside and outside of five commercial laying facilities were positive for salmonellae (110). Airborne transmission of experimental *S.* Enteritidis infection has been demonstrated, perhaps mediated by contaminated dust (165). Negative air ionization has been proposed as a mechanism for reducing *Salmonella* transmission in poultry flocks by limiting the circulation of contaminated dust particles. In experimental settings, ionizers have reduced both airborne dust levels and the airborne transmission of *S.* Enteritidis infection to chickens (363).

Clinical Signs

PT infection of poultry is usually associated with disease only in very young birds. The contamination of eggs with salmonellae may lead to a high level of embryo mortality and the rapid death of newly hatched birds before clinical signs are observed. Morbidity and mortality can be high during the first 2 weeks of life, with significant body weight loss or growth retardation (120), but signs of disease are observed much less often in older birds. The course of illness is normally relatively brief in individual birds. Signs of severe PT infection in young poultry are generally similar to those observed in connection with other avian *Salmonella* infections (pullorum disease and fowl typhoid) and with other bacteria that can cause acute septicemia. Although clinical disease is not normally associated with PT infections in mature poultry, some *S.* Enteritidis strains have been found to cause anorexia, diarrhea, and reduced egg production in experimentally infected laying hens (147, 387).

Typical signs of PT infection in chicks and poults include progressive somnolence with closed eyes, drooping wings, and ruffled feathers. Anorexia and emaciation are common. Affected birds are often seen to shiver and huddle near heat sources. Profuse watery diarrhea is frequently observed, often resulting in dehydration and pasting of the vent area. Blindness and lameness have occasionally been reported.

Pathology

In severe outbreaks of PT infection in newly hatched poultry, rapidly developing septicemia can cause a high incidence of mortality with few or no apparent lesions. When the course of disease is longer, severe enteritis is often accompanied by focal necrotic lesions in the mucosa of the small intestine. Cheesy cecal cores are sometimes observed. Spleens and livers are commonly swollen and congested, with evident hemorrhagic streaks or necrotic foci. Kidneys may also sometimes be enlarged and congested. Fibrinopurulent perihepatitis and pericarditis have been reported on numerous occasions. Slight inflammatory processes with heterophil infiltration ranging from focal to diffuse in distribution have been observed in the ovaries and oviducts of flocks naturally infected with *S.* Enteritidis (222). Unabsorbed, coagulated yolk material may be present in the yolk sac. Other lesions occasionally observed include peritonitis, yolk sac infection, pneumonia, hypopyon, panophthalmitis, purulent arthritis, serous typhilitis, airsacculitis, and omphalitis (370).

Pathogenesis of the Infectious Process

Although salmonellae can invade epithelial cells throughout the intestinal tract, the ceca and the ileocecal junction are often sites of particular affinity (416). After oral inoculation of day-old chicks, *S.* Enteritidis was observed to adhere to epithelial cells at the tips of villi (117). The invasion of intestinal epithelial cells by salmonellae leads to a series of pathologic changes that affect intestinal fluid and electrolyte regulation. This process can ultimately cause cell death and thereby produce and exacerbate diarrhea. Oral inoculation of laying hens with *S.* Enteritidis can produce inflammation of the epithelium and lamina propria of the colon and ceca related to heterophilic infiltration (199). In addition, epithelial invasion may also allow the removal of salmonellae through the basement membrane into the lamina propria by macrophages (43). *S.* Enteritidis was recovered from several internal organ sites of laying hens within as little as 1 hour after oral inoculation (231). The ability of salmonellae to survive and multiply in internal organs, particularly the liver and spleen, has been correlated with the comparative virulence of salmonellae in different host species (24). The spleen may provide a protected site where intracellular bacterial multiplication can continue without exposure to host defense mechanisms (125).

Immunity and Resistance

The immune response of poultry to PT salmonellae minimizes the duration and severity of infection and protects against reinfection. This response also permits the serologic detection of infected flocks and serves as the basis for efforts to protect birds against infection by vaccination. The development of immunity was demonstrated when oral reinfection of chickens with *S.* Typhimurium (10 weeks after the initial inoculation) resulted in reduced fecal shedding and more rapid clearance from tissues than was observed in previously uninfected birds (196). Administering immunosuppressive agents to chicks has been reported to increase mortality associated with PT infection (129). The progeny of immune laying hens can apparently acquire some degree of protective immunity (35). However, the development of protective immunity against further *Salmonella* challenges does not necessarily lead to the clearance of ongoing, persistent infection (399). Moreover, *Salmonella* infection of chickens can also cause lymphocyte depletion, atrophy of lymphoid organs, and immunosuppression, thereby facilitating the establishment of a persistent carrier state (193).

PT salmonellae can elicit strong antibody responses from infected poultry. Serologic positivity to *S.* Enteritidis and *S.* Typhimurium was reported to persist in different groups of infected chickens throughout a one-year study period (389). Experimental infection of chicks with *S.* Typhimurium induced strong IgG, IgA, and IgM responses in serum, intestinal contents, and bile which could be detected by antigens composed of whole bacterial cells, LPS, flagella, and outer-membrane proteins (196). When laying hens were orally infected with *S.* Enteritidis, serum antibodies were produced by most birds by 1 week postinoculation and reached peak values at 2 weeks postinoculation (149, 162). High serum IgG titers have been detected in laying hens for at least 27 weeks after experimental oral inoculation

with *S.* Enteritidis (26). In a naturally infected broiler breeder flock, 70% of the birds were found to be positive for serum antibodies to *S.* Enteritidis LPS at 35 weeks of age (76). Antibodies to *S.* Enteritidis have also been found in the yolks of eggs laid by infected hens. Specific antibodies were found as early as 9 days postinoculation and reached peak levels at 3–5 weeks postinoculation in eggs from hens experimentally infected with *S.* Enteritidis (150). Antibodies to *S.* Enteritidis have also been detected in eggs from naturally infected flocks (76).

Although less completely characterized than the antibody response, cell-mediated immunity to PT salmonellae has also been observed in poultry. A strong delayed hypersensitivity reaction was detected, using either whole bacterial cells or outer membrane proteins, between 2 and 5 weeks after experimental infection of chicks with *S.* Typhimurium (196). Heterophils of chickens and turkeys are strongly phagocytic and bactericidal for salmonellae (396) and apparently play a vital role in restricting organ invasion during the early phases of *S.* Enteritidis infection (256). The phagocytic and bactericidal activities of avian heterophils increase substantially during the first few weeks of life (439). Cytokines produced by sensitized T lymphocytes may play a particularly important role in conferring immunity on poultry, perhaps by expanding the pool of circulating phagocytic heterophils (254) and recruiting them to the site of infection (255).

The relative contributions of the antibody and cell-mediated responses in providing poultry with protective immunity against *Salmonella* infection have not been completely resolved. Strong antigen-specific cellular and humoral immune responses have both been temporally linked to clearance of *S.* Typhimurium infection in chickens (31). Likewise, a decline in the isolation of *S.* Enteritidis from reproductive tissues of laying hens during the second week of infection was associated with the proliferation of both T and B cells (450). Bursectomized chickens, deficient in the ability to mount an antibody response, were less able to clear *S.* Enteritidis infection from the intestinal tract and internal organs (119). Increased IgG and IgM levels in oviducts of experimentally infected hens were followed by partial clearance of *S.* Enteritidis (449). A group of hens infected with *S.* Enteritidis at 20 weeks of age produced high levels of IgM antibodies and showed no adverse signs, whereas a group of hens infected at 1 year of age produced much lower levels of antibodies and experienced significant mortality (232). However, other investigators have suggested that cellular responses are more critical for effective immunity (451). In one study, B cells were not found to play an essential role in the clearance of *S.* Typhimurium infection in chickens despite the induction of high antibody levels (29). In another study, intestinal clearance of experimental *S.* Enteritidis infection in chickens did not correlate with the musocal IgA response (218). Both the opsonic activity of specific antibodies and the phagocytic and lytic activity of cellular effectors may be necessary for the full expression of immunity (298). In addition to the antigen-specific adaptive immune responses, innate host phagocytic capabilities also contribute significantly to resistance against infection by salmonellae. Chicken macrophages have been reported to internalize higher numbers of *S.* Enteritidis cells and to clear intracellular salmonellae more rapidly than lymphocytes (260).

Genetically based differences in the innate resistance and immunity of lines of chickens to *Salmonella* infection have been widely discussed and studied in recent years. Chicks from distinct lines have been found to vary in their susceptibility to the lethal effects of *Salmonella* infection (183). Differences in the incidences of fecal shedding, organ invasion, and egg contamination have been observed between lines of mature chickens infected with *S.* Enteritidis (124, 174). Both innate and adaptive mechanisms have been proposed to explain differences in *Salmonella* susceptibility between lines of chickens. Macrophages from resistant lines showed greater and more rapid expression of pro-inflammatory cytokines and chemokines upon *Salmonella* challenge (443). Resistance to *S.* Typhimurium infection has also been correlated with an increased T cell response (30). However, although another study found reproducible significant differences between lines of chickens in the level and duration of fecal shedding of several *Salmonella* serotypes, no corresponding significant differences in antibody titers or circulating heterophil numbers were evident (22).

Diagnosis

Although clinical observations may suggest the likelihood of a PT infection, final diagnosis depends on the isolation and identification of causative organisms. Using conventional culture methods, this requires 48 to 96 hours (and even longer for some culturing protocols). A concise summary of traditional methods for isolating salmonellae from poultry was provided by Waltman *et al.* (434). Numerous faster alternative strategies for detecting and identifying salmonellae have also been proposed in recent years. Serologic detection of specific antibodies is often employed effectively as a rapid preliminary screening device to identify flocks that have been exposed to salmonellae.

Isolation and Identification of Causative Agent
Sample Selection
To identify PT infection in poultry flocks, samples are obtained and cultured from a variety of sources, principally including tissues, eggs, and the poultry house environment. The number of samples that must be processed to achieve a predetermined level of confidence of detection of PT infection in a flock is directly related to the size of the flock and inversely related to the actual prevalence of infection (1). In very large flocks estimated to have very low prevalences of *Salmonella* infection, samples from more than one bird are often pooled together before culturing to allow an adequate sample size to be attained within the limitations of existing laboratory resources.

As many PT *Salmonella* serotypes are highly invasive and can be systemically disseminated to numerous internal tissues, a diversity of different sites (including the liver, spleen, ovary, oviduct, testes, yolk sac, heart, heart blood, kidney, gallbladder, pancreas, synovia, and eye) can provide samples for diagnostic culturing. As lesions cannot be relied upon to indicate infected tissues, several different organs should be cultured from each bird (separately or together). As some highly invasive PT serotypes, particularly *S.* Enteritidis*,* can be deposited in the con-

tents of eggs before oviposition, culturing eggs has been applied as a test for assessing the potential threat to public health posed by infected laying flocks.

Because infections of poultry with PT salmonellae almost invariably involve colonization of the intestinal tract, samples of intestinal tissues and contents are frequently the focus of *Salmonella*-culturing efforts. In a survey of birds submitted to a diagnostic laboratory, salmonellae were found exclusively in intestinal samples in 78% of the chickens and 70% of the turkeys (135). In experimentally inoculated laying hens, *S.* Enteritidis was recovered more often from the intestinal tract than from any other tissue sampled (148). The caudal ileum, ceca, cecal tonsils, and cecal contents are the intestinal sites most often recommended for recovering salmonellae. Cloacal swabs or samples of voided feces have been used to provide evidence of persistent intestinal colonization by salmonellae in individual birds. The often intermittent pattern of shedding of salmonellae in the feces of infected birds tends to diminish the overall reliability of cloacal swabs for diagnosing infection (446).

Fecal shedding of salmonellae into the poultry house environment by infected birds makes culturing environmental samples a useful diagnostic tool. Moreover, environmental samples also provide an opportunity to monitor for the introduction of salmonellae into poultry houses by vectors, personnel, equipment, and other sources. Although sampling fresh feces themselves likely provides the most sensitive test for the shedding of salmonellae (203), sampling floor litter can sometimes provide a comparable level of detection (377). Experimental *S.* Typhimurium infection in laying flocks was detected more consistently over a period of 1 year by culturing floor litter than by any other testing approach evaluated (332). Drag-swab samples, obtained by dragging moistened gauze pads across the floor of poultry houses, have been reported to detect salmonellae with greater sensitivity than litter sampling (251). The use of multiple-swab assemblies can further improve the sensitivity of this method (50). Swabs dragged through wet areas of manure appear to be more productive than swabs from dry areas (368). Foot covers worn in poultry houses can also provide an effective sample for detecting environmental salmonellae (292). Nest boxes, egg belts, dropping belts or scrapers, fan blades, and dust have been identified as particularly productive sources for *Salmonella* sampling in commercial egg laying houses (100, 248). Dust can remain contaminated with salmonellae even after cleaning and disinfection of poultry houses (203). Air sampling has detected *Salmonella* in both hatching cabinets and rooms containing infected chickens (36, 166). Hatcher fluff is frequently contaminated with salmonellae, offering an opportunity for early detection of infection in flocks (304). Culturing poultry feed for salmonellae is often important in establishing the source of infection of a flock with a particular serotype (392).

Standard Culture Methods for Salmonella Detection
Although a very diverse assortment of culture conditions has been proposed for the isolation and identification of PT salmonellae, most standard methods follow a general scheme that involves four principal stages. First, nonselective pre-enrichment is used to encourage the growth of very small numbers of salmonellae or to allow the recovery of injured *Salmonella* cells. Pre-enrichment is not advisable when testing samples (such as intestinal contents or feces) with large numbers of competing organisms that might overgrow salmonellae in the nonselective broth. Second, selective enrichment is used to allow additional expansion of the *Salmonella* population while suppressing the growth of other organisms. Third, plating on selective agar media is used to obtain isolated colonies, each derived from a single cell. Nonselective agar plating media are also sometimes used with swabs from internal organs. Fourth, colonies with appearances characteristic of salmonellae are subjected to biochemical and serologic tests to confirm their genus and serotype identity. Virtually all proposed methods require the last two of these steps, but enrichment requirements vary according to the nature of the sample.

Tissue samples (except for samples of intestinal tissues or contents) from infected birds ordinarily contain relatively few competing organisms. Swab or loop samples taken from internal organs are often transferred directly to plates of both selective and nonselective agar media, without broth enrichment. Excised tissue samples, and any samples derived from the intestinal tract, are generally transferred initially into selective enrichment broth.

Because fecal contamination may result in the presence of diverse flora, eggshells are usually sampled for *Salmonella* without pre-enrichment (unless detecting the presence of other bacterial contaminants is also of interest). The surface of eggshells can be sampled by immersion or rinsing in broth media or the entire shell (including interior structures and shell membranes) can be sampled by aseptic breaking to release the contents followed by manual crushing and the addition of enrichment broth. In a study of commercially produced eggs, shell rinse and shell crush methodologies yielded similar frequencies of *Salmonella* recovery (319). Before culturing egg contents for contamination by salmonellae, the shell exterior must be disinfected to prevent fecal contaminants of the shell from being transferred to the contents during breaking.

Because of the very low prevalence of salmonellae (primarily *S.* Enteritidis) in egg contents, and because *Salmonella* contaminants tend to be present in eggs in very small numbers, the entire liquid contents of 10–20 eggs are often pooled together for sampling to minimize demands on laboratory resources. Egg contents pools are usually incubated before further culturing to allow the *Salmonella* population to expand to a consistently detectable level (157). Supplementation of whole egg pools with iron (63, 157) or concentrated broth enrichment media (159) can increase the multiplication of some *S.* Enteritidis strains during incubation. Pre-enrichment of egg contents has been shown to lead to a greater sensitivity of *S.* Enteritidis detection than direct selective enrichment (145), probably by allowing very small initial levels of salmonellae to expand to levels that will survive the harsher conditions of selective enrichment. Direct plating of incubated egg pools onto selective agar media can markedly reduce the time, media, and labor demands of culturing, but does so at a significant loss in detection sensitivity (145, 157).

Environmental samples are typically collected in sterile plastic

bags and subsequently cultured by transfer into selective enrichment broth. Moistened gauze pads can be used to sample environmental surfaces or can be dragged across floor litter or dropping pits. Transporting environmental drag-swab samples in double-strength skim milk is often used to support *Salmonella* detection, although good recovery has also been obtained using dry swabs. Feed should be tested by collecting several representative samples from each lot and transferring into selective enrichment broth. Pre-enrichment of poultry feed samples has been reported to be unnecessary or even counterproductive (90).

Culture media are generally incubated for 24 hours at 37° C. Longer (48-hour) incubation in nonselective media has been reported to be useful for recovering small numbers of *S.* Enteritidis from egg contents (147, 234). Shorter (6-hour) selective enrichment has been found inadequate to suppress competing microflora in heavily contaminated samples (99). Incubation of selective enrichment cultures at elevated temperatures (42–43° C) has been recommended to restrict the growth of competing organisms, especially in intestinal samples or samples containing fecal material (99). Delayed secondary enrichment, in which selective enrichment broth cultures are held for an additional 5 days at room temperature to allow salmonellae an extended opportunity to grow to detectable levels, has been found to improve the recovery of PT salmonellae from poultry diagnostic and environmental samples (434, 371).

Culture Media

A diverse assortment of media has been developed and recommended for isolating and identifying salmonellae. Although some evidence has suggested that proper selection of culture media is somewhat contingent upon the type of sample being tested, several commercially available formulations have been consistently effective for a variety of applications.

Suggested broth media for the pre-enrichment of samples for salmonellae include buffered peptone water and trypticase soy broth. The selective broth media most often used for isolating PT salmonellae in recent years are tetrathionate broth and Rappaport-Vassiliadis broth. Tetrathionate broth preparations have been found to yield a higher frequency of *Salmonella* detection than Rappaport-Vassiliadis broth or selenite-cystine broth from a variety of types of samples, including cloacal swabs, intestinal tissues, pooled egg contents, and poultry feeds (90, 145). Rappaport-Vassiliadis broth has been effectively used to isolate salmonellae from environmental samples and egg contents pools (234, 371). Concern about selenium toxicity for human laboratory workers has led to diminished use of selenite-cystine broth.

Numerous agar media are available for the isolation of PT salmonellae. Among the most commonly used plating media are brilliant green agar, XLD agar, XLT4 agar, bismuth sulfite agar, and Hektoen enteric agar. Brilliant green agar is perhaps the most widely used medium for *Salmonella* isolation from poultry sources and has been shown to be effective in application to diverse tissue, environmental, egg, feed, and air samples (166, 434). XLT4 agar has been successfully applied to detect salmonellae efficiently from poultry house environmental drag swabs (302). The addition of novobiocin to agar plating media has been

demonstrated to improve *Salmonella* recovery by suppressing the growth of some competing organisms (notably *Proteus*) that might otherwise overgrow the salmonellae (404). Samples should always be streaked onto two different media, preferably with dissimilar indicator systems for differentiating salmonellae from other organisms.

Confirmation of Genus and Serotype

Colonies on selective agar plates that have the characteristic appearance of PT salmonellae must be tested further to confirm their genus identity and to determine their serotype. The combined use of triple sugar-iron agar and lysine-iron agar provides an effective presumptive test for identifying PT salmonellae. The observed pattern of fermentation with a battery of 6 carbohydrates can provide further differentiation of PT *Salmonella* isolates from other organisms (95). The serogroup of each isolate can be determined by agglutination tests with polyvalent antisera to groups of somatic O antigens, and the serotype can then be determined by slide agglutination tests with monovalent antisera to specific O antigens and tube agglutination tests with antisera to flagellar H antigens.

Rapid Detection Technologies

Obtaining negative results using conventional culturing methods for salmonellae requires several days for most types of samples, and confirming positive results adds even more time. A number of considerably faster techniques have become available and are steadily acquiring recognition for their usefulness in recent years, but these rapid methods have not yet supplanted traditional culturing for detecting *Salmonella* in poultry in most situations. Most of the rapid methods reduce the time requirements of testing by 1 or more days, and many are adaptable to some degree of automation. The principal concerns about rapid methods center around their typically high cost and poor sensitivity (commonly requiring at least one enrichment step to achieve a detectable cell density). For example, one study reported that small numbers of *S.* Enteritidis could not be consistently detected by rapid methods within a single working day (< 12 hours) of incubation for inoculated egg pools (163).

Although diverse other approaches have been applied with success, most efforts to develop rapid *Salmonella*-detection methods have centered around the use of specific antibodies or DNA probes. Specific antibodies to *Salmonella* antigens have been used to develop a variety of enzyme-linked immunosorbent assay (ELISA) methods. These tests, using polyclonal antibodies to *Salmonella* LPS or flagella, have been reported to detect salmonellae in eggs, tissues, cloacal swabs, environmental drag swabs, litter, and feed (197, 289). Monoclonal antibodies to outer membrane proteins or flagella have been used as the basis for ELISA tests to specifically detect *S.* Enteritidis in eggs, tissues, and environmental samples (241, 243). Although not apparently quite as sensitive as standard culture methods (402, 404), ELISA tests are usually reported to detect salmonellae at a frequency comparable to conventional culturing, and to do so at least 1 day sooner (456). One or more initial enrichment culturing steps, however, are generally necessary to allow the expansion of the

Salmonella population into the range detectable by ELISA, which is often estimated at between 10^5 and 10^7 salmonellae per ml (197, 241). Other antibody-based detection formats have demonstrated sensitivities similar to ELISA (164). Like conventional culturing methods, ELISA tests are also somewhat prone to false-positive results from competing flora able to grow in enrichment media (32).

Another application of antibodies for detecting salmonellae involves coating small magnetic beads with specific antibodies. When mixed with the sample to be tested, the antibody-coated beads will bind to any *Salmonella* target antigens present and a magnetic field can then be applied to recover the bead-antibody-antigen complex. In essence, immunomagnetic separation (IMS) thus serves as an alternative to broth enrichment for concentrating salmonellae, but with the advantages of requiring less time and having no adverse effect on sublethally injured cells (385). Concentration of salmonellae by IMS has also been reportedly more effective than by centrifugation (114). Using IMS to concentrate salmonellae before plating on selective agar has detected an equal or higher frequency of *Salmonella* contamination in samples of poultry meat, tissues, eggshells, feed, environmental samples, and cloacal or fecal swabs than did either traditional selective enrichment or motility-based enrichment (98, 285). IMS has also been used to detect small levels of *S*. Enteritidis contamination in pools of egg contents by both culturing and ELISA (216). IMS-based culturing removed up to 93% of *S*. Enteritidis from liquid eggs contaminated with 10^2–10^3 cells per ml (303) and detected <10 cells per ml in whole egg extracts (288).

An increasingly prominent approach to rapid testing for *Salmonella* in poultry involves using probes for particular DNA sequences unique to salmonellae or even to individual serotypes. Hybridization of the probe with DNA extracted from the sample indicates a positive result. The sensitivity of detection of salmonellae by DNA hybridization is similar to that of ELISA, and thus generally also requires one or more enrichment culturing steps (395). Moreover, some DNA hybridization assays are procedurally complex and are more expensive than most other available methods. The development of polymerase chain reaction (PCR) technology has allowed the specific amplification of particular target segments of DNA, thereby enabling hybridization reactions with probes to detect salmonellae in tissues, feces, environmental drag-swab samples, and eggs with a very high level of sensitivity (61, 384). Carefully chosen DNA probes can be used along with PCR to detect salmonellae with specific characteristics, such as those carrying genes for particular virulence properties (267), biochemical properties (279), or surface structures such as fimbriae (454). After appropriate enrichment culturing, PCR methods have detected initial contamination loads of <10 *Salmonella* cells in poultry environmental samples (282). PCR methods have similarly been capable of detecting very small numbers of salmonellae following the concentration of cells by IMS or centrifugation (294, 365).

Serologic Diagnosis of Infection

Specific antibodies to PT salmonellae have been found in the sera of both naturally (222, 427) and experimentally (21, 149) in-

fected poultry with a high degree of sensitivity using diverse agglutination and enzyme immunoassay methods. Detectable serum antibody titers are often still present long after the clearance of all salmonellae from tissues and the cessation of fecal shedding (191). Because antibody tests only document prior exposure to salmonellae, and do not provide unequivocal evidence of a currently ongoing infection in a flock, positive serologic results must generally be followed by bacteriologic culturing for confirmation. Serology also generally provides positive results much later than bacteriologic culturing (240). Other problems with serologic testing include the possibility that subclinical infections will lead to fecal shedding without sufficient invasion and dissemination to elicit a detectable antibody response (332), the general immunologic unresponsiveness of very young birds to *Salmonella* infection (437), and cross-reactions between antibodies to similar PT serotypes (168).

Agglutination tests have detected both natural and experimental infections of chickens with PT salmonellae (149, 222). The principal agglutination assay formats include rapid whole-blood plate, serum plate, tube, and microwell plate tests. All of these tests rely on the ability of specific antibodies to cause visible agglutination when mixed with antigen preparations of killed whole *Salmonella* cells. Except for the tube test, all agglutination assays use stained antigens to improve the ease of visualization of the agglutination reaction. An additional incubation period with a secondary antibody (antiglobulin) directed against chicken immunoglobulins, by increasing the overall agglutination of the target antigen, has been reported to provide greater sensitivity for detecting PT infections than other agglutination test methods (72).

PT *Salmonella* infections in poultry have also been detected using numerous ELISA approaches. For example, ELISA tests with antigens including LPS, flagella, or outer membrane proteins have identified chickens infected naturally or experimentally with *S*. Typhimurium or *S*. Enteritidis (21, 245). An international collaborative effort reported a generally high degree of correspondence in the performance of a wide assortment of ELISA formats and antigens for detecting *S*. Enteritidis infections (23). By using very precisely defined antigens, ELISA tests often achieve a high degree of specificity and are thus frequently associated with fewer false-positive results due to cross-reactions between serotypes than are agglutination reactions (191, 245). Assays employing fimbrial antigens have shown a particularly high degree of specificity for identifying *S*. Enteritidis infections in chickens (355). The discriminatory potential of ELISA tests often depends on judicious selection of positive/negative cut-off values (293). Screening for serum antibodies using a flagella-based ELISA test has been applied successfully for controlling *S*. Enteritidis in Dutch breeder flocks (427).

Antibodies deposited in egg yolks can also be used to detect poultry infected with PT salmonellae. Both agglutination (150) and ELISA (167) tests have been applied to find antibodies to *S*. Enteritidis and *S*. Typhimurium in eggs from naturally and experimentally infected chickens. Egg yolk antibodies have been consistently detected by flagella-based ELISA in egg yolks from hens inoculated orally with as few as 10^3 cfu of *S*. Enteritidis (170). The detection of specific antibodies in eggs from commercial lay-

ing flocks in the USA was directly correlated with the presence of *S.* Enteritidis in tissue samples from those flocks (150). Likewise, a direct relationship was observed between specific egg yolk antibody titers and the incidence of shedding of *S.* Enteritidis in the feces of laying flocks in the Netherlands (422). Egg yolk antibody detection was slightly more effective than bacteriological culturing of voided feces for predicting *S.* Enteritidis contamination of eggs laid by experimentally infected hens (169).

Intervention Strategies

Risk Reduction and Testing

The diversity of sources from which salmonellae can be introduced into flocks or houses complicates efforts to establish specific critical control points for preventing PT infections in poultry (250). Effective prevention and control programs must involve coordinated and simultaneous implementation of risk reduction practices throughout the production continuum (224). Eggs and chicks (or poults) should be secured only from demonstrably *Salmonella*-free breeding flocks. Hatching eggs should be properly disinfected and hatched according to stringent sanitation standards. Poultry houses should be thoroughly cleaned and disinfected by recommended procedures between flocks. Rodent and insect control measures should be incorporated into house design and management and verified by periodic testing. Rigidly enforced biosecurity practices should be implemented to restrict movement of personnel and equipment onto poultry housing premises and between houses. Only pelleted feed or feed containing no animal protein should be used to minimize the likelihood of using contaminated rations. Water provided to poultry should come only from sources treated to ensure purity. Treatments such as medication, competitive exclusion cultures, or vaccination can be applied to reduce the susceptibility of birds to *Salmonella* infection. Finally, the *Salmonella* status of poultry and their environment should be monitored by frequent testing to verify the effectiveness of risk reduction practices. Such multifaceted prevention and control programs in individual states have been associated with a decreased incidence of *S.* Enteritidis infections in both egg-type chickens and humans in the USA (442, 314) and have accordingly been incorporated into a proposed federal regulatory plan (419). Significant progress in controlling salmonellae in poultry and poultry products has been attributed to similar national programs in a number of countries (287, 436).

Increased international interest in controlling *S.* Enteritidis in poultry has led to the development and implementation of numerous serotype-specific testing and monitoring programs in recent years. In the United States, the National Poultry Improvement Plan (NPIP) defines stringent sanitation and testing standards for breeder flocks to prevent the transmission of *S.* Enteritidis infection to egg-laying stock (362). Participation in this plan requires compliance with standards for feed selection and handling, disinfection of hatching eggs, and hatchery sanitation. NPIP testing for *S.* Enteritidis involves bacteriologic monitoring of the environment and serologic monitoring of birds, with culturing of tissues from selected birds used for confirmation. A proposed national *S.* Enteritidis testing protocol for laying flocks

in the USA would screen for infection with drag-swab environmental samples and then confirm the threat posed to public health by culturing eggs (419).

Gastrointestinal Colonization Control

Newly hatched chicks and poults are highly susceptible to infection by PT salmonellae, but quickly become more resistant. This age-associated decrease in susceptibility to *Salmonella* is largely attributable to the acquisition of protective intestinal microflora from the environment. The ability of the normal bacterial flora of the gastrointestinal tract to inhibit colonization by salmonellae and other pathogens has served as the basis for the development of a diverse group of treatments often referred to collectively as competitive exclusion (CE). CE treatments involve administering defined or undefined bacterial cultures to poultry in order to diminish gastrointestinal colonization by enteric pathogens. Various nonmicrobial manipulations of gastrointestinal biochemistry have also been explored as colonization control options.

The efficacy of CE treatment has been illustrated repeatedly in both chickens and turkeys, using intestinal or fecal material from mature birds or undefined anaerobic cultures derived from such material. Administration of CE cultures has been shown to diminish both intestinal colonization and subsequent invasion to internal tissues by various PT salmonellae (329). The conditions under which CE preparations are obtained and handled can affect their efficacy. Administration of fresh turkey cecal material protected poults against *Salmonella* colonization better than day-old cecal material (208). Nevertheless, the protective efficacy of CE cultures can be maintained by continuous flow culturing (210). In field trials in commercial broiler chicken flocks, treatment with CE cultures has led to significant reductions in the incidence of salmonellae in live birds and on carcasses (17). CE administration to egg-type pullets before transfer into a contaminated laying house reduced the subsequent isolation of salmonellae from fecal and environmental samples (102). Treatment with CE cultures has sometimes been observed to enhance the clearance of concurrent or preexisting *Salmonella* infections (78). CE cultures have been shown to be effective against salmonellae following administration to poultry in a variety of forms, including crop gavage, application to the vent lip, whole-body spraying or droplet application, addition to drinking water, and encapsulation in lyophilized alginate beads added to the feed (80, 82). Protection has also been obtained by fogging CE cultures onto or injecting them into the air cell of hatching eggs (88, 350). Combined use of more than one route of administration has sometimes produced maximum protection (64).

Considerable research has sought to identify the microflora constituents responsible for protection against salmonellae. Specific individual microbial cultures including *Escherichia coli* (455), *Bacillus subtilis* (268), *Lactobacillus* species (188), *Bifidobacterium* species (139), and the yeast *Saccharomyces boulardii* (281) have been reported to exhibit protective (probiotic) activity against salmonellae in chickens. Some investigators have argued that a defined mixture of microorganisms can protect poultry with greater consistency than undefined cultures and

can also provide a greater assurance of safety than is available with mixtures of unknown organisms. The protective efficacy of mixtures of small numbers of intestinal bacteria is typically very limited (397), but more diversely defined mixtures can provide significant protection (84). Administration of a mixture of 29 defined bacterial cultures to broiler chicks significantly reduced colonization of the crops and ceca by *S*. Typhimurium (83). Used litter has also been used as a source of CE cultures (79).

The protective benefits of CE treatments have been attributed both to direct steric interference with the attachment of salmonellae to the intestinal epithelium and with inhibition of *Salmonella* growth in the intestinal tract as a consequence of lowered pH and increased levels of undissociated volatile fatty acids (379). Diverse feed additives have been investigated for their ability to either directly inhibit pathogen colonization or to support the growth of protective microflora. Adding various complex carbohydrates (including lactose, mannose, glucose, and fructooligosaccharide) to the feed or water of chickens has sometimes reduced crop or cecal colonization by salmonellae (59, 81). Dietary supplementation with formic, propionic, or caproic acids has also been associated with reduced isolation of *Salmonella* (411, 424). Administration of chlorate, lactic acid, or sucrose in the drinking water of broilers has been found to reduce the frequency of isolation of salmonellae from the crop after preslaughter feed withdrawal (49, 205).

Several factors have been identified that affect the overall usefulness of CE cultures for controlling PT salmonellae infections in poultry. Although CE treatment generally reduces the incidence of intestinal colonization by salmonellae, it does not prevent it altogether. Moreover, the protective efficacy of CE cultures can sometimes be overcome by severe *Salmonella* challenges (394). Because protection is most effective when CE cultures are given to chicks before they are exposed to pathogens, infection with salmonellae during hatching can compromise the protective value of CE treatment (12). Administration of CE cultures can thus contribute significantly to an overall *Salmonella* control effort, but proper cleaning and disinfection, biosecurity, rodent reduction, and other similar measures are still necessary to minimize the chances of exposure to salmonellae (336). Disruption of the normal intestinal microflora by antibiotic administration or feed and water deprivation can also interfere with the activities of CE cultures (10, 438).

Vaccination

Vaccination with either killed or live preparations has been found to reduce the susceptibility of poultry to PT infection. A decreased incidence of human *S*. Enteritidis infections in the United Kingdom followed the widespread vaccination of egg-laying hens (70). Vaccination of laying flocks has been observed to reduce the frequency of egg contamination with *S*. Enteritidis even when the pathogen is still detectable in the laying house environment (104). Live *Salmonella* vaccines have often been associated with a stronger or longer-lasting protective response in poultry, perhaps either because of adverse effects on relevant protective antigens during the preparation of killed vaccines or because live vaccines present relevant antigens to the host immune system more persistently (9). Killed vaccines may also fail to fully elicit the cell-mediated portion of the protective response (315). Nevertheless, both killed and live vaccines have been associated with significant protection against salmonellae, although neither type of vaccine has consistently provided an impenetrable barrier against infection, especially when high *Salmonella* challenge doses are involved (171, 367). Moreover, feed or water deprivation and environmental stresses such as heat may compromise the effectiveness of vaccines (323). Like competitive exclusion, vaccination is most effectively used as a component in a comprehensive program of risk reduction practices. Selecting or designing vaccines that provide protection but do not interfere with serological detection of infected birds has become a focus for research in recent years (306).

Interest in the use of killed vaccines (bacterins) in poultry has been renewed in the past two decades by escalating concerns about *S*. Enteritidis. Subcutaneous or intramuscular administration of adjuvanted bacterins to laying hens has been reported to reduce significantly the incidence of *S*. Enteritidis isolation from feces, internal tissues, and eggs following subsequent oral challenge (69, 171). Chickens vaccinated with bacterins have likewise been reported to exhibit reductions in mortality, lesions, clinical signs, organ invasion, and egg contamination for up to 12 weeks post-vaccination when challenged with *S*. Enteritidis by intravenous or intramuscular routes (413, 453). Bacterin administration to laying hens has moderated the increase in fecal shedding of *S*. Enteritidis that often follows induced molting (324). Field studies have associated bacterin administration with a reduced incidence of *S*. Enteritidis infection in Dutch broiler breeder flocks (137) and with consistently *S*. Enteritidis-negative fecal and environmental testing results from a British laying flock after vaccinated hens were transferred into previously contaminated facilities (101). Subunit vaccines composed of *Salmonella* outer-membrane proteins administered with adjuvants or incorporated into lipid-conjugated immunostimulating complexes have been efficacious against *S*. Enteritidis in chickens and turkeys (60, 244). Immunization of laying hens with purified *S*. Enteritidis fimbriae has provided protection against reproductive organ invasion and egg contamination (113).

Live attenuated vaccines need to persist in tissues long enough to induce a protective immune response, but should be avirulent and eventually cleared from vaccinated birds. PT *Salmonella* vaccine strains attenuated by several different approaches have been tested for their protective efficacy in poultry. Oral or intramuscular administration of various *aroA* mutants of *S*. Enteritidis (auxotrophs that do not grow well *in vivo* because of their inability to synthesize particular aromatic compounds) has reduced fecal shedding, horizontal transmission, organ invasion, and egg contamination after intravenous or aerosol challenge (73, 74). This protection has been found to persist for up to 23 weeks after administration of the vaccine strain (75). An orally administered δ*cya* δ*crp S*. Typhimurium strain (a double mutant with deletions of both adenylate cyclase and the cyclic AMP receptor protein) provided very strong protection against intestinal colonization and organ invasion by *S*. Typhimurium (192). A temperature-sensitive mutant (57) and a strain attenuated by repeated passage

in chicken heterophils (261) have also been shown to protect chickens against *S.* Enteritidis infection. Vaccination of hens with an avirulent *S.* Typhimurium strain was reported to reduced intestinal colonization of their progeny when challenged with virulent wild-type strains (194). A live vaccine was also useful for addressing the increase in susceptibility to *S.* Enteritidis infection associated with induced molting by feed deprivation (217). Evidence for cross-protection by live vaccine strains against other epidemiologically important *Salmonella* serotypes has been inconsistent. An avirulent *S.* Typhimurium vaccine reduced colonization, organ invasion, and egg contamination by *S.* Enteritidis (195), but *aroA- S.* Enteritidis strains did not cross-protect very effectively against *S.* Typhimurium challenge (74). The *S.* Gallinarum 9R vaccine strain has been evaluated extensively because it can generate protective immunity against *S.* Enteritidis without impairing serological detection of infected flocks (138). Even antigenically unrelated *Salmonella* strains have sometimes been observed to generate some degree of protection against subsequent challenge with *S.* Enteritidis, perhaps via a combination of immunological and competitive exclusion mechanisms (215). Several safety concerns about live *Salmonella* vaccines have also been raised, based on evidence that some vaccine strains may be genetically unstable (19) and can be detected for longer than anticipated in vaccinated hens if sufficiently sensitive culturing methods are used (403).

Prophylactic administration of lymphokines from immunized chickens has been shown to protect chicks against organ invasion after subsequent *S.* Enteritidis challenge (295). This effect appears to be due to increased phagocytosis and killing of *S.* Enteritidis by avian heterophils (117). Subcutaneous, oral, nasal, and *in ovo* administration of immune lymphokines to poultry have all provided some protection against *S.* Enteritidis challenge (252, 296), but this effect may be of relatively transient duration (172). Cross-protection against other *Salmonella* serotypes has also been observed (464).

Treatment

The efficacy and wisdom of medication with antibiotics to prevent or treat PT infections in poultry are topics of considerable debate. Antibiotics have a long history of widespread utilization in poultry at both therapeutic and subtherapeutic (growth-promoting) levels (388). Their usefulness for these purposes has been extensively documented in a variety of experimental and commercial settings. Antibiotics were employed effectively both as therapeutic and prophylactic agents as part of control efforts for *S.* Enteritidis in broiler and broiler breeder flocks in Northern Ireland (297). Preventive treatment of chickens with a variety of different antibiotics has been observed to prevent intestinal colonization of chicks by subsequently administered *S.* Enteritidis (58), and in some instances to clear pre-existing infections (176). Several antibiotics have likewise been reported to decrease fecal shedding of *Salmonella* when used as feed additives (40, 94). Provision of a competitive exclusion culture to restore a protective normal microflora after treatment with a fluoroquinolone antibiotic reduced fecal shedding of *S.* Enteritidis by broiler breeders (361), egg-type pullets, (105) and molted laying hens (383).

In ovo administration of gentamicin was apparently effective against *Salmonella* infection without interfering with competitive exclusion treatment of the hatched chicks (15).

However, in the USA and in many other nations, current control practices for salmonellosis in poultry no longer regularly rely on antibiotics because of the inconsistent history of these drugs in eliminating *Salmonella* colonization and because indiscriminate veterinary and agricultural uses may imperil their medical usefulness by promoting microbial resistance (175, 388). Several investigators have documented limitations in the efficacy of antibiotics in controlling *Salmonella* in poultry. One study reported that five antimicrobial agents had very minimal value for preventing or eliminating experimental *S.* Typhimurium infection (333). Other investigators observed that feed additive antibiotics were associated with increased cecal *S.* Enteritidis numbers in chicks (7). Another study suggested that drug excretion by infected birds might have interfered with the recovery of salmonellae from cloacal swabs or feces and created an erroneous impression that treatment was effective (447). Combined administration of enrofloxacin and a competitive exclusion product reduced the incidence of *S.* Enteritidis carriage, but failed to eliminate infection from internal organs (227). The administration of some antibiotics has been reported to increase the susceptibility of poultry to *Salmonella* infection, perhaps by suppressing the growth of other microflora capable of exerting inhibitory activity against salmonellae (290). Discontinuing the use of antimicrobials for growth promotion in Denmark was followed by a decrease in the *Salmonella* prevalence in broilers (132). Both therapeutic and subtherapeutic antibiotic administration has been shown to select for drug-resistant strains of salmonellae (28, 357), thereby potentially compromising the effectiveness of those (and related) drugs in both animals and humans (106). Very high incidences of drug resistance have been reported among *Salmonella* isolates from both poultry production facilities and poultry products (6, 327), with a large proportion of these strains often displaying resistance to multiple antimicrobial agents (283).

Arizonosis

H.L. Shivaprasad

Introduction

Arizonosis is a septicemic disease of young turkey poults caused by the bacterium *Salmonella enterica* subsp. *arizonae* (*S. arizonae*). Other species of birds such as chickens, ducks and wild birds, canaries and parrots are also susceptible. *S. arizonae* used to be one of the most frequently identified *Salmonella* serotypes in turkeys in the United States (30) and is related to significant morbidity and mortality. However, sporadic and serious outbreaks still occur through out the US (11, 31, 81. 96, 97). The disease is clinically indistinguishable from salmonellosis caused by other serotypes of salmonellae such as *S.* Typhimurium and *S.* Heidelberg.

S. arizonae represents an antigenically diverse group of bacteria (over 300 serotypes have been identified), which can be distinguished biochemically from other species in the genus *Salmonella.* Historically, the organisms now classified as *S. enterica arizonae* were included in the genus *Arizona,* and have commonly been referred to as the arizona group, arizonas, and paracolons. In 1982, the International Subcommittee on Taxonomy of Enterobacteriaceae decided that the arizona group should

be classed as two subspecies of the genus *Salmonella* based on the relatedness of their DNA with that of *Salmonella* spp. Earlier reviews on the arizona group and arizonosis have been published (3, 4, 46).

Definition and Synonyms

Arizona infection or avian arizonosis (AA) is an acute or chronic egg-transmitted disease of primarily of young turkey poults characterized by septicemia and neurological signs and blindness and increased mortality. Once disease caused by *Salmonella enterica arizonae* used to be called "paracolon" infection and members of the genus *Arizona* once were referred as "paracolons," *Arizona arizonae* and *Arizona hinshawii*.

Economic Significance

Avian arizonosis is of considerable economic significance to the turkey industry of North America and certain parts of the world through increased morbidity and mortality in young turkey poults and decreased egg production in turkey breeders and decreased hatchability (18, 19, 39, 51, 63, 94, 96, 100). The cost incurred in testing of carrier birds and eggs, supplies such as swabs, culling of birds, dipping of eggs and cleaning and disinfection, use of antibiotics for treatment of breeders and poults and labor adds substantially to the cost of eradicating the disease.

Public Health Significance

Infection in people due to *S. enterica arizonea* associated with birds and turkeys in particular has not been reported. However, arizonosis in humans associated with reptiles have been reported numerous times (8, 32, 60, 89, 103 and others).

History

Caldwell and Ryerson were the first to isolate the *Salmonella*-like organisms from diseased reptiles from the semiarid regions surrounding Tucson, Arizona (9). It is probable, however, that the bacteria were isolated earlier from poultry. Lewis and Hitchner (68) had previously reported recovery of slow lactose-fermenting bacteria from a disease of chicks resembling salmonellosis. This infection was probably due to a member of the arizona group, and may represent the first report of AA. In Great Britain, the first report of avian arizonosis in poultry was in 1968 (57).

Etiology

Classification

Since 1939, many attempts have been made to find a generally acceptable taxonomic position for this group of bacteria; several classification systems have been used and a wide variety of names and designations has been applied to the organisms.

Edwards and associates (cited in 72), established the biochemical and antigenic similarity of the arizonae and salmonellae. Enough differences were found between the groups, however, to justify classification of the arizonae in a separate genus. Kauffmann and Edwards (59) first employed the name *Arizona arizonae*, which was also used by Ewing (23) for members of the genus *Arizona* (genus II of the tribe Salmonellae). A new type species name *Arizona hinshawii* had been proposed by Ewing (25) to pay honor to the pioneering work of W.R. Hinshaw on AA in turkeys, reptiles, and other animals. Kauffmann (58) subsequently included the arizonae in his subgenus III of the genus *Salmonella*, designating them *S. enterica arizonae* and listing their antigenic formulas only in the simplified Kauffmann-White scheme. The arizonae have been classified in the *Salmonella* genus in the 9th edition of *Bergey's Manual* (7) and all organisms in the group are designated *Salmonella arizonae*.

Ewing and his colleagues (24, 27, 28, 29, 72) have further clarified the definition by which the biochemical and antigenic characteristics of members of the genus *Arizona* may be readily differentiated from other Enterobacteriaceae. The terminology used by Centers for Disease Control and Prevention will be followed in this subchapter, e.g., *S. enterica arizonae*, 18:Z4, Z32 (see Antigenic Structure).

Morphology and Staining

The *S. enterica arizonae* resemble other enteric organisms. They are Gram-negative nonsporogenic bacilli that are motile by peritrichous flagella.

Growth Requirements

Members can be readily cultivated on ordinary liquid and solid laboratory media, revealing an abundant growth similar to that of the salmonellae. Most cultures grow very well on *Salmonella-Shigella* and brilliant green (BG) agars, as well as other solid media recommended for isolation of salmonellae. On initial isolation, colonies usually resemble those of salmonellae but may develop an indicator change typical of lactose fermenters after incubation for several days or weeks. Rapid lactose-fermenting strains, rare in poultry, cannot be distinguished from normal coliforms, which are usually inhibited by these media. Routine use of bismuth sulfite plating medium was recommended (21, 46, 72) to aid in preliminary recognition of lactose-fermenting Arizona strains before they are possibly discarded as coliforms.

Colony Morphology

Colonies of *S. enterica arizonae* appear similar to other salmonellae and do not have any special characteristics that would distinguish them. On blood agar they appear as dull white with round, convex, butyrous colonies. On XLT4 media they appear round, convex to flat, butyrous colonies with a black center or completely black and on BG agar round, convex to flat, butyrous colonies pink to pinkish red in color.

Biochemical Properties

Cultures possessing the biochemical characteristics shown in Table 16.2 are almost invariably classifiable serologically as members of *S. enterica arizonae* (14, 26, 28).

Most isolates from poultry, unlike other salmonellae, ferment lactose usually within 7–10 days' incubation. Failure of cultures

Table 16.2. Typical biochemical characteristics of *S. enterica arizonae.*

Dextrose	Fermented with gas
Lactose	Fermented, as a rule, slowly or promptly
Sucrose	Not fermented, as a rule
Mannitol	Fermented with gas
Maltose	Fermented with gas
Dulcitol	Not fermented
Inositol	Not fermented
Indole	Not produced, as a rule
Methyl red	Positive
Voges-Proskauer	No reaction
Hydrogen sulfide	Positive
Urea	Not hydrolyzed
Gelatin	Liquified slowly
Potassium cyanide	Negative, as a rule
Nitrates	Reduced
Motility	Positive
Betagalactosidase	Positive
Decarboxylases	
Lysine	Positive
Arginine	Positive, usually delayed
Ornithine	Positive
Malonate	Positive
Phenylalanine deaminase	Negative

to ferment dulcitol and inositol or to use D-tartrate, their slow liquefaction of gelatin, and their positive reactions in sodium malonate and betagalactosidase are most useful in distinguishing them from other members of the *Salmonella* group.

Citrobacter

For purposes of classification and identification, the *S. enterica arizonae* must be differentiated not only from other salmonellae, but also from the antigenically related genus *Citrobacter* of the tribe Salmonellae. Members of this genus are not known to be pathogenic for poultry, but from a diagnostic standpoint they may be confused with *Salmonella* cultures on initial isolation from fecal specimens. The former Bethesda-Ballerup "paracolons" (*P. intermedium*) are included in the genus *Citrobacter* along with cultures previously classified as *Escherichia freundii.*

Resistance to Chemical and Physical Agents

Arizonae are readily destroyed by heat and common disinfectants, but have survived in contaminated water for 5 mo, in contaminated feed for 17 mo, in soil on turkey ranges for 6–7 mo, and for 5 to 25 or more wk on materials and utensils in poultry houses (2, 35, 62, 63, 86, 91). Resistance properties are very similar to those of salmonellae.

Antigenic Structure

S. enterica arizonae strains are related serologically to the salmonellae and other Enterobacteriaceae, and procedures for study and identification of their antigenic structure are identical to those for paratyphoid organisms. Thirty-four somatic (O) and 43 flagellar (H) antigens have been demonstrated.

The serotype nomenclature system used in designating members of the genus *Salmonella* has been applied to *S. enterica arizonae.* In writing antigenic formulas, commas are used to separate O antigen factors, a colon to distinguish the O and H antigens, commas to separate H antigenic factors within a single phase, and a hyphen or dash to separate the first phase from the second and the second from the third, etc. Thus, the monophasic type species would be designated *S. enterica arizonae* 18:Z4, Z32.

Evolution of the nomenclature for salmonellae has resulted in some confusion over the identification of strains. Two serotypes that were previously designated as 7:1,7,8 and 7:1,2,6 are now recognized as 18:Z4,Z32 and 18:Z4,Z23, respectively. Confusion also exists because, even though there are only 34 O and 43 H antigens, sometimes an isolate is designated as 65:Z52,Z53. The latter is the designation that conforms to the system recognized by the Centers for Disease Control and Prevention, and the World Health Organization.

Pathogenesis and Epidemiology

Incidence and Distribution

Avian arizonosis occurs worldwide wherever poultry is raised. At one time, *S. enterica arizonae* 18:Z4, Z32 was endemic in turkey flocks of North America. Very high rates of isolation were reported in California in 1968 and 1969, but decreased considerably by 1972 (73). However, a resurgence of AA in the form of serious outbreaks has occurred in California between 1999 and 2006 (11, 96). The most common serotype isolated was *S. enterica arizonae* 18:Z4, Z23 followed by 18:Z4, Z32 (11). *S. enterica arizonae* has been eliminated from the turkey industry in Great Britain (5, 57, 101).

Natural and Experimental Hosts

S. enterica arizonae recognize no host barriers and are widely distributed in nature in a variety of avian, mammalian, and reptilian species (10, 17, 18, 19, 72, 82, 95, 110, 111).

Among poultry, AA is most frequently encountered in turkeys. Greenfield (43) noted that AA in chickens does not appear to be economically important, although chickens are affected by AA both naturally and experimentally (17, 68, 99). Dougherty (12) isolated *S. enterica arizonae* from duck livers, revealing lesions very similar to those produced by paratyphoid infections.

For a review of AA as a human disease causing gastroenteritis and frequently more serious enteric fever and focal infections, see Guckian *et al.* (49), Johnson *et al.* (56), Kelly *et al.* (60), Martin *et al.* (72), Waterman *et al.* (103), Weiss *et al.* (104), and Williams and Hobbs (108).

Transmission

The transmission cycle of AA in poultry is identical with that established for motile salmonellae (see Paratyphoid Infections). Infected adult birds are frequently intestinal carriers and spreaders of *S. enterica arizonae* for long periods (16). Wild birds (75), rats and mice (39), and reptiles (50, 52) have been cited as com-

mon sources of the organisms for poultry flocks but reptiles are probably the primary source of *S. enterica arizonae*.

Intestinal infections have been reported (51, 93), and Adler and Rosenwald (1) reported that AA in adult turkeys is confined primarily to the intestinal tract.

Transmission of AA through eggs has been reported by many workers (6, 16, 17, 18, 19, 41, 51), and recovery of *S. enterica arizonae* from ovaries and oviducts of adult turkeys (33, 51, 94, 96) suggests that transovarian transmission can occur. This can result in eggs contaminated with the bacteria and as a consequence there is decreased hatchability and increased mortality during the first week in the poults hatched. Direct contamination of the ovary by systemic infection can follow ingestion of the organisms (64, 94, 98). Perek *et al.* (84) isolated *S. enterica arizonae* from semen of cockerels.

S. enterica arizonae from fecal contamination have a penetration pattern through the shell and shell membranes of chicken eggs very similar to that of *S.* Typhimurium when incubated at 37.2°C, resulting in frequent presence of the organisms in chicken and turkey eggs (16, 41, 94, 107). Fecal contamination may spread the infection from other animal species to poultry. Goetz (39) found an AA infection rate of 90% in rats and 50% in mice on the premises of a turkey farm where the infection was a problem in poults. Various types of wild birds, reptiles, and many common animal species can also infect poultry flocks.

AA is transmitted in the incubator and brooder by direct contact and through contaminated feed and water (22, 63).

Clinical Signs

Although signs of AA in poultry are not specific, infected poults and chicks may appear listless, depressed and weak and develop anorexia, diarrhea, leg paralysis, and twisted necks (Fig. 16.5). There may be blindness due corneal opacity and/or caseous material in the anterior chamber and vitreous of the eye (Fig. 16.6) (10, 63, 93, 96, 99). Infected birds tend to sit on their hocks and huddle together. Nervous signs, including paralysis, torticollis, opisthotonus, convulsions, may follow brain and internal ear infection in poults (Fig. 16.5) (55, 82, 96). Sato and Adler (93) noted that clinical signs of AA are rarely seen in adult turkeys and they seldom die from this infection.

Mortality due to AA in poults and chicks is variable. Lewis and Hitchner (68) recorded mortality of 32–50% from the infection in chicks. In one study mortalities of 70 % by 7 days and 60% by 23 days after hatching have been reported (96). Mortality can be exacerbated by secondary or concurrent infections such as colibacillosis, poult enteritis, aspergillosis, coccidiosis, paratyphoid infections, crop mycosis, etc. (96).

Others have observed mortality generally between 10 and 50%, in chicks or poults especially susceptible within the 1st few days after hatching, and with mortality continuing for up to 3–5 wk (1, 17, 48, 63, 85, 96, 100). Geissler and Youssef (34) inoculated or dipped chicken eggs with *S. enterica arizonae*; 100% and 40–79% of embryos in the respective groups died during the incubation period. Hatchability for the latter group varied from 0 to 21–70%, with evidence that the organisms penetrated to the inner structures of the eggs.
16.5. Two-week-old turkey poults exhibiting depression and neurological signs due to arizonosis.
16.6. Eye of a three-week-old turkey poult with severe ophthalmitis.

Worcester (112) noted that *S. enterica arizonae* can penetrate the wall of the intestinal tract and stay there indefinitely.

Pathology

Gross Lesions

Gross and microscopic lesions due to AA in poults have been well described (11, 40, 90, 96, 99, 105). Lesions in poults, either naturally or experimentally infected with *S. enterica arizonae*, are comparable to lesions induced by paratyphoid organisms. In natural outbreaks there are retained yolk sacs, yolk sac with watery or caseous yellow contents (Fig. 16.7), prominent yolk stalks (navel buttons), cores in the ceca, and exudate on the meninges of the brain. Livers may be enlarged and mottled with white foci; there may be caseous exudate in the abdominal cavity, and discolored hearts. Pericardium and air sacs can be cloudy and there may be swollen joints (96). One of the most frequently noted pathologic changes in somewhat protracted cases is the presence of pale
16.7.   Severe yolk sac infection in a 5-day-old poult.

16.9.   Histopathology of brain with meningitis and encephalitis due to *Salmonella enterica arizonae* infection. ×300

16.8.   Ceca from a 5-day-old turkey poult with a core in the lumen.
16.10.   Histopathology of internal ear with severe otitis and bacteria of *Salmonella enterica arizonae* infection. ×500

white or yellow exudate in the anterior chamber and vitreous of one or both eyeballs in poults (Fig. 16.6). However, lesions in the eye and brain develop in slightly later stages of the disease.

Lesions typical of generalized septicemia, including peritonitis, retained yolk sacs, enlarged, yellowish mottled livers and discolored hearts, were also described in experimentally infected chicks by Lewis and Hitchner (68). Goetz and Quortrup (40) and Shivaprasd *et al*. (96) have described caseous cores (Fig. 16.8) in the ceca similar to those seen in pullorum disease. Hinshaw and McNeil (51) observed that *S. enterica arizonae*-infected adult turkeys had a small amount of caseous exudate in the abdominal cavity and cystic ovules.

Histopathology

Microscopically, there is moderate to severe fibrinosuppurative inflammation associated with Gram-negative bacteria in the yolk sac and yolk stalk. In the brain, there is severe meningitis with in-

filtration of heterophils mixed with fibrin and bacterial colonies (Fig. 16.9). Similar exudate can also be seen in the ventricles of the brain, and there is malacia, inflammation and vascular thrombosis in the cerebral cortex. Interestingly, changes in other organs are minimal, such as necrosis of hepatocytes and infiltration with mononuclear inflammatory cells, increased numbers of mononuclear phagoctyic system cells in the spleen, and vascular congestion in various organs. Occasionally inflammation of the pericardium, air sacs, synovium, and intestine especially the ceca due to *S. arizona enterica* can be seen (96).

Otitis interna with bacteria (Fig. 16.10) and neuritis and ganglionitis of the vestibulocochlear nerve (VIIIth cranial nerve) most likely due to spread of *S. enterica arizonae* from the brain meninges in 9- to 21-day-old turkey poults have been described (97).

Pathogenesis

There is little or no information available regarding the pathogenesis of *S. enterica arizonae* but it can be assumed that it causes

disease similar to other salmonellae. Being a Gram-negative bacteria it can elaborate endotoxins causing inflammation in various organs most notably in the yolk sac, ceca, brain, eye, etc. *S. enterica arizonae* can invade the bloodstream, especially of young fowl resulting in high mortality (18).

Virulence Factors

The virulence factors of *S. enterica arizonae* are poorly understood. However recent study has shown that the *spv* virulence locus is present in *S. enterica arizonae* and that it was found to be located on the chromosome (69). Sequence analysis of the *spv* locus revealed that it contains homologues of spv^{RABC} but lacks spv^{D}. The Spv^{B} protein is an ADP ribosyltransferase that modifies actin and destabilizes the cytoskeleton of infected cells. This may explain the ability of *S. enterica arizonae* to cause disseminated infection in various species of animals including humans (69)

Diagnosis

High mortality, neurologic signs, blindness coupled with gross lesions in turkey poults can be used for a presumptive diagnosis of AA. These clinical signs, as well as lesions, however, can be seen in other *Salmonella* infections, including those of paratyphoid organisms. The organisms can usually be recovered from liver, spleen, heart blood, unabsorbed yolk sac, intestine, lung, kidney, brain, and eye.

Isolation and Identification of Causative Agent

Cultural procedures identical to those outlined and discussed under Paratyphoid Infections are employed for isolation and identification of arizonae. Standard methods for isolation and biochemical or serologic identification of *S. enterica arizonae* from poultry tissues, eggs and embryos, and environmental samples have been described (21, 26, 101, 109). Bismuth sulfite medium can be used for plating enrichment broths in addition to BG sulfa if desired. The two serotypes of *S. enterica arizonae* common in turkeys are slow lactose fermenters and, therefore, identical to paratyphoids on initial isolation on BG agar.

Selenite cysteine broth may be used in enrichment of fecal and organic tissue cultures (63, 93, 94). Selenite broth incubated at 43°C yielded fewer isolations of arizonae than did tetrathionate or selenite F broth at 35°C (44).

Forty-nine strains of *S. enterica arizonae* isolated from turkeys all had similar cultural and biochemical characteristics, varying only in use of citrate and melibiose (102). Most *S. enterica arizonae* strains were sensitive only to chloramphenicol and nalidixic acid among the antibiotics tested. Kumar *et al.* (65) found that selenite BG with sulfapyridine (SBGS) and tetrathionate BG broths gave comparable results with *S. arizonae,* but at 48 hr there was considerable reduction in recovery of arizonae from SBGS in tubes initially inoculated with high numbers of organisms. Littell (70) described a differential plating medium for isolation of *S. arizonae* that produces a uniform reaction of both lactose-negative and lactose-positive *S. arizonae*, and differentiates them from other salmonellae.

Snoeyenbos and Smyser (100) believed that litter culturing

may aid epidemiologic studies and identify infected turkey flocks as part of a control program. Greenfield and Bigland (45) noted that culture of turkey litter might be a useful means of detecting insidious AA.

Culture of turkey shell membranes and shells is recommended over yolk material for rapid detection of arizonae-contaminated eggs (13, 47, 87).

Serology

Serologic analysis of cultures is essential in epizootiologic studies of AA of fowl; cultures can be submitted to the Salmonella Serotyping Laboratory, National Veterinary Services Laboratories P.O. Box 844, Ames, IA 50010, for biochemical characterization and antigenic typing.

Edwards and Galton (15) noted that it is essential to use a polyvalent *S. enterica arizonae* antiserum in preliminary examination of cultures, since arizona types may not be agglutinated by *Salmonella* polyvalent antiserum. Kowalski and Stephens (63) employed formalinized broth cultures and *S. enterica arizonae* polymonophasic antiserum in serologic identification of arizonae cultures. Snoeyenbos and Smyser (100) used *S. enterica arizonae* flagellar polyvalent, *Salmonella* flagellar Z32, and *Salmonella* somatic 18 antisera in screening cultures suspected to be *S. enterica arizonae.*

Differential Diagnosis

The clinical signs, as well as lesions of AA can be seen in other *Salmonellae* infections, including those of paratyphoid organisms. Neurologic signs can also be caused by Newcastle disease, aspergillosis, and vitamin E deficiency (encephalomalacia). Blindness in turkey poults can be due to aspergillosis or other causes such as cataracts. Therefore, AA must be confirmed by isolation and identification of the causative bacteria.

Prevention and Control

Because *S. enterica arizonae* is egg transmitted, primary breeding stock must be developed free of *S. enterica arizonae*. The control program at the multiplier breeder level is dependent on having available *S. enterica arizonae*-free stock. Management procedures outlined under Paratyphoid Infections are applicable for the control and reduction of AA. The program outlined by Ghazikhanian *et al.* (38) for the primary breeder level is applicable to the multiplier level except for the treatment of hatching eggs with antibiotics. Total confinement, bird proof and rodent proof buildings that can be cleaned and disinfected, quality feed and feed ingredients, and microbiologic monitoring at the hatchery and breeder farm levels are essential.

Ghazikhanian *et al.* (38) reviewed the program of a primary breeder to reduce and eliminate *S. enterica arizonae* from a basic breeding operation. A combination antibiotic hatching-egg treatment (dipped and injected) was successful in producing *S. arizonae*-free pedigree stock (37, 74). In addition to the egg treatment program, an autogenous oil-emulsion *S. enterica arizonae* bacterin was used on infected flocks to reduce transmission.

Because of contamination of ranges, a new capital building program was initiated (total confinement, paved floors, bird proof). A cleaning and disinfecting program was initiated after each depopulation and the facilities were monitored to determine the effectiveness of the program. Finally, special emphasis was placed on frequent egg-collection practices. Only pelleted feed containing no animal or poultry by-products was used. The program has been highly successful.

Serologic Testing

Serologic tests have not been entirely effective in detecting or controlling AA in turkeys (1, 86, 112).

Methods for preparing and using *S. enterica arizonae* antigens for serologic testing of chickens and turkeys have been outlined (4).

Timms (101) found that the most reliable and satisfactory methods for detecting *S. enterica arizonae* at various stages of infection in adult turkeys were the rapid serum plate (SP) test and the somatic tube agglutination (TA) test. The rapid whole-blood (WB) test was found to be a useful tool in testing large numbers of birds in the field, but it required confirmation by the TA test. Uses of the agar gel diffusion, indirect hemagglutination, immunofluorescene, and H agglutination tests in providing supporting evidence of infection were discussed. Lamont and Timms (67) reported use of O and H TA tests, rapid WB test, and agar gel precipitin tests for detection of AA in turkeys. They also found the rapid WB test particularly useful for flock screening.

Sato and Adler (93, 94) used a formalin-treated broth culture of actively motile arizona strains in preparing H antigen, and ethanol-treated cell suspension from beef heart infusion agar for O antigen. They found that naturally infected turkeys had positive O agglutination reactions at some time during the period they were observed; however, some of the same birds were negative when tested with H antigen. The H agglutinins disappeared earlier than O agglutinins. Not all infected birds revealed positive O agglutination tests at time of necropsy. There was little correlation between serologic results and persistence of infection.

Kumar *et al.* (66) developed a tetrazolium-stained microagglutination (MA) test antigen for detection of *S. arizonae* infections in turkeys. The MA test was demonstrated to be far more sensitive and superior to the TA and SP tests in detecting turkeys infected with *S. enterica arizonae*. Attempts to detect infection with the microantiglobulin test were unsuccessful.

Adult carriers may lack detectable antibodies 12–14 wk after exposure, and infected turkey hens go through an antibody-negative phase at 16–20 wk of age when most breeder flocks are tested (66, 101). When the ovary becomes activated following a lighting regime at 28–32 wk of age, antibodies may be detectable. At that stage in the breeding cycle, it is too late to eliminate the flocks. Greenfield (42) noted that antibody titers do not persist for lengthy periods and may not be detectable in birds with subclinical infections.

An enzyme-linked immunosorbent assay (ELISA) using outer-membrane proteins extracted from *S. enterica arizonae* as antigens was found by Nagaraja *et al.* to be sensitive and specific for the detection of *S. enterica arizonae* infection in breeder flocks of turkeys (77, 79). It was considered to be a valuable tool to de-

termine which breeder flock is infected, allowing the hatchery program to be adjusted to reduce *S. enterica arizonae* dissemination at the time of hatching.

Vaccination

Several types of bacterins have been applied to turkey breeding stock. Holte (54) found that vaccinated breeders exposed to *S. arizonae* 18:Z4,Z32 had reduced shedding and were protected from systemic infection, thus, preventing egg transmission of arizonae. Parental immunity was found to be transmitted to poults of vaccinated hens.

Sato and Adler (92) found varying degrees of protection afforded by arizona bacterins in both mice and turkeys. A formalin-treated whole culture in aluminum hydroxide gel provided the best protection, based on the number of organisms that migrated to the spleen following intramuscular challenge. In turkeys, a chrome-alum-treated arizona bacterin provided protection against both oral and intraperitoneal challenge (76). Fecal shedding for the first 3 wk after challenge may be reduced by immunization with bacterins (1).

Gerlach *et al.* (36) found serum from nonimmunized turkey hens had both bacteriostatic and bactericidal effects on cultures of *S. arizonae* 18:Z4,Z32, but there was no inhibitory activity in the serum of birds vaccinated with arizona bacterin or in serum from naturally infected breeders. Inhibition of growth was not associated with presence of agglutinating antibodies; in fact, the opposite appeared to be true. In contrast, a bactericidal substance in the albumen of eggs from vaccinated turkeys was reported (1).

Ghazikhanian *et al.* (38) reported encouraging results using oil-emulsion bacterins; egg transmission following challenge was reduced from 12% in nonvaccinated controls to 2% in vaccinated turkeys. Vaccination against *S. arizonae* infection with a mineral oil-adjuvant vaccine was evaluated in turkey breeder flocks under laboratory and field situations by Nagaraja *et al.* (78, 80). The results were encouraging; it was possible to obtain *S. arizonae*-free progeny from vaccinated breeder flocks held in infected environments.

Lowry *et al.* (71) reported that immunoprophylactic administration of *S.* Enteritidis-immune lymphokines in turkey poults significantly reduced the horizontal transmission and organ invasion of *S. enterica arizonae*.

Treatment

Chemotherapy may reduce losses in acute outbreaks of AA and may be recommended to prevent spread of the disease in market flocks. Williams (106) reviewed various treatments for AA. In the United States, the only drugs approved by the Food and Drug Administration for treatment of AA are antibiotic injectables, gentamicin and spectinomycin. These injectables, given at the hatchery, have dramatically controlled the acute losses and morbidity that may occur during the first 3 wk of age. Isolates of *S. enterica arizonae* resistant to gentamicin have been reported (20, 53). Addition of 30 ppm of zinc from zinc-methionine to the diet of young turkeys increased the reduction of intravenously administered *S. arizonae* from the spleen (61).

Chapter 17

Campylobacteriosis[*]

Qijing Zhang

Introduction

Avian species, especially domestic poultry including chickens, turkeys, ducks, and geese, are frequently infected with the members of thermophilic *Campylobacter*, primarily *Campylobacter jejuni* and *Campylobacter coli* (172, 179, 196). As enteric organisms, *C. jejuni* and *C. coli* are well adapted to the avian host and reside in the intestinal tract of birds. Despite extensive colonization, *Campylobacter* infections produce little or no clinical diseases in poultry (40, 107, 137). However, infectious hepatitis associated with *C. coli* and *C. jejuni* has been reported in ostriches, causing a high morbidity and mortality (194).

Although thermophilic campylobacters are not significant pathogens for poultry, they are of importance to food safety and public health, with *C. jejuni* being responsible for the majority of human campylobacteriosis, followed by *C. coli,* and rarely by *C. lari*. *Campylobacter* has now emerged as a leading bacterial cause of foodborne gastroenteritis in humans around the world (124). Most of *Campylobacter*-related illnesses in humans are sporadic and characterized by self-limiting watery and/or bloody diarrhea, abdominal cramp, and possible fever; however, severe conditions may occur in immunocompromised patients, requiring antibiotic treatment (61, 124). In addition, *Campylobacter* infection is associated with Guillain-Barre syndrome, a postinfectious autoimmune disease characterized by acute and progressive neuromuscular paralysis(103, 131).

The high prevalence of *Campylobacter* in the intestinal tract of market-age poultry results in frequent contamination of poultry carcasses in the processing plants. Thus, poultry products at retail are often contaminated by *Campylobacter* (40, 85, 91, 95, 223, 232). Handling and eating raw or undercooked poultry meat is considered a significant risk factor for human campylobacteriosis (8, 46, 60, 61, 120, 224). In addition, many avian *Campylobacter* isolates have become resistant to clinically important antimicrobials such as fluoroquinolones and macrolides (14, 65, 115, 230), which may potentially result in treatment failures in patients receiving antibiotic therapy. Therefore, reduction or eli-

mination of *Campylobacter* from poultry and poultry products constitutes a major effort in improving food safety.

Etiology

At present, the genus *Campylobacter* contains 16 species, with *Campylobacter fetus* being the type species (141). Based on recent extensive DNA-rRNA hybridization studies and 16S rRNA sequence data, the family Campylobacteraceae was found to represent a diverse but phylogenetically distinct group, rRNA superfamily VI, within the group of gram-negative bacteria (141, 212). This lineage is also known as the epsilon division of the Proteobacteria, and comprises rRNA homology groups I (*Campylobacter* and *Bacteroides ureolyticus*), II (*Arcobacter*), and III (*Helicobacter* and *Wolinella succinogenes*). Members of this lineage are characterized by their low chromosomal G + C content, inability to ferment carbohydrates, and microaerobic growth requirements.

The members of the genus *Campylobacter* are associated with a wide variety of diseases in humans and animals although they are commensals in poultry (187). Within the genus, three species (*C. jejuni*, *C. coli*, and *C. lari*) known as thermophilic *Campylobacter* are of clinical significance as they are the dominant causative agents of human campylobacteriosis (61,132).

Thermophilic *Campylobacter* spp. grow optimally at 42°C on artificial media (132, 179). They are slowly-growing fastidious organisms, and require a microaerobic atmosphere for optimal growth (132, 154, 205). In general, *Campylobacter* is sensitive to oxygen, desiccation, osmotic stress, low pH, and high temperatures (59, 144). *Campylobacter* cells are S-shaped spirally curved rods in size of 0.2 to 0.8 μm wide and 0.5 to 6.0 μm long, although cells may transform to spherical or coccoid forms in response to stress or deleterious conditions (132, 179). The members of the genus are Gram-negative, nonsporeforming, and posses a single polar flagellum, mediating a characteristic corkscrew-like or darting motility (132,179). *Campylobacter* spp. are unable to ferment or oxidize carbohydrates, and thus energy is derived from the degradation of amino acids or tricarboxylic acid cycle intermediates (99).

Pathobiology and Epidemiology
Incidence and Distribution

C. jejuni and C. coli are widespread in avian hosts (40, 136, 172, 196). Generally, the carriage rate of *Campylobacter* in domestic poultry is found to be much higher than that in wild birds (179,

196, 206, 227). This is probably due to the high bird density in commercial poultry houses, which facilitate the spread of *Campylobacter* between birds. The numbers of *Campylobacter* positive poultry flocks are generally high, but vary by regions, seasons, and the production types (conventional, free-range, and organic, etc.). It appears that the prevalence of *Campylobacter* is lower in Scandinavian countries (e.g. Norway, Sweden, Finland, and Iceland) than in other European countries, North America, and developing countries (137). Many prevalence studies have been conducted in Europe and the United States, which reported *Campylobacter*-positive flocks ranging from 3% to 97% (13, 17, 20, 26, 56, 68, 72, 74, 79, 82,97, 149, 161, 198, 209, 219, 225). Despite the fact that the majority of on-farm surveys were conducted with broiler chickens, breeder flocks and laying hens are also commonly infected by *Campylobacter* (88, 170, 179).

Seasonal variations were observed in the prevalence of *Campylobacter* flocks with a peak in warm months (17, 26, 161, 198, 219). The exact reason(s) for this seasonal variation is unknown, but it is proposed that the peaking prevalence of *Campylobacter* in warm months is due to increased fly population and fly-mediated transmission (67). Although this hypothesis is plausible, direct evidence is still needed to prove that flies are an important vector in transmitting *Campylobacter* in summer. On commercial poultry farms, *Campylobacter* is rarely detected in birds < 3 weeks of age. Typically, the prevalence of *Campylobacter* increases as the birds grow and reaches to the highest point at the slaughter age for broiler chickens. There is a general trend that *Campylobacter* is more prevalent in organic and free-range flocks than in conventional productions (53, 74, 115, 163, 211, 225). For organic and free-range operations, birds have free access to the outside environments and are slaughtered at an older age, both of which may account for the increased prevalence rates of *Campylobacter*. Once a broiler flock is infected with *Campylobacter*, the majority of the birds within that flock can become colonized in a short time period (17, 20, 32, 64, 198).

With respect to species distribution of campylobacters isolated from chickens, *C. jejuni* accounts for the majority of isolates, followed by *C. coli*, and rarely by *C. lari* (20, 26, 28, 32,56, 74, 82, 115, 161, 164, 179, 185). However, a higher or even sometimes predominant proportion of *Campylobacter* isolates from turkeys or organic and free-range productions are *C. coli* (74, 115, 164, 225). The isolation of other *Campylobacter* spp. including *C. upsaliensis* and *C. hyointestinalis* in poultry is at a low rate (179, 219). Poultry *Campylobacter* isolates are of multiple genotypes and great genetic diversities. Chicken flocks can be colonized by a single or multiple genotypes of *Campylobacter* (20, 28, 54, 77, 137, 145, 164, 199, 225). Even during a single rearing cycle, a broiler flock can be infected by different species or genotypes of *Campylobacter* at different time points (28, 72, 164, 172), reflecting the dynamic changes of *Campylobacter* populations on poultry farms.

Transmission, Carriers, Vectors
Horizontal Transmission
Many farm-based studies have suggested that horizontal transmission from the environment to poultry houses is the most common mode of transmission of *Campylobacter* on poultry farms. Potential sources of infection include old litter, untreated drinking water, other farm animals, domestic pets, wildlife species, house flies, insects, equipment and transport vehicles, and farm workers. Since *Campylobacter* growth is very sensitive to oxygen and temperature, the organism is usually unable to grow in feed, litter or water under normal ambient conditions (82, 85, 98). The organism is usually absent in fresh litter or feed before broilers are infected. Used litter may become contaminated by *C. jejuni* and may play a role in maintaining *C. jejuni* in the farm environment (112, 127). However, surveys conducted in the USA and Europe indicated that there were no marked differences in the prevalence and onset time of *Campylobacter* shedding among flocks on different farms with different litter usage practices (55, 198). These findings suggest that used litter may play a role in transmitting *Campylobacter*, but is not the only source of *Campylobacter* for commercial poultry production. Due to its low moisture content, feed is unlikely an original source for the introduction of *C. jejuni* into the poultry houses (90, 210). However, feed can be contaminated by feces in chicken houses (64), which may facilitate the spread of *Campylobacter* within production facilities.

Unchlorinated water supplies have been implicated as a source of *Campylobacter* infection in broiler chickens (97, 146). Due to its requirement for microaerobic conditions and its inability to grow below 31–32°C (69), *C. jejuni* is unlikely to propagate in environmental water. The presence of this organism in water systems is probably a sign of a recent contamination by feces of livestock or wild birds (93, 191). Therefore, it is likely that contaminated water serves as a passive carrier of *Campylobacter* rather than a niche for growth of *Campylobacter*. Also, drinking water on poultry farms usually becomes positive with *C. jejuni* only after chickens are colonized (20, 210, 233), questioning the role of drinking water in transmitting *Campylobacter* on poultry farms. Water supplies of intensively reared broilers are often inhabited by protozoa. It was shown that *Campylobacter* could enter into protozoan cells and was able to survive for prolonged periods inside the protozoan cells (15, 190). The same studies also found that *Campylobacter* was more resistant to disinfectants (e.g., chlorine) when co-cultured with protozoa than when cultured alone. These results suggest that protozoa in the aquatic environments could serve as a potential reservoir for *Campylobacter* and may facilitate the survival and transmission of *Campylobacter* in animal reservoirs.

Insects (houseflies, darkling beetles, cockroaches, mealworms, etc) can act as mechanical vectors, and may transmit *Campylobacter* to poultry houses (90, 161, 165). Several studies reported that identical serotypes and genotypes of *Campylobacter* were isolated from both broiler and insects within broiler houses (19, 90, 166). There were also reports indicating that insects in poultry houses were not positive for *C. jejuni* until the organism was isolated from broilers chickens in the same houses (19, 135). A recent study by Hald *et al.* (67) reported that in summer months about 10% of flies around a broiler house were contaminated with *Campylobacter* and that hundreds of flies could enter a poultry house through the ventilation system. Further-

more, the same study demonstrated that *Campylobacter* isolates from the broiler chickens and from flies captured in the environment were of the same genotypes. These findings suggest the possibility that flies serve as a vector for transmitting *Campylobacter* on farms, especially during the summer months.

Several studies have shown that rodents and other small wild animals such as raccoons harbor *Campylobacter* in their intestine, and thus these wild animals can potentially introduce *Campylobacter* into grow-out houses (12, 97, 135). In the study reported by Petersen and Wedderkopp (151), the persistence of some *C. jejuni* clones during successive broiler flock rotations was suggested to be a result of survival of the organism in such reservoirs as rodents and insects that were able to evacuate the house during cleaning and disinfection and then return. However, no direct evidence existed to prove this theory (64, 90, 210). In addition, other studies found that *Campylobacter* was not isolated from rodents in the vicinity of broiler houses (64,92). Considering the fact that vermin control programs are implemented in most commercial poultry production facilities, rodents/small animals are unlikely a common source of *Campylobacter* infection for broiler flocks.

Campylobacter has a wide distribution in wild birds (109, 160, 215). Wild birds in the vicinity of poultry production facilities are often found to be infected with *C. jejuni*; however, the *Campylobacter* isolates from wild birds are usually different from those of chicken origin (64, 135, 166). Since wild birds often carry *Campylobacter* in their intestines, and owing to their great mobility, wild birds may spread *Campylobacter* to domestic poultry through fecal contamination of pastures, forage, surface water, or feed.

Presence of other farm animals on broiler farms including pigs, cattle, sheep, and fowl other than chickens has been found to be associated with an increased risk of *Campylobacter* infection in broiler chickens (20, 26, 97, 210). In the study by Gregory *et al.*, cattle and chickens on the surveyed farms were found to be concurrently infected with *C. jejuni* (64). In a follow up study, *C. jejuni* isolates from these cattle were shown to have the same *flaA* type as the isolates from the broilers on the same farm (199). Identical genotypes between cattle and broiler isolates from the same farm were observed in another study, and cattle were suggested to be a source of infection to the broilers on the farm (210). However, as it was indicated by the authors (210), the direction of the transmission was unknown, and the vectors/carriers mediating the transmission between cattle and chickens were not revealed. In other studies, *C. jejuni* isolated from cattle was found to be different from the isolates recovered from the broilers on the same farm (28, 87, 90, 135, 166), suggesting that cattle and broilers were infected by *Campylobacter* from different sources. Pigs are also frequently colonized by *Campylobacter* (12, 64, 135). Tending pigs before entering broiler houses was indicated as a risk factor for *Campylobacter* colonization of chickens (97). Some earlier studies found pigs and broilers to be infected with the same serotype of *C. jejuni* (12, 166), while studies using more discriminatory typing tools showed that pigs and broilers on the same farm were usually infected with different strains of *C. jejuni* (89, 90, 199, 208, 210). Also, pigs are usually

infected with *C. coli* instead of *C. jejuni* (22, 204), while poultry (especially chickens) are frequently colonized by *C. jejuni* (196, 210). Other farm animals (e.g. sheep and horses) and pets (e.g. cats and dogs) can also be infected with *C. jejuni* (196); however, their potential role as a source of broiler infection has not been established.

Farm workers may carry *Campylobacter* into poultry houses (20). *Campylobacter* was isolated from footbath water, farmer's boots, and transport crates (28, 198, 210). Therefore, it is possible that *Campylobacter* may spread between broiler flocks or farms by the movement of personnel or farm equipment.

In summary, it appears that poultry houses can be invaded by *Campylobacter* in many different ways from various sources. The complexity of *Campylobacter* transmission and the widespread presence of *Campylobacter* in the production system greatly undermine the success in control of *Campylobacter* on poultry farms by using management-based strategies.

Vertical Transmission

It has been a major debate if vertical transmission plays a role in introduction of *Campylobacter* to poultry flocks. The current notion is that vertical transmission of *Campylobacter* does not occur or occurs very rarely. Underlying this argument are several reasons. First, young broiler chickens usually lack *Campylobacter* before 2 or 3 weeks of age even though they are hatched from eggs originated from breeder flocks infected by *Campylobacter* (17, 19, 28, 182, 208, 210). Second, progeny broiler flocks are frequently infected with strains different from those of their breeder flocks (28, 34, 150, 210). Third, chicken flocks originating from the same parent flocks do not always show similar serotypes (20), but broilers from different hatcheries may be infected with the same *Campylobacter* clones (151). A well-conceived longitudinal study conducted in Iceland by Barrios reported the lack of vertical transmission of *Campylobacter* in poultry production (17). Finally, isolation of *Campylobacter* from eggs has been scarce, and to date no studies have reported isolation of live *Campylobacter* cells from hatcheries or young hatchlings (48, 76, 84, 170, 182).

However, there are some studies suggesting that vertical transmission of *Campylobacter* may occur from breeder flocks to progeny broilers. Some earlier studies showed that *C. jejuni* could be isolated from both the outer (48) and inner (182) surface of eggshells laid by naturally infected commercial layers or broiler breeders. Shane *et al.* (180) isolated the organism from both the interior surface of eggshell and egg contents after swabbing feces containing *C. jejuni* onto the surface of the eggs. Following experimental infections of eggs with *C. jejuni* by either the temperature differential method (37) or inoculation of egg albumen via direct injection (182), the organism was recovered from both the contents of unhatched eggs and from the newly hatched chicks. Investigations using sensitive molecular detection methods demonstrated the presence of *Campylobacter* DNA in embryos and newly hatched chicks (35, 36, 84), and in hatcheries (76). Furthermore, *C. jejuni* has been isolated from the reproductive tract of healthy hens (27, 31, 75, 87) and from semen of commercial broiler breeder roosters (43). The same

genotypes of *C. jejuni* have been identified from breeder flocks and their progeny flocks (28, 42, 84, 147). These studies suggested the possibility of vertical transmission, but did not prove that vertical transmission actually happened.

Incubation Period

Birds can be readily infected by *Campylobacter* naturally or experimentally; however, the infection usually does not cause clinical diseases, and C*ampylobacter*-associated diarrhea in poultry is a rare event. Experimental studies demonstrated that colonization could occur as early as one day after inoculation (18, 102, 171, 183, 197, 220, 229). In a few cases where diarrhea was observed, the incubation time ranged between 2 to 5 days (167, 175, 220). The minimal infective dose to establish colonization in day-old chicks was shown to be as low as 2 cfu (102), although other studies indicated higher infectious doses (183, 197, 229). Once *Campylobacter* colonization is established, it can persist in the intestinal tract for multiple weeks (5, 102, 172), but gradual decrease in the level of colonization usually occurs after a prolonged plateau period (116, 171, 196).

On poultry farms, *Campylobacter* is rarely detected in birds of less than 2–3 weeks of age. The reason for this lack of infection in young birds is unclear and may be related to multiple factors including the presence of maternally-derived antibodies (171, 173) or differences in environmental or host-related factors. Once a flock is infected, *Campylobacter* spreads rapidly within the flock, leading to colonization of the majority of the birds within a few days (20, 56, 64, 184). Despite the fact that *Campylobacter* infection rarely occurs in young flocks on poultry farms, newly-hatched chickens can be readily infected experimentally with *Campylobacter* (172, 179, 183).

Clinical Signs and Pathological Lesions

Campylobacter infections in poultry usually produce no clinical signs of disease under natural conditions. However, it has been reported that in ostriches natural *Campylobacter* infection can cause clinical illness and pathological lesions in liver and intestines (136, 194). Vibrionic hepatitis was prevalent during 1950s and 1960s in commercial laying hens but is only occasionally reported nowadays (29, 44). It was suspected that *Campylobacter* might be the cause of the disease, but the etiologic agent(s) for vibrionic hepatitis was not formally identified (181).

Some studies reported that experimental challenge of young chickens with *Campylobacter* can induce clinical diseases including watery/mucoid/bloody diarrhea, weight loss, or even mortality (167, 175, 220). In an early report, 3-day-old chickens inoculated with a high dose of *C. jejuni* developed diarrhea within 72 h, which lasted for 10 days and resulted in considerable weight loss as well as a mortality of 32% (167). Welkos (220) reported that almost one-third of the day-old chicks and nearly all of the newly-hatched chicks, but none of the 3-day old chickens, developed signs of gastroenteritis after challenge orally with *C. jejuni*. Similarly Sanyal *et. al*. (175) observed watery/mucoid diarrhea in 81% of 36 to 72-hr-old birds 5 days after inoculation with *C. jejuni*, and also found that the Starbro strain of chickens was more likely to develop diarrhea than the white leghorns

strain. *Campylobacter* infection in commercial broilers of less than 2 weeks of age (a rare event) was found to be associated with diarrhea, decreased weight gain, and excess mortality (134). Another study using newly hatched or 4-day-old turkey poults also observed reduced weight gain and transient watery diarrhea in the birds after inoculation with *Campylobacter* (106). Oral inoculation of 3-week-old Japanese quails with *C. jejuni* resulted in diarrhea that lasted for 2 weeks (119). Despite these isolated reports, many other studies did not observe any clinical diseases associated with *Campylobacter* infections in poultry (18, 102, 171, 183, 197).

Gross pathologic lesions associated with *Campylobacter* infection in experimentally infected chicks are minimal and mainly confined to the gastrointestinal tract. Due to accumulation of fluid, gas, or excess mucus, distention of intestines including ceca with watery/foamy material may be a common finding (175, 220). Blood and mucus in the lumen of small intestine, and petechial hemorrhages in the gizzard mucosa of chicks can be seen occasionally (220). There is a report that *Campylobacter* was isolated more frequently (21% of 223 livers) from broiler chicken livers with necrotic lesions than from normal livers (12% of 50 livers) obtained from slaughter plants in Canada (25); however, there was no evidence that *Campylobacter* directly contributed to the lesion.

Microscopic lesions following experimental infection of chicks are mostly unapparent or minimal, but exceptions occur in birds with severe clinical and gross pathological signs. Usually examination of gastrointestinal tissue reveals no necrosis or invasion of the epithelium or any other pathological changes; however, a mild edema of the lamina propria and submucosa of the intestines, mostly in ceca, was reported with *Campylobacter* infections in chickens (18, 102, 175, 183, 197). In some cases, *Campylobacter* cells can be seen attaching to the brush borders on enterocytes, within intestinal epithelial cells, and inside or outside of the cells of lamina propria with minimal tissue or cell damage (167, 175, 220). Mononuclear infiltration in the submucosa and villous atrophy resulting in accumulation of red blood cells and leucocytes in small and large intestinal lumen may occur in more severe cases (220).

Pathogenesis of the Infectious Process

Birds become infected with campylobacters via the fecal-oral route. As enteric organisms, *Campylobacter* spp. are able to survive the harsh conditions in the stomach (gizzard) as well as in small intestine and eventually reach the lower intestines, where the organisms colonize in cecal and cloacal crypts (4, 18, 172). To a lesser extent, the organism can also be recovered from the small intestines and the gizzard, and infrequently from the liver, spleen, blood, and gallbladder (4, 96, 175). Several distinct features are associated with colonization of *Campylobacter* in chickens. First, it appears that *Campylobacter* does not adhere directly to intestinal epithelial cells, but mainly locates in the mucous layer of the crypts (18, 126). Second, usually no gross or microscopic lesions are induced in the chickens. Third, invasion of the intestinal epithelium rarely occurs with *Campylobacter.* Even when the invasion of internal organs occurs in some cases, no

clinical signs of illness are observed (18, 102, 229). Once a broiler chicken becomes infected, large numbers of the organism (up to 10^9 cfu/ g feces) can be detected in ceca and excreted in feces for a prolonged period (172).

It is likely that many genetic factors contribute to the colonization of *Campylobacter* in poultry. Published studies using genetically defined mutants revealed that flagella, DnaJ (heat shock protein), CiaB (*Campylobacter* invasin antigen B), PldA (phospholipase A), CadF (*Campylobacter* adhesin to fibronectin), CmeABC (multidrug efflux pump), MCP (a methyl-accepting chemotaxis protein), RpoN (sigma factor), the Kps locus (capsule biosynthesis proteins), the Pgl locus (protein glycosylation system), SOD (superoxide dismutase), Fur (ferric uptake regulator), and CbrR (a response regulator) all contributed to *Campylobacter* colonization in chickens (63, 70, 104, 111, 133, 158, 218, 234, 235). *C. jejuni* produces a cytolethal toxin (CTD), which is suggested to be a potential virulence factor of *Campylobacter* (16, 57, 216). Although most *Campylobacter* isolates from poultry harbor the *cdt* genes and produce toxic activity *in vitro* (16, 57), the role of CDT in colonization of chickens has not been established.

Immunity

Despite the commensal relationship between *Campylobacter* and the avian host, the infection indeed elicits both systemic and mucosal humoral responses (33, 130, 138, 162, 221). Following experimental infection of day-old chickens via oral gavage, production of *Campylobacter*-specific IgM and IgA antibodies in serum reached significant levels within 1–2 weeks of infection and peaked at weeks 4–6 postinfection, followed by gradual decreases as birds age (33, 130). In contrast, detectable levels of IgG responses developed later than IgM and IgA responses, peaked at 8–9 weeks of the infection, and persisted for a longer period (33, 130). Naturally occurring *Campylobacter* colonization in chickens also elicits overt immune responses, and anti-*Campylobacter* antibodies readily transfer from hens to their progenies as maternally-derived (173, 228). Maternal antibody plays a partial role in protecting young chickens from infection by *Campylobacter* (171). A wide variety of *Campylobacter* antigens are recognized by chicken sera (33, 162, 173, 222). There is a trend that with the development of specific anti-*Campylobacter* antibodies, the level of *Campylobacter* colonization diminishes and some infected chickens eventually clear the infection (4, 96, 137, 171, 197). However, the nature of protective immunity has not been elucidated, and it is unknown if humoral immunity or cellular immunity (or both) contributes to the clearance of *Campylobacter* from the host. To date there are no reports documenting cellular immune responses induced by *Campylobacter* infection in poultry.

Diagnosis

Culture-based Isolation and Detection Methods

Thermophilic campylobacters are fastidious and slow-growing, requiring microaerobic atmosphere (containing 5% O_2, 10%

CO_2, 85% N_2) and elevated temperature (42°C) for optimal growth under laboratory conditions (41, 50, 174, 186). Thus, culturing *Campylobacter* spp. from fecal or environmental materials with a high level of background flora requires the use of selective culture media and special culture conditions. The first selective medium for culturing *C. jejuni* and *C. coli* was developed in 1977 by Skirrow (186). Since then, approximately 40 solid and liquid selective media for culturing of *Campylobacter* from clinical and food samples have been reported, which have been reviewed by Corry *et al*.(41). Some of the most commonly used ones are Skirrow, Preston, Karmali, modified charcoal cefoperazone deoxycholate agar (mCCDA), cefoperazone amphotericin teicoplanin (CAT) agar, Campy-CVA (cefoperazone vancomycin amphotericin), and Campy-Cefex medium. The selective media contain a variety of different combinations of antibiotics to which thermophilic campylobacters are intrinsically resistant, such as polymyxin, vancomycin, trimethoprim, rifampicin, cefoperazone, cephalothin, colistin, cycloheximide and nystatin. The multidrug efflux pump CmeABC in *Campylobacter* contributes, at least partly, to the intrinsic resistance to these selective agents (110). Use of these antibiotics inhibits the growth of many background microbial flora present in samples and allows the isolation of slow-growing *Campylobacter* spp.

Since *Campylobacter* spp. are sensitive to oxygen levels above 5%, *Campylobacter* selective media often contain various oxygen-quenching agents in order to neutralize the toxic effect of oxygen radicals (41). The commonly used oxygen quenching agents include blood (e.g. Skirrow and Campy-CVA media), a combination of ferrous sulfate, sodium metabisulfite and sodium pyruvate (e.g., Campy-Cefex agar), charcoal (e.g., mCCDA agar), and hematin (e.g., in Karmali agar).

Depending on the type of specimen, selective media can be used either for direct plating or for an enrichment step followed by plating for isolation of *Campylobacter*. An enrichment step in liquid medium followed by plating on solid agar plates is usually superior to direct plating alone for isolation of *Campylobacter* from processed foods in which bacteria are usually in relatively low numbers and/or in an "injured" state (41, 85). However, the enrichment step may not always perform better than direct plating when culturing fecal samples. Although enrichment can be used for fecal samples of cattle for better recovery of *Campylobacter* (24, 94, 192), it may greatly reduce the recovery rate of *Campylobacter* spp. from different sites of the intestinal tract of poultry (129). Musgrove *et al.* (129) compared enrichment and direct plating for isolation of *Campylobacter* from ceca and crops, which showed that direct plating of cecal samples on selective media resulted in a significantly higher recovery rate than the enrichment method. However, enrichment was slightly better than direct plating for the recovery of *Campylobacter* spp. from crop samples. When an enrichment step is used, it should be controlled for less than 24 hrs since a prolonged incubation in enrichment broth may actually decrease the isolation rate.

To isolate thermophilic campylobacters from environmental water, two methods can be used to increase the detection sensitivity. A large volume of water can be filtered through a single membrane with a pore size of 0.2 μm. Subsequently the mem-

brane can either be placed directly on a selective agar plate, or first cultured in an enrichment broth followed by selective plating (142, 146). If large particles are present in water, pre-filtering with a membrane of a larger pore size may be required prior to the final filtering with a membrane of 0.2 μm. Alternatively, water samples can be concentrated by high-speed centrifugation from which the supernatant is discarded and the pellet is cultured by direct plating or enriched in broth followed by plating.

Usually typical *Campylobacter* colonies are visible on solid media after 48 h incubation (24, 41), but it may take up to 72–96 hrs to observe some slow-growing strains (41, 132, 174). Depending on the media used, colonies of *Campylobacter* spp. may appear differently. If the agar is moist, the colonies may appear grey, flat, irregular, and thinly spreading. Round, convex, or glistening colonies may be formed when plates are dry (41). Presumptive identification of thermophilic *Campylobacter* spp. can be done according to colony morphology, typical cellular shapes (spiral or curved rods), and characteristic rapid darting motility as observed under phase-contrast microscopy. The most commonly used phenotypic tests for identification of *Campylobacter* to genus or species level include biochemical tests (catalase, oxidase, nitrate reduction, hippurate hydrolysis, indoxyl acetate hydrolysis), antibiotic susceptibility patterns (nalidixic acid, cephalothin), and growth characteristics at different temperatures (25°C, 37°C, and 42°C) (140, 193). Differentiation between *C. jejuni* (hippurate-positive) and *C. coli* can be done with the hippurate test. However, hippurate-negative *C. jejuni* isolates have been reported (193), emphasizing the need for further testing of hippurate-negative strains with other methods when species identification is considered important.

Immunology-based Diagnostic Methods

Enzyme immunoassays (EIA), based on antigen-antibody interaction, have been developed for direct detection of *Campylobacter* spp. in animal feces or processed food. These EIA assays are commercially available in a very similar format to sandwich-ELISA assays, which use two different antibodies, to detect *Campylobacter* spp. directly in crude samples (78) or after a selective enrichment step (108, 174). Some examples of these commercial kits include VIDAS Campylobacter (bioMerieux), EIA-Foss Campylobacter (Foss Electric), and ProSpecT (Alexon-Trend). EIAs are not as sensitive as culture methods for detecting *Campylobacter* spp., and are not suitable for testing samples in which *Campylobacter* spp. are suspected to be in low numbers. They are more rapid than traditional culture methods and can be automated for easy handling (52, 78, 80, 157).

Nucleic Acid-Based Diagnostic Methods

DNA-based methods have been widely used for detection and identification of *Campylobacter* spp. The majority of the methods are designed in the formats of PCR tests, which can be used for culture confirmation or for direct detection of *Campylobacter* from environmental or clinical samples. Depending on the purposes, PCR primers can be designed from either variable or conserved gene sequences of *Campylobacter* spp. PCR primers directed to conserved sequences are usually used for general detection, while primers designed from variable sequences can be used for differentiation of species or strains. A variety of PCR assays targeting genus- or species-specific sequences have been developed to detect and identify *Campylobacter* spp. from poultry feces, and environmental samples (36, 73, 159, 174, 202, 213). When applied to crude samples, PCR-based tests tend to have a low detection sensitivity due to presence of PCR inhibitors in feces and food matrices and are unable to differentiate dead bacteria from live cells. However, PCR assays can be used in conjunction with conventional culture methods to improve the speed and accuracy of *Campylobacter* detection and identification.

In addition to PCR, many other molecular typing tools have been developed for epidemiological studies of *Campylobacter* in animal reservoirs. The majority of these molecular methods are used for typing or differentiation of pure *Campylobacter* cultures and are not suitable for detection purposes. Examples of commonly used molecular typing tools include pulsed-field gel electrophoresis (PFGE), random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), ribotyping, and sequence-based methods [reviewed in reference (217)]. Sequence-based typing methods target the variable region of the *fla* gene (encoding the flagellin subunit), several housekeeping genes (multilocus sequence typing, MLSP), or the *cmp* gene (encoding the major outer membrane protein) (81, 118, 125, 231). Comprehensive reviews on various typing tools have been published previously (101, 217).

Public Health Significance

Campylobacter enteritis, caused primarily by *C. jejuni*, has become a leading bacterial foodborne illness in humans in the United States and other developed countries (2, 8). In the United States the incidence of laboratory-confirmed cases, as determined by the Foodborne Diseases Active Surveillance Network (FoodNet), was reported to be 12.72 cases per 100,000 in 2005 (1). The estimated annual cases of human campylobacteriosis are 2.1 to 2.4 millions in the United States (8, 61). *C. jejuni* is also frequently associated with diarrhea in patients <6 months of age in developing countries (21, 39). The rates of *Campylobacter* isolation ranged between 5 to 20% in children with diarrhea in some regions of Asia, Africa, and South America (139). In some developing countries, *Campylobacter* can be isolated as often as rotaviruses and enterotoxigenic *Escherichia coli* (51, 139, 203).

Clinical cases of human campylobacteriosis are characterized by a self-limited watery and/or bloody diarrhea; however, serious complications such as reactive arthritis (Reiter's syndrome), Guillain-Barre syndrome, osteomyelitis, nephritis, myocarditis, cystitis, pancreatitis, septic abortion, and bacteremia may occur infrequently (8, 21, 188). Deaths due to *Campylobacter* infection are rare but occur primarily in immunocompromised patients, infants, and the elderly (124).

Campylobacter-contaminated poultry meat is considered a major source of sporadic cases of human campylobacteriosis (8, 60, 61, 224). Worldwide up to 70% of human *Campylobacter* infections have been epidemiologically linked to consumption of chickens (7). Other risk factors including contact with house pets

and consumption of raw milk, untreated water, and undercooked beef or pork have been reported (21, 40). Outbreaks due to *Campylobacter* are rare and mostly associated with consumption of raw milk and contaminated surface water (38, 62, 105, 120, 152, 176).

Although *Campylobacter* is normally susceptible to various antimicrobials, increasing resistance to several antibiotics including fluoroquinolones (FQ), erythromycin, and tetracycline has been documented with *Campylobacter* isolates derived from animals and humans (14, 47, 148, 155, 168). Of particular concern is the resistance to FQ antimicrobials (65, 230). Both laboratory treatments (86, 117, 121) and farm studies (83) showed that treatment of *Campylobacter*-infected chickens with fluoroquinolones resulted in selection of FQ-resistant *Campylobacter* mutants that propagated rapidly and persisted in chickens. Many epidemiological surveys reported the prevalence of FQ-resistant *Campylobacter* in poultry in different regions of the world (45, 115, 143, 156, 230). There is a temporal link between the approval of FQ antimicrobials for animal production and the subsequent increase of FQ-resistant *Campylobacter* isolated from both animals and humans (3, 10, 153, 169, 189, 230). Resistance to erythromycin, a clinically important drug, has also been increasingly reported, especially among *C. coli* isolates (14, 47, 115, 169). As poultry is considered a main source of human *Campylobacter* infections, development of FQ-resistant *Campylobacter* in poultry is regarded as a threat to public health (11, 155, 189, 230), which has led to the recent withdrawal of fluoroquinolone use in poultry in the U.S.

Intervention Strategies

At present no effective control measures are available for prevention and control of *Campylobacter* infections on poultry farms. Several approaches including stringent biosecurity, competitive exclusion, phage treatment, bacteriocin-based treatment, and vaccination have been reported in published studies.

Biosecurity

Several epidemiological investigations have found a correlation between decreased *Campylobacter* infection in broiler flocks and the employment of stringent biosecurity measures and hygienic practices on farms (20, 32, 56, 82, 97, 164, 210). In most of these studies, adherence to biosecurity measures either reduced the colonization level or delayed the onset time of colonization of birds by *Campylobacter*, but was largely unsuccessful in preventing introduction of *Campylobacter* into broiler flocks (20, 82, 136, 164, 184). Although on-farm biosecurity measures appear to be effective in reducing the incidence of *Campylobacter* infection in North Europe such as Norway, Sweden, and Finland, these measures have met limited success in other countries such as the UK, the Netherlands, and Denmark (2, 209, 219). Because *Campylobacter* spp. are commonly present in the poultry farm environment and poultry flocks can be infected by multiple sources, it is rather difficult to eliminate *Campylobacter* from poultry houses by use of biosecurity practices alone. In addition, stringent biosecurity measures are cost-prohibitive and hard to maintain.

Competitive Exclusion

A number of studies investigated the feasibility of competitive exclusion as a mean of preventing *Campylobacter* colonization in broiler chickens (122). These studies used fecal or cecal mucus suspensions, intestinal homogenates, undefined cecal mucus culture, or defined flora from cecal mucus. Although some level of protection was observed in chickens challenged under laboratory conditions, the degree of reduction was inadequate for practical purposes (122). Ideally, competitive exclusion should use pure (defined) cultures instead of crude intestinal mucous suspensions. However, the effect of defined competitive exclusion flora on *Campylobacter* was variable and inconsistent (123, 177, 178, 195). Also, treatment of broiler chickens with pure cultures of *Saccharomyces boulardii* (113) or *Lactobacillus acidophilus* and *Streptococcus faecium* (128) was only partially successful in reducing *Campylobacter* colonization. Currently none of the commercially available competitive exclusion products appears effective for excluding *Campylobacter* from chickens under production conditions (122). In several studies assessing the effectiveness of the competitive exclusion product Broilact®, substantial reduction in *Campylobacter* colonization was observed in one study, but was not reproduced by others (6, 66, 122).

Vaccination

Currently there are no commercially available vaccines for control of *Campylobacter* in poultry. The commensal nature of *Campylobacter* colonization and the great genetic/antigenic diversity among different *Campylobacter* strains create a great challenge for developing effective vaccines that can confer a broad-spectrum protection. The reported immunization studies used killed whole cells, flagellin-based subunit vaccines, or genetically engineered live vectors expressing *Campylobacter*-specific antigens. Most of the studies showed some, but not a biologically significant protective effect in chickens (100, 136, 162, 221). However, a recent study by Wyszynska *et al.* reported a drastic reduction of *Campylobacter* colonization by immunizing chickens with an attenuated *Salmonella* strain expressing the *C. jejuni* CjaA antigen (the substrate-binding component of a ABC transport system) (226). In this work, chickens were orally immunized with the recombinant *Salmonella*-CjaA vaccine at 1 and 14 days of age and challenged at 4 weeks with a wild-type *C. jejuni* strain. Following the challenge, most of the immunized birds had undetectable ($< 1 \times 10^3$ cfu/g feces) levels of *Campylobacter* organism in the ceca, while all of the nonvaccinated control birds were heavily colonized by *Campylobacter* (up to 10^9 CFU/g cecal content). It is unknown if this vaccine can provide protection against different *Campylobacter* strains, but the encouraging results suggest the possibility of using vaccination to control *Campylobacter* infection on poultry farms.

Other Intervention Strategies

Several other potential intervention strategies have been evaluated to eliminate *Campylobacter* colonization in chickens, including phage therapy, bacteriocin-based treatment, and feed/water additives (49, 114, 200, 201, 214). *Campylobacter*-specific bacteriophages are commonly recovered from broiler chickens

and the farm environment. Experimental challenge studies, in which broiler chickens were used to assess the prophylactic or therapeutic effect of bacteriophages against *Campylobacter* colonization, showed a significant decrease in *Campylobacter* numbers in chickens treated with phages (114, 214). However, the level of reduction was variable and was affected by the phage types and doses. Additional studies are needed to determine if phages can be used as an effective and practical means to control *Campylobacter* in poultry. Different diet formulations were evaluated for their effects on *Campylobacter* colonization in broiler chickens (58, 207). Although some differences were observed among the formulations, the effects were biologically insignificant. Similarly, fermented or acidified feed (71) or lactic acid treated drinking water (30) did not result in significant reduction in the level and rate of *Campylobacter* colonization in chickens. Supplementation of feed with prebiotics (e.g., lactose, fructooligosaccharide, mannose-oligosaccharide), immune response stimulators (selenium, beta-glucan), antimicrobials (flavophospholipol, salinomycin), other compounds (chlorate or nitro-based substances), or activated charcoal also had limited success in reducing the incidence of *Campylobacter* colonization in chickens (9, 23, 49). Recently Stern *et al.* evaluated the effect of bacteriocins purified from *Paenibacillus polymyxa* and *Lactobacillus salivarius* on *Campylobacter* colonization in chickens (200, 201). When given to chickens as feed supplements, both bacteriocins were highly effective in reducing *C. jejuni* infections. Notably, the bacteriocins had broad anti-*Campylobacter* activities and were effective against different strains of *C. jejuni* when tested in chickens. As the authors indicated, treatment of broiler chickens with bacteriocins before slaughter may be used to reduce carcass contamination in processing plants (200, 201).

Chapter 18

Colibacillosis

H. John Barnes, Lisa K. Nolan, and Jean-Pierre Vaillancourt

Introduction

Definition and Synonyms

Colibacillosis refers to any localized or systemic infection caused entirely or partly by avian pathogenic *Escherichia coli* (APEC), including colisepticemia, coligranuloma (Hjarre's disease), air sac disease (chronic respiratory disease, CRD), swollen-head syndrome, venereal colibacillosis, and coliform cellulitis (inflammatory process), peritonitis, salpingitis, orchitis, osteomyelitis/synovitis (turkey osteomyelitis complex), panophthalmitis, omphalitis/yolk sac infection, and enteritis. Lesions alone should not be used to infer an *E. coli* infection without the descriptor "coli" or "coliform" being added, because other opportunistic bacteria can behave similarly to *E. coli* in secondary infections. Colibacillosis in mammals is most often a primary enteric or urinary tract disease, whereas colibacillosis in poultry is typically a localized or systemic disease occurring secondarily when host defenses have been impaired or overwhelmed by virulent *E. coli* strains (29). Strains of *E. coli* that cause disease outside the intestinal tract of any species share common characteristics and are called extraintestinal pathogenic *E. coli* (ExPEC)(249, 449). Most APEC are ExPEC and share characteristics with mammalian ExPEC.

Several reviews on APEC and colibacillosis in poultry have been published (28, 109, 131, 186, 292, 436, 524). Earlier information on colibacillosis can be found in previous editions of *Diseases of Poultry*.

Economic Significance

There is general agreement that colibacillosis is the most common infectious bacterial disease of poultry and that collectively, *E. coli* infections in their various forms are responsible for significant economic losses. Often colibacillosis is among the most frequently reported diseases in surveys of poultry health or condemnations at processing. For example, 43% of broiler carcasses condemned for disease at processing had lesions consistent with colisepticemia (556), and colibacillosis was the major cause of infections causing condemnation of processed chickens in Switzerland (241). Flocks with airsacculitis at processing had, in general, lower average body weights of 84 g/bird, and more processing errors, fecal contamination, and *Campylobacter* contamination (447). *E. coli* was isolated from 88.2% of chickens with airsacculitis from flocks in Jordan (126). In Greece colibacillosis

was the most frequent respiratory disease of broilers over a 10-year period (1992–2001) and caused considerable economic losses (155). APEC infections were identified as a major factor in poultry disease in Belgium. Data collected at the East-Flanders regional laboratory between 1997–2000 on groups of healthy and sick broilers, layers, and breeders showed the incidence of APEC infection to be 17.7%, 38.6%, and 26.9% respectively. Resistance to antibiotics was also found to be high (525). Colibacillosis was second only to enteritis as a disease of turkey flocks in California affecting 6 of 26 flocks (77). However, in spite of its recognized importance no studies to accurately define the economic significance of colibacillosis in poultry appear to have been done. In people the impact of ExPEC infections amounts to losses of, ". . . billions of health care dollars, millions of work days, and thousands of deaths annually" (450).

Public Health Significance

Most APEC isolated from poultry are specific clonal types that are pathogenic only for birds and represent a low risk of disease for people or other animals (67, 439). However, chickens are readily infected experimentally with *E. coli* O157:H7, an important enterohemorrhagic pathogen of humans that produces Shiga toxin, and can shed the organism for months (40). Infection with the organism in chickens is strain dependent and requires flagella but not intimin, the surface adhesin responsible for attachment of the organism to epithelial cells in mammals (44, 295). Natural infection with O157:H7 has been identified in both chickens and turkeys in different geographic areas (191, 212, 417). Contamination of poultry meat with this organism can occur as evidenced by a food-borne outbreak of diarrheal disease that was associated with contaminated turkey meat (40, 115, 176, 488). Free-living waterfowl can serve as carriers and be a source of *E. coli* O157. Infection of cattle with *E. coli* O157 in Scotland was epidemiologically linked to contact with wild geese (501), and the organism was isolated from duck feces in an outbreak in people that followed swimming in a lake (457).

Poultry, especially pigeons in certain geographic areas, are a natural reservoir for Shiga toxin producing *E. coli* (STEC), which is a potential health hazard to people (104, 189, 351, 461). Pigeons may be infected with STEC but show no clinical disease (104, 351, 461, 484). Pigeon STEC produce the toxins Stx1, Stx2, and a variant of Stx2 identified as Stx2f, which is considered to be specific for pigeons (189). Stx2f is only weakly detected by conventional immunoassays (461). Clonally related, Shiga toxin-producing *E. coli* infected between 6–16% of urban

691

pigeons in Rome. Infection was significantly higher in young pigeons compared to older pigeons (17.9% vs. 8.2%) (351). Shiga toxin producing enterohemorrhagic *E. coli* O128 were isolated from an 11-month-old child and 5 pigeons from the same area. Isolates were indistinguishable by molecular analyses (484). In poultry 52 of 97 APEC isolates from lesions of avian cellulitis, colisepticemia, swollen head syndrome, or diseased turkeys, along with 5 fecal isolates from healthy chickens, had Shiga toxin gene sequences. Most had *stx1*; only 3 had *stx2* (403). In contrast, pigeons in Colorado (406), chickens and pigeons in India (532), and chickens, pigeons, and gulls in Finland (277) were not a source of STEC.

Functional receptors for heat-stable enterotoxin occur throughout the avian intestinal tract (282). However, serotypes associated with diarrheal disease in humans and strains that produce both heat-labile and heat-stable enterotoxins have been isolated infrequently from chickens (5, 52).

Serotypes, virulence factors, and antimicrobial resistance of APEC in other animals are often shared. Avian strains potentially can be a source of genes and plasmids that encode for antimicrobial resistance and virulence factors (1, 339, 342, 352, 357, 435, 439) (see Virulence Factors below). APEC often share multiple virulence factors that are also commonly found in human uropathogenic *E. coli* and APEC plasmids can contribute to uropathogenicity of *E. coli* in a murine model of human disease (475). Poultry products can be a source of *E. coli* for people. Fresh poultry products, especially turkey, in grocery stores were frequently contaminated with *E. coli* that contained virulence and antimicrobial resistance factors (250, 251). An unexpected finding in a current study (L. Nolan, unpublished data) was that the majority of *E. coli* isolates from retail poultry products was more consistent with APEC than commensal *E. coli*. Additionally these APEC have considerable similarity to human uropathogenic strains suggesting the possibility that organisms causing urinary tract infections in people could potentially come from contaminated poultry products.

Salmonella enterica subsp. *enterica* serovar Newport, a disease-producing organism in people, and another *E. coli* serotype readily acquired antibiotic resistance in the absence of antibiotic selection pressure through transfer of a large conjugative resistance plasmid from antibiotic-resistant *E. coli* in the intestines of turkey poults. The plasmid was transferred to over 25% of *Salmonella* serovar Newport strains following co-infection (418). Antibiotic resistance of fecal *E. coli* was greater in broilers and turkeys that received antibiotics relatively frequently compared to layers, which had little exposure to antibiotics (517). Similar antibiotic resistance patterns were present in *E. coli* isolated from people who worked with these birds, and in some instances specific strains were shared among the birds and workers indicating that transmission of resistant organisms and/or plasmids from poultry to people occurs commonly. Resistance of chicken *E. coli* isolates to antimicrobials used mainly in people was minimal (6, 517).

History

Mortality of fowls and isolation of a bacterium from heart, liver, and spleen that was consistent with *E. coli* was first reported by

Lignieres in 1894 (400). Following experimental inoculation, the isolate was virulent for pigeons, variably virulent for chickens depending on dose and route of administration, and not virulent for guinea pigs or rabbits. Subsequently diseases in grouse, pigeons, swans, turkeys, quail, and additional chicken flocks associated with a similar organism were documented between 1894 and 1922 (400).

The first description of colisepticemia was published in 1907 based on chickens dying from a cholera-like disease while being transported. It was concluded that, "*Bacterium* (*Escherichia*) *coli* may, under certain conditions, take on the ability to leave the intestines, become virulent, and cause a septicemia in hens, especially if their resistance has been weakened by hunger, thirst, cold, or lack of good ventilation" (400).

Infectious enteritis characterized by birds "going light" (infectious asthenia) and paralysis from which *E. coli* could be isolated was described in 1923 (400). In 1938 a pullorum-like disease caused losses of 15–40% in chicks less than 10 days of age that came from the same hatchery. The chicks had pericarditis, perihepatitis, and white spots on the liver. *E. coli* was isolated from tissues. Poor incubation resulting in weak chicks was identified as the reason for their susceptibility to infection (95).

Between 1938 and 1965, coligranuloma (Hjarre's disease) and the role of *E. coli* in a variety of lesions including air sac disease, arthritis, plantar abscesses (bumblefoot), omphalitis, panophthalmitis, peritonitis, and salpingitis were identified and described. Presence of *E. coli* in eggs (152) and *E. coli* infections following vaccination or natural virus infections were also documented (480).

Etiology

The etiology of colibacillosis is *Escherichia coli*. Other infectious agents and noninfectious factors usually predispose a bird to infection or contribute to the severity of the disease.

E. fergusonii is a closely related species that has been isolated from turkeys (137). Colicins (antibacterial substances) produced by *E. fergusonii* are similar to those produced by *E. coli* (477). *E. fergusonii* caused acute death in adult ostriches after a short period of anorexia, prostration, and severe hemorrhagic diarrhea. Lesions consisted of fibrinonecrotic typhlitis with intralesional colonies of Gram-negative bacteria (210).

Classification

Escherichia is the type genus of the family Enterobacteriaceae, which is composed of organisms that can grow aerobically or anaerobically and utilize simple carbon and nitrogen sources (45, 134). *E. coli* is the type species of the genus *Escherichia*. Additional species have been assigned to the genus but *E. coli* occurs most commonly and is most important as a pathogen. Although *Shigella* is still recognized as a genus with 4 species, they actually are *E. coli* strains (298, 543).

Name and Synonyms
Escherichia coli was initially named *Bacterium* (*Bacillus*) *coli commune*, which was shortened and modified to *B. coli* before

(+) growth or reaction occurs
(−) growth or reaction does not occur
(v) reaction or character is variable among isolates

being given its present name by Castellani and Chalmers in 1919 (134). The genus is named for Theobald Escherich, a pediatrician who first identified and described the organism, which appeared in the feces of infants soon after they began nursing. It is typical of bacterial species within the family Enterobacteriaceae (59). Diagnostic characteristics of *E. coli* and *E. fergusonii* are presented in Table 18.1.

Morphology and Staining
Escherichia coli is a Gram-negative, non-acid-fast, uniform staining, non-spore-forming bacillus, usually 2–3×0.6 μm. Organisms grown in culture are more variable in size and shape. Intracellular organisms are often smaller than extracellular bacteria. Most strains are motile and have peritrichous flagella.

Growth Requirements
Escherichia coli grows aerobically or anaerobically on ordinary nutrient media at temperatures of 18–44°C. It ferments carbohy-

Table 18.2. Effect of temperature on generation time and numbers of *Escherichia coli* that could develop within 24 hours in the absence of limits on growth (nutrition, accumulation of inhibitory substances, etc.).

Temperature		Generation	
(°F)	(°C)	Time (hours)	No. of *E. coli* in 24 hours
32	0	20	2
40	4.4	6	8
50	10.0	3	128
60	15.6	2	2,048
70	21.1	1	8,388,608
80	26.7	0.75	3,435,973,800
90	32.2	0.50	24,073,749,000,000
100	37.8	0.30	236,118,320,000,000,000,000

drates, often producing gas. Generation time and number of organisms during a specific time period are related to temperature (see Table 18.2).

Colony Morphology
On agar plates incubated for 24 hours at 37°C, colonies are low, convex, smooth, and colorless. Colonies are bright pink and surrounded by a precipitate on MacConkey's agar, have a dark green-black metallic sheen on eosin-methylene blue (EMB) agar, and are yellow on tergitol-7 agar. Although colony morphology may vary they are usually 1–3 mm in diameter with granular structure and an entire margin. Rough colonies are larger with irregular margins. Mucoid colonies are raised, larger, appear wet, and are sticky when probed. In contrast to the frequent occurrence of hemolysis by mammalian pathogenic *E. coli* on blood agar, hemolysis is not a common characteristic of APEC. *E. coli* rapidly produces diffuse turbidity in broth cultures.

Biochemical Properties
Acid and gas are produced from fermentation of glucose, maltose, mannitol, xylose, glycerol, rhamnose, sorbitol, and arabinose, but not dextrin, starch, or inositol. Substituting sorbitol for lactose in MacConkey agar is useful for distinguishing *E. coli* O157:H7 from other *E. coli* because O157:H7 typically does not ferment sorbitol and will not appear as pink colonies in contrast to typical *E. coli* isolates. Most *E. coli* isolates ferment lactose, but negative strains, which must be differentiated from *Salmonella*, are occasionally isolated. Fermentation of adonitol, sucrose, salicin, raffinose, and dulcitol is variable. Isolates that fermented raffinose and sorbose produced high mortality in an embryo lethality test (349). *E. coli* produces indole, a positive methyl red reaction, and reduces nitrate to nitrite. Voges-Proskauer and oxidase reactions are negative and hydrogen sulfide is not produced on Kligler's iron medium. *E. coli* does not grow in the presence of potassium cyanide, hydrolyze urea (urease negative), liquefy gelatin, or grow in citrate medium. Biochemical tests can be used to distinguish *E. coli* from other *Escherichia* species (45) and bacteria in the family Enterobac-

teriaceae (134). *E. fergusonii* does not ferment lactose, sucrose, raffinose, or sorbitol, which helps distinguish it from *E. coli* (Table 18.1).

Susceptibility to Chemical and Physical Agents

Escherichia coli possess no unique resistance capabilities and have a susceptibility pattern to chemical and physical agents typical of vegetative, Gram-negative bacteria. Inactivation of most strains will occur at temperatures ranging from 60°C for 30 minutes to 70°C for 2 minutes. Thorough pre-cleaning and/or presence of a germicide enhance thermal inactivation. The organism survives freezing and persists for extended periods at cold temperatures. Thermal inactivation in litter to achieve a 90% reduction in the number of bacteria is dependent on time and temperature ranging from 1–2 days at 37°C to 6–22 weeks at 4°C. Inactivation in litter is slower in the presence of high moisture and more rapid when free ammonia is present (213).

Reproduction of most strains is inhibited by a pH of less than 4.5 or greater than 9, but the organism is not killed. Some virulent strains, *e.g.*, O157:H7, are acid tolerant, which permits them to pass through the stomach without being killed. Organic acids are more effective than inorganic acids at inhibiting growth. Treatment with citric, tartaric, or salicylic acids significantly reduces coliform counts in poultry litter (240). A salt concentration of 8.5% prevents growth but does not inactivate the organism (41).

Stabilized chlorine dioxide is highly effective when used as a water disinfectant (405). Chlorate in feed selectively reduces the number of *E. coli* and related bacteria in the digestive tract by converting relatively nontoxic chlorate to highly toxic chlorite via the same pathway *E. coli* uses to convert nitrate to nitrite (14). Solar disinfection of water through the action of ultraviolet light and temperature is a low-cost method of treating drinking water for people in developing areas to reduce or eliminate enteric bacteria that may have application in the poultry industry (42).

Drying is detrimental to the organism. When samples of flooring from broiler transport coops were contaminated with *E. coli* and allowed to dry for 24 or 48 hours, only very few organisms were still viable (43). Washing before drying completely eliminated the organism.

Resistance to Metals and Disinfectants

Escherichia coli has the ability to acquire resistance to a broad range of heavy metals (arsenic, copper, mercury, silver, tellurium, zinc) and disinfectants (chlorhexidine, formaldehyde, hydrogen peroxide, quaternary ammonium compounds). Specific strains can vary substantially in their susceptibility to heavy metals and disinfectants (2, 458). Strains develop resistance to disinfectants when subjected to environmental selection pressures. Limited studies have indicated that resistance to disinfectants is not widespread or common in *E. coli* infecting animals (2), but it is transferable via mobile genetic elements and will likely become more frequent (34). In one study, no resistance to hydrogen peroxide or formaldehyde was found (2). Formaldehyde resistance in *E. coli* is based on a plasmid mediated DNA fragment known as the formaldehyde resistance gene, which encodes for formaldehyde dehydrogenase (285).

Plasmids that provide resistance genes for antibiotics also often provide resistance genes for disinfectants and heavy metals (255, 258). In addition to antibiotic resistance, the APEC IncHI2 plasmid, p-APEC-O1-R, conferred resistance to potassium tellurite, silver nitrate, copper sulfate, and benzalkonium chloride following transfer of the plasmid to a recipient strain by conjugation (259). Similarly the APEC IncF plasmid, pAPEC-O2-R also encoded for resistance to quaternary ammonium compounds and silver and other heavy metals, as well as several antibiotics (256).

Antigenic Structure and Toxins

Serotypes of *E. coli* are classified according to the Kauffmann scheme (134). At present there are approximately 180 O, 60 H, and 80 K antigens (490); the numbers change as new ones are identified and previous ones that are duplicated or attributable to another bacterial species are removed. In most serologic typing schemes only the O and H antigens are determined, e.g., O157:H7. The O antigen determines serogroup while the H antigen determines serotype. Rough strains autoagglutinate and cannot be serotyped. Additional serotypes with O antigens that have not been recognized also are found in most surveys. Fimbrial (pilus) antigens are included in serotyping when considered important.

O (Somatic) Antigen

Lipopolysaccharide (LPS) in the cell wall, also known as endotoxin, is a polysaccharide-phospholipid complex that is released when the cell undergoes lysis. O antigen is the antigenic portion of LPS whereas the toxic portion of the molecule is lipid A. O antigen is resistant to boiling. Methods to prepare and use antisera, which typically agglutinate O antigen at high titers (usually over 1:2560) when antigen-antibody mixtures are incubated at 50°C for 24 hours, have been described (548).

H (Flagellar) Antigen

To examine for H antigens, isolates must be grown under conditions that promote motility. H antigens are proteins found in the different types of flagellin that comprise the flagella. Heating to 100ºC destroys them. Tube agglutination tests are read after incubation at 50°C for 2 hours (548).

K (Capsular) Antigen

K antigens are polymeric acids containing 2% reducing sugars, are associated with virulence, are on the surface of the cell, interfere with O agglutination, and can be removed by heating for 1 hour at 100°C. A few strains require heating for 2.5 hours at 121°C. On the basis of heat stability, K antigens are subdivided into L, A, and B forms. Antisera are prepared in rabbits by inoculating live organisms intravenously. Tube agglutination titers are determined by incubating antigen-antibody mixtures at 37°C for 2 hours and overnight at 4°C. Titers are low (1:100–1:400). Most of these antigens can be identified by the slide agglutination test using appropriately diluted serum (548). Presently K antigens are not commonly included in serotyping.

F (Pilus) Antigen

F antigens are involved in attachment to cells. They are variably expressed depending on the environment in which the organism is growing both *in vitro* and *in vivo*. Pili are classified as being mannose sensitive or mannose resistant depending on whether or not agglutination is inhibited or unaffected respectively when mannose is present. A variety of tests have been developed for detecting fimbrial antigens (548).

Toxins

APEC are much less toxigenic than pathogenic *E. coli* in mammals and human beings. While APEC do not commonly produce enterotoxins, other toxins are elaborated but their roles in diseases of poultry are currently uncertain (see Virulence Factors Toxins). Pigeons can be a significant source of Shiga-toxin producing *E. coli* strains (see Public Health Significance).

Strain Classification

Antigenicity

Even though molecular methods for identifying specific virulence genes are available, serotyping remains a useful tool for epidemiologic studies. Serotyping provides a means of relating previous work with new work. Also it is important to know the serotype of an APEC strain because the immune response in poultry primarily is directed against O antigens. Numerous surveys have been made in many parts of the world to determine serotypes most frequently associated with diseases in poultry caused by *E. coli* (440, 466, 507). Variations according to geographic region occur, but in most studies the common serotypes have been O1, O2, O35, O36, and O78 (208, 480). Many other serotypes have been found less frequently, while some APEC do not belong to known serotypes or are untypeable (561). Some outbreaks are consistently associated with a specific serotype, *e.g.*, O111 causing mortality, septicemia, and polyserositis in egg-laying chickens (560).

Sixty-two different O types were found among typeable strains in a study comparing serotypes of 458 *E. coli* isolates from chickens with colibacillosis to 167 isolates from healthy chickens. Only 15% of the strains belonged to the serogroups O1, O2, O35, O36, or O78, which previously had been associated with avian colibacillosis. Several isolates from diseased birds belonged to 5 serogroups (O18, O81, O115, O116, O132), which have not previously been associated with colibacillosis. Although serotypes from diseased birds were significantly different from ones from healthy birds, intestinal infection of healthy birds with serotypes isolated from diseased birds still occurred frequently (53).

Genetic or Molecular

In addition to phenotyping and serotyping, isolates of *E. coli* can be further characterized by antibiotic resistance, toxigenicity, presence of adhesins including piliation or other virulence factors, cell attachment, hemagglutination, lysogeny (phage typing), and plasmid profiling. DNA probes and polymerase chain reactions (PCRs) have been developed to detect specific genes important in virulence (281, 291, 314, 548). Detection of multiple genes that encode virulence factors by multiplex PCR is an effi-

cient method for identifying several characteristics of APEC and commensal strains simultaneously (133, 436, 474).

Methods of "fingerprinting" isolates including pulsed-field gel electrophoresis (PFGE), amplified fragment length polymorphism (AFLP), restriction fragment length polymorphism (RFLP), and random amplification of polymorphic DNA (RAPD) can be used in epidemiological studies (252, 330). PFGE permitted fingerprinting of *E. coli* isolates from chickens with cellulitis. Specific types of the organism were found consistently associated with farms and successive flocks (471, 472).

RAPD is a rapid, cost-effective procedure for determining clonal types of *E. coli* in epidemiologic studies (71, 330). It is less costly and quicker than molecular fingerprinting using RFLP (330). RAPD analysis of 55 isolates revealed 50 subtypes in three clusters. It was not helpful for discriminating between pathogenic and nonpathogenic isolates (71). Sixteen different RAPD types were identified in a collection of isolates from diseased and healthy poultry in Georgia. Differences in the types were discovered but, with the exception of one RAPD type that occurred only in diseased chickens and accounted for 23% of the isolates, the differences were not absolute. Also, RAPD types did not correlate with antibiotic resistance profiles (330).

Multilocus enzyme electrophoresis (MLEE) identified specific genotypes, which demonstrated that relatively few clonal types are responsible for different forms of colibacillosis in chickens and turkeys in widespread geographic areas. Virulence varied little among isolates within a clonal group but varied considerably between clonal groups (539). MLEE applied to a large number of *E. coli* isolates showed that they could all be placed into one of 4 clonal groups designated A, B1, B2, and D. Several clonal groups were identified among isolates from chickens with omphalitis, swollen head syndrome, septicemia, and intestines of healthy chickens in Brazil. MLEE permitted better discrimination of the isolates than ribotyping; most pathogenic isolates clustered together in two clonal subgroups while most commensal isolates occurred in other clonal groups (94).

Assignment of APEC to phylogenetic typing can also be accomplished with a multiplex PCR-based method (81). This method assigns isolates to A, B1, B2, and D phylogenetic groups. Clonal groups B2 and D are considered to contain most of the pathogenic isolates. However, Rodriguez-Siek *et al*. (435) found that the majority of 524 APEC isolates fell into the nonpathogenic clonal groups. MLST (multilocus sequence typing) also can be used to construct phylogenetic trees, providing insight into the evolution of each of these clones. Highly virulent strains tend to be hybrids that evolved relatively recently by homologous recombination (543).

Genomes of *E. coli* contain multiple sequences, which can be identified by PCR and used to characterize individual isolates of the organism and determine their relatedness to each other. The procedure is known as enterobacterial repetitive intergenic consensus (ERIC). ERIC can be combined with repetitive extragenic palindromic (REP) PCR, which determines repetitive sequences outside of the genome. Using these methods dendrograms based on the different patterns revealed extensive genetic diversity among avian *E. coli* strains. Pathogenic and nonpathogenic iso-

lates tended to group in different clonal groups whereas serotypes were distributed among all groups. No specific genotype or serotype could be identified as being the cause of colibacillosis (99). In a subsequent study commensal and omphalitis isolates grouped together while APEC from poultry with septicemia or swollen head syndrome occurred in different clonal groups indicating the opportunistic nature of the omphalitis isolates (93).

Signature-tagged transposon mutagenesis (STM) (308) and genomic suppression subtractive hybridization are methods that have been useful in identifying previously unknown putative virulence genomic sequences in APEC (61, 268, 342, 462, 491). The newly recognized genetic sequences did not occur in commensal strains suggesting their importance in virulence. Mutant strains lacking the putative novel virulence factors were less virulent than the APEC strains from which they originated. Furthermore, these novel virulence factors were more frequent in other avian and mammalian pathogenic strains than commensal strains. The specific nature of the genes and their role in the pathogenesis of colibacillosis in poultry remain to be determined.

When two virulent avian strains (O2 and O78) from colisepticemia cases were compared, they were found to be very different with only a few shared genes. Analysis of additional strains of each serogroup of human and animal origin showed similar genetic diversity leading to a "mix-and-match" theory, *i.e.*, different virulence factors can combine to provide an ability to cause septicemia (342).

Presence of *E. coli* in water indicates fecal pollution since the organism does not normally live outside of the intestinal tract and is present in high numbers in feces. To determine the source of the pollution, *E. coli* isolates can be classified as to species of origin by ribotyping (66, 190). Riboprints of fecal *E. coli* provided the most accurate determination of source when comparisons were made among no more than three. For example, the source of *E. coli* from geese, turkeys, or chickens was correctly determined for approximately 96% of the isolates by the procedure (66).

Pathogenicity

Ability to cause mortality in embryos or chicks differentiates APEC from commensal *E. coli* strains (158, 159, 160, 349, 392). An embryo lethality test can be used to test avian *E. coli* isolates for virulence. Eleven 12-day-old chicken embryos were inoculated via the allantoic cavity with 100 cfu of the test organism. Two-day mortality was <10% for nonvirulent strains, 10–29% for intermediate strains, and >29% for virulent strains (547). Extending the post-inoculation observation time resulted in higher mortality, but the pattern of mortality among various strains remained essentially unchanged (349). Intravenous and subcutaneous inoculation of chicks correlated with embryo lethality, whereas intratracheal inoculation did not (160). Compared to the embryo lethality test, virulence of an isolate correlated with complement resistance and presence of ColV plasmid, but neither of these tests conclusively identified all isolates as virulent strains. The embryo lethality test remains the best single test for discriminating APEC from commensal *E. coli* (158).

Virulence Factors

It is widely believed that avian colibacillosis is a secondary disease and that APEC, the etiologic agents of colibacillosis in birds, are opportunists. However, increasing evidence has shown that clones of APEC exist that are especially well adapted to life as pathogens, suggesting that APEC infections might not always be opportunistic or secondary to some predisposing condition. Certainly, APEC, like other pathogenic *E. coli*, have acquired genes by horizontal transfer that encode virulence factors, which serve to distinguish APEC from commensal strains (111, 436, 491). These virulence genes may be clustered into chromosomal- or plasmid-located pathogenicity islands (PAIs). Acquisition of virulence genes, plasmids, and/or PAIs enables APEC to survive within the host, which can result in clinical disease. Since APEC usually cause extraintestinal disease, they are commonly classified into a group of *E. coli* known as extraintestinal pathogenic *E. coli* or ExPEC (263, 449). ExPEC also include uropathogenic *E. coli* (UPEC) and meningitis-associated *E. coli* (MNEC) that cause disease in human beings and other hosts (263). ExPEC share certain virulence attributes enabling their extraintestinal lifestyle, including adhesins, toxins, protectins, iron acquisition mechanisms, and invasins (263, 435, 436). Identification of such traits among APEC has fostered development of a rudimentary definition of an APEC pathotype (436) and has led to interest in the potential of APEC to infect non-avian hosts (357, 435, 439).

Despite the fact that most APEC infections are extraintestinal, some APEC contain traits associated with the intestinal *E. coli* pathotypes, including enteropathogenic *E. coli* (EPEC) (264, 291), enterotoxigenic *E. coli* (ETEC) (264, 292), enteroinvasive *E. coli* (EIEC) (440, 441), and enterohemorrhagic *E. coli* (EHEC) (292, 484). Furthermore, APEC strains causing the same disease may differ substantially in their gene content (342). In view of this high level of genomic plasticity, it is not surprising that no single virulence factor has been identified that will distinguish all APEC from all commensal *E. coli* strains. Genes encoding virulence factors in APEC are summarized in Table 18.3.

Adhesins

Adhesins may be fimbrial or nonfimbrial. The role of fimbriae in the pathogenesis of avian colibacillosis is unclear, although it seems likely that these virulence factors would be important in APEC's colonization of the host (23). Fimbriae can undergo phase variation depending on the types present on the organism and tissue being colonized. Several fimbrial types have been described among APEC, including AC/I (avian *E. coli* I) (23, 386, 555), P (F11) (292), type 1 (F1) (17, 292), Stg (316), and curli (172, 287, 291). Also, a ColV plasmid, encoding type 4 pili, has been found in an APEC O78 strain. Although type 4 pili are known to contribute to host cell adherence of some bacteria, their roles in APEC adherence and virulence, if any, are unknown (174).

F1 fimbriae are expressed during initial colonization of tracheal epithelial cells, whereas P fimbriae are expressed later when the organism is in the lower respiratory tract or body tissues. Bacteria are rapidly killed by macrophages when they express F1 fimbriae (420, 422). Although the F1 fimbrial adhesin, FimH, is required for adhesion to cultured chicken epithelial pha-

Table 18.3. Putative APEC virulence and virulence-associated genes and regions. Modified from 248, 263, 436.

Gene, Operon or Region	Description	Gene, Operon or Region	Description
Iron-Related Genes		F1C-fimbriae (Foc)	
feoB	Primary gene mediating ferrous (Fe^{2+}) iron uptake	*focG*	Encodes a component of F1C fimbriae
ireA[1]	Iron regulated, siderophore receptor, outer membrane protein	*focA*	Encodes the major fimbrial subunit
Yersiniabactin operon[1]		S/F1C-related fimbriae (Sfr)	
irp2	Encodes iron repressible gene associated with yersiniabactin synthesis	AC/I fimbriae (Fac)	
		facA	Encodes major subunit of avian *E. coli* I (AC/I) fimbriae
fyuA	Encodes ferric yersiniabactin uptake receptor	Curli operon	
Sit operon[1,2]		*crl*	Gene cluster encoding for curli fibers; involved in cell adhesion and internalization
sitA	Putative iron transport operon	*iha*	IrgA homologue adhesin
Aerobactin operon[2]		*afa*	Afimbrial adhesin, a member of the Dr family of adhesins
iutA	Ferric aerobactin outer membrane receptor gene	*gafD*	G fimbrial adhesin
iucC	Involved in aerobactin synthesis Aerobactin operon is involved in iron uptake and transport	*bmaE*	Blood group M-specific adhesin
		Stg operon	
Salmochelin operon[2]		*stgA*	On the C-terminus of the Stg fimbrial operon
iroN	Catecholate siderophore receptor gene	*tsh*[2]	Temperature-sensitive hemagglutinin gene
Eit operon[2]		*bfp*	Bundle-forming pilus, initiates attaching and effacing lesions in typical AEEC isolates
eitA	ABC iron transporter; periplasmic-binding protein	*eae*	*E. coli* attaching and effacing gene that encodes intimin
Toxin/Bacteriocin-Related Genes		**Protectins**	
stx1, stx2[3]	Shiga toxins; inhibit protein synthesis	*iss*[2]	Encodes an outer membrane protein involved in increased serum survival and surface exclusion
hlyD	Transport gene of the α-hemolysin operon	*traT*[2]	Encodes an outer membrane protein involved in serum resistance and surface exclusion
hlyF[2]	Avian *E. coli* hemolysin		
cdtB	Cytolethal distending toxin; DNase I activity; blocks mitosis	*bor*	Virulence determinant encoded by λ bacteriophage; involved in serum resistance
vat[1]	Vacuolating autotransporter toxin		
cnf1	Cytotoxic necrotizing factor 1; altered cytoskeleton, necrosis	*ompA*	Outer membrane protein A is involved in serum resistance
usp	Uropathogenic-specific protein (bacteriocin)	*kps* cluster	Involved in encoding capsular (K) antigens
ColV operon[2]		**Invasins**	
cvaC	Structural gene of the ColV operon	*ibeA*[1]	Promotes invasion of brain microvascular endothelial cells
ColB operon[2]			
cbi	Immunity gene of the ColB operon	*ipa*	Cell penetration and intracellular survival
ColM operon[2]			
cma	Structural gene for ColM activity	*tia*[1]	Tia invasion determinant
Adhesins		**Miscellaneous**	
Type 1 fimbrial adhesin operon (Fim)		*ompT*[1,2]	Encodes a protease able to cleave colicin
fimH	D-mannose-specific adhesin of Type 1 fimbriae	*malX*	Pathogenicity island marker from UPEC CFT073
Pap pilus operon[1]		*fliC* (H7)	Produces flagellin protein associated with the H7 antigen group
papC	Acts as a molecular usher in P pilus assembly	Ets operon[2]	
papA	Encodes the major structural subunit	*etsA*	Encodes ABC transporter, efflux pump protein
papG	Encodes the pilus tip adhesin		
S fimbrial operon			
S fimbrial family of adhesins differ in receptor specificity			
S fimbriae (Sfa)			
sfaS	Encodes pilus tip adhesin of S fimbriae; S fimbriae interact with glycoproteins containing sialic acid		

[1]localized to an APEC chromosomal PAI
[2]localized to APEC plasmid-linked PAIs
[3]encoded by phage

ryngeal or tracheal cells, lack of FimH favors *in vivo* colonization of the trachea of chickens (17). Curli may contribute to bacterial invasion of eukaryotic cells (172) and APEC's persistence in the cecum (287).

Intimin is a non-fimbrial adhesin encoded by the *E. coli* attaching and effacing (*eae*) gene, which is found in EHEC and EPEC. It permits the bacterial cell to adhere to the surface of the enterocyte, which initiates a characteristic attaching and effacing (AE) lesion. Several genetic variants of intimin, identified by letters of the Greek alphabet, have been identified. The most common type in APEC is ß-intimin followed by λ-intimin (281, 492). A highly virulent APEC (O86:K61), which has caused mass mortality of passerine birds in Britain, produces λ-intimin (291).

Organisms producing AE lesions are known as attaching and effacing *E. coli* (AEEC). In mammals a specific pilus (bfp, bundle-forming pilus) occurs together with intimin to cause the AE lesion. AEEC that do not have bfp are referred to as "atypical AEEC." Avian AEEC are usually atypical AEEC as isolates infrequently have bfp. AEEC are either absent or found infrequently in most surveys of poultry (281, 492) except for pigeons infected with Shiga toxin strains (189, 484). However, high percentages of *eae+* isolates were obtained from dead-in-shell embryos and chicks with yolk sac infections in Mexico (30%) (440) and feces of healthy chicks in Kenya (60%) (264), suggesting there may be certain geographic areas where AEEC commonly infect chickens.

A novel avian respiratory soluble lectin, distinct from pulmonary collectins and ficolins, that binds with surface polysaccharides of pathogenic *E. coli* (serogroups O2 and O78) has been discovered in air sac fluids of turkeys. Its role, if any, in colibacillosis has yet to be defined (534). Also, temperature-sensitive hemagglutinin (Tsh), the first described serine protease autotransporter of the Enterobacteriaceae (SPATE) (424), is secreted by some APEC strains. It is a bifunctional protein that acts as an adhesin and protease (279) and mediates colonization of the host's respiratory tract during early infection (116). The contribution of Tsh to the pathogenesis of colisepticemia appears to be restricted to the early stages of infection, as *tsh⁻* mutants cause less severe and less frequent lesions in air sacs. Tsh does not appear to be required for high levels of APEC virulence (510). Reports of its prevalence among different APEC populations vary widely (9, 98, 102, 103, 132, 133, 243, 329, 335, 435, 436, 523, 553, 561).

Toxins
APEC tend to be less toxigenic than mammalian pathogenic *E. coli* (52, 243, 337). This difference may be due to the lack of toxin production or that toxins produced by avian strains are not detectable with tests for toxins produced by mammalian strains. In addition to endotoxin, a structural component of the organism's cell wall, APEC can elaborate several toxins that are important in disease (402, 403, 454, 455, 456); low level occurrence of certain toxin genes among APEC has been reported. These genes include those encoding cytolethal distending toxin (292, 435, 436, 440), cytotoxic necrotizing factor 1 (435, 436) and various hemolysins (9, 257, 258, 335, 352, 365, 430, 435, 436, 549).

Some of the genes encoding toxins occur in a substantial number of APEC. A *Salmonella* virulence homologue, *hlyF*, was first described in an avian *E. coli* isolate in 2004 (352). It shares significant homology with the *E. coli* K12 "silent" hemolysin gene *she* and occurs commonly among APEC. The gene is found within a virulence cluster of large, conjugative ColV and ColBM plasmids (257, 258). Its role in APEC virulence is not yet known.

Vacuolating autotransporter toxin (Vat), which is encoded by the *vat* gene, also occurs commonly among APEC (132). Vat is a 148.3-kDa protein, which has a structure typical of SPATE. It causes cytotoxic effects in cultured cells similar to those caused by *Helicobacter pylori* VacA toxin. Vat appears to be a virulence factor for APEC, as deletion of the *vat* gene results in attenuation of virulence (404).

Iron Acquisition Mechanisms
The ability of APEC to obtain iron is well documented and likely due to various iron-acquisition mechanisms (aerobactin, yersiniabactin, *sit*, and *iro* systems) (110, 117, 173, 296, 451, 544). Genes of these operons occur frequently among APEC, but are significantly less common in commensal *E. coli* strains (436). APEC frequently contain several of these operons, one or more of which may be found on large plasmids (112, 117, 162, 237, 254, 258, 259, 435, 436, 451, 510). This apparent redundancy in iron acquisition mechanisms and widespread distribution of these systems among APEC suggest that the ability to obtain iron is important in the pathogenesis of avian colibacillosis.

The *sit* operon was originally described in a *Salmonella enterica* serovar Typhimurium isolate (563) and more recently identified in APEC using genomic subtractive hybridization and signature-tagged mutagenesis (308, 462). The *sit* operon encodes an ABC transport system involved in metabolism of iron and manganese and resistance to hydrogen peroxide (451). In at least one APEC, this operon occurs in both chromosomal and plasmid-located PAIs (257). In its plasmid location, *sit* is closely associated with the aerobactin siderophore operon and *iro* locus (257). The yersiniabactin operon in at least one APEC is found in a chromosomal PAI (GenBank accession no. NC 008563).

Protectins
Ability to resist complement is a common characteristic of APEC, regardless of the syndrome or avian host species of origin (393). Resistance of *E. coli* to complement is related to several structural factors including K1 capsule (89, 90, 154, 338) or other capsule type (448, 494), a smooth lipopolysaccharide (LPS) layer (90, 167) or particular LPS type (338), and certain outer membrane proteins (OMPs), including TraT, Iss, and OmpA (47, 78, 79, 343, 537). When 294 APEC were compared with 75 fecal *E. coli* isolates from clinically healthy birds for possession of a capsule, smooth LPS layers, *ompA*, *traT*, and *iss*, only *iss* was found to occur significantly more often in APEC relative to commensal strains (414).

The increased *serum survival* gene (*iss*), first described by Binns and coworkers in 1979 for its role in complement resistance associated with a ColV plasmid, increased the virulence of an *E. coli* 100-fold for day-old chicks (46) and its complement

resistance over 20-fold (31, 78, 79). The gene *iss* encodes Iss, a lipoprotein exposed on the outer membranes of *E. coli* (318). It occurs frequently among APEC (435, 436, 553, 561) compared to a low rate of occurrence in commensal strains. Although it has been proposed that the substantial difference in distribution of *iss* between APEC and commensal strains might reflect its importance in APEC virulence (393), Mellata *et al*. (338) reported that *iss* did not play a major role in resistance of APEC strain χ7122 to serum. In contrast, Tivendale *et al*. (510) found a strong association between APEC virulence and carriage of *iss* and/or *iucA*, a gene of the aerobactin operon. From such disparate observations it is evident that much remains to be learned about complement resistance in APEC, its mediators, and its role in disease pathogenesis.

The ability of APEC to resist the detrimental effects of heterophils and macrophages is likely another important determinant that contributes to successful infection. Resistance to phagocytosis or its effects may be related to complement resistance or possession of other traits. Kottom *et al*. (280) reported that a complement-sensitive mutant bound significantly more C3 subunits and was phagocytosed significantly more often than the wild-type APEC strain from which it had been derived. It was hypothesized that the mutant's decreased virulence resulted from its increased sensitivity to complement-mediated bacteriolysis or enhanced susceptibility to complement-opsonized phagocytosis. However, subsequent studies by Mellata *et al*. (338) showed that non-opsonized APEC were eliminated by phagocytes to the same or greater extent than serum-opsonized bacteria.

Phagocytosis of APEC by avian phagocytes is promoted by presence of type 1 fimbriae and absence of P fimbriae, K1 capsule, O78 antigen, and an uncharacterized pathogen-specific chromosomal region. Presence of type 1 and P fimbriae, O78 antigen, and the 0-minute chromosomal region contributed to protection of APEC against the bactericidal effect of phagocytes, in particular, heterophils (338).

Certain strains of APEC can survive within macrophages and cause their destruction through apoptosis (35, 434). Caspases, enzymes essential for apoptosis, were activated by a strain of APEC (APEC17), which resulted in cytotoxicity within 8 hours of infection (35).

Invasins
